Background: To quantitatively evaluate the contribution of plant roots to soil shear strength, the generalized equivalent confining pressure (GECP), which is the difference in confining pressure between the reinforced and un-reinforced soil specimens at the same shear strength, was proposed and considered in terms of the function of plant roots in soil reinforcement.

Methods: In this paper, silt loam soil was selected as the test soil, and the roots of *Indigofera amblyantha* were chosen as the reinforcing material. Different drainage conditions (consolidation drained (CD), consolidation undrained (CU), and unconsolidated undrained (UU)) were used to analyse the influences of different root distribution patterns (horizontal root (HR), vertical root (VR), and complex root (CR)) and root contents (0.25%, 0.50%, and 0.75%) on the shear strength of soil-root composites.

Results: The cohesion (c) values of the soil-root composites varied under different drainage conditions and root contents, while the internal friction angle (ϕ) values remain basically stable under different drainage conditions. Under the same root content and drainage conditions, the shear strength indexes ranked in order of lower to higher were HR, VR and CR. The GECP of the soil-root composites with a 0.75% root content was 1.5-2.0 times that with a 0.50% root content and more than 5 times that with a 0.25% root content under the CD and CU conditions. The GECP in reinforced soil followed the sequence of CD > CU > UU. The GECP of the plant roots increased as confining pressure increased under CD and CU conditions while showed a complex change to the confining pressure under the UU condition.

Conclusion: It was concluded that the evaluation of plant root reinforcing soil based on GECP can be used to measure effectively the influences of roots on soil under different drainage conditions and root distribution patterns.

17 ABSTRACT

18 **Background:** To quantitatively evaluate the contribution of plant roots to soil shear strength, the
19 generalized equivalent confining pressure (GECP), which is the difference in confining pressure
20 between the reinforced and un-reinforced soil specimens at the same shear strength, was
21 proposed and considered in terms of the function of plant roots in soil reinforcement.

22 **Methods:** In this paper, silt loam soil was selected as the test soil, and the roots of *Indigofera*
23 *amblyantha* were chosen as the reinforcing material. Different drainage conditions (consolidation
24 drained (CD), consolidation undrained (CU), and unconsolidated undrained (UU)) were used to
25 analyse the influences of different root distribution patterns (horizontal root (HR), vertical root
26 (VR), and complex root (CR)) and root contents (0.25%, 0.50%, and 0.75%) on the shear
27 strength of soil-root composites.

28 **Results:** The cohesion (c) values of the soil-root composites varied under different drainage
29 conditions and root contents, while the internal friction angle (ϕ) values remain basically stable
30 under different drainage conditions. Under the same root content and drainage conditions, the
31 shear strength indexes ranked in order of lower to higher were HR, VR and CR. The GECP of
32 the soil-root composites with a 0.75% root content was 1.5-2.0 times that with a 0.50% root
33 content and more than 5 times that with a 0.25% root content under the CD and CU conditions.
34 The GECP in reinforced soil followed the sequence of $CD > CU > UU$. The GECP of the plant
35 roots increased as confining pressure increased under CD and CU conditions while showed a
36 complex change to the confining pressure under the UU condition.

37 **Conclusion:** It was concluded that the evaluation of plant root reinforcing soil based on GECP
38 can be used to measure effectively the influences of roots on soil under different drainage
39 conditions and root distribution patterns.

42 INTRODUCTION

43 Plant roots play an important role in improving the overall stability of the superficial slope soil
44 and increasing the safety coefficient of the slope (Zegeye *et al.*, 2018; Zhou & Wang, 2019). The
45 plant root system is a complex and dynamic system, for which non-destructive monitoring is
46 difficult, so it is always a challenging aspect to consider in research regarding the mechanism of
47 plant root reinforcing soil.

48 At present, the evaluation of slope vegetation protection mainly includes mechanical and
49 hydraulic mechanisms (Gonzalez-Ollauri & Mickovski, 2017; Feng, Liu & Ng, 2020). Based on
50 both mechanisms, three vegetation protection theories were proposed, namely, mechanical
51 reinforcement is provided by plant roots (Jin *et al.*, 2019), the excess pore-water pressure in soil
52 is dissipated by root water uptake (Liu, Feng & Ng, 2016) and soil matric suction is induced via
53 plant transpiration (Ng *et al.*, 2013; Gadi *et al.*, 2019). The most obvious way in which
54 vegetation enhances slope stability is root reinforcing.

55 The effect of root reinforcement on slope stability can be evaluated directly in terms of the
56 additional shear strength provided by plant roots in reinforced soil. To analyse the effect of plant

57 roots on slope stability, many in situ and laboratory tests have been carried out on vegetated soil
58 (*Wu & Watson, 1998; Operstein & Frydman, 2000*), and corresponding analytical models for
59 soil-root composites have also been developed (*Waldron, 1977; Waldron & Dakessian, 1981;*
60 *Wu et al., 1988*). For example, a linear equation of root population density and soil shear strength
61 was obtained (*Endo & Tsuruta, 1969*), in which the cohesion strength extending to the sliding
62 layer has a stabilizing effect on shallow slopes, by in situ shear tests (*Gray & Ohashi., 1983;*
63 *Greenway, 1987*).

64 In addition, some mechanistic models like the Wu-Waldron model, the modified Wu-Waldron
65 model, the fiber bundle model, the root bundle model and have been developed to evaluate the
66 additional shear strength provided by plant roots (*Wu, 1976; Waldron, 1977; Wu, McKinell &*
67 *Swanston, 1979; Gray & Sotir, 1998; Pollen & Simon, 2005; Schwarz et al., 2010*). However, as
68 the most classic and representative model, the Wu-Waldron model potentially significantly
69 overestimates the actual cohesion of soil-root composites (*Waldron & Dakessian, 1981;*
70 *Operstein & Frydman, 2000; Pollen & Simon, 2005*), because the Wu-Waldron model or the
71 modified Wu-Waldron model is derived based on the assumption that plant roots are elastic and
72 initially oriented perpendicular to the shear surface and that the friction angle of the soil is
73 unaffected by the plant roots (*Waldron, 1977; Greenway, 1987*). Therefore, a correction factor
74 ranged from 0.34 to 0.50 for roots of herbs and shrubs was proposed by *Schwarz et al. (2010)* to
75 reduce the error of the Wu-Waldron model. The equation of generalized equivalent confining
76 pressure (GECP) is derived based on the limit equilibrium state of reinforced soil and un-
77 reinforced soil (*Huang et al., 2007*), in which the assumptions of root characteristics and root
78 distribution can be ignored. The effect of root distribution or root shear failure angle on soil can
79 be shown by the deviator of the failure principal stresses of reinforced and un-reinforced soil
80 under the same confining pressure. Therefore, we try to introduce this method to assess the
81 additional shear strength provided by plant roots.

82 Decisive factors controlling shallow landslides are the mechanical properties of the sloping
83 soil characteristics (e.g., texture), frequency and duration of the rainfall, and plant species (root
84 morphology) (*Matsushi, Hattani & Matsukura, 2006; Normaniza, Faisal & Barakbah, 2008*).
85 Rainfall may give rise to shallow landslides because it can increase in soil moisture content so
86 that make the slope in instability stage when other conditions were the same. The effect of plant
87 roots on the shear strength of vegetated soil significantly decreases because of the rainfall
88 (*Normaniza & Barakbah, 2006; Jiang, Dong & Wang, 2009*).

89 Differences in depth, soil moisture content and root characteristics may result in a substantial
90 change in soil shear strength. The effect of plant roots in reinforced soil is understood as an
91 additional confining pressure to the soil, in excess of the traditional equivalent confining pressure.
92 Therefore, the expression of generalized equivalent confining pressure (GECP) was derived to
93 investigate the influence of root contents and root distribution patterns on the shear strength of
94 reinforced soil under different drainage conditions (consolidation drained (CD), consolidation
95 undrained (CU), and unconsolidated undrained (UU)) and was used to analyse the influences of
96 different root distribution patterns (horizontal root (HR), vertical root (VR), and complex root

97 (CR) patterns) and root contents in this research. This research provides new sight to assess the
98 additional shear strength provided by plant roots for the soil-root composite.

99 MATERIAL AND EXPERIMENTAL METHODS

100 Experimental materials

101 In this paper, the soil was taken from the cutting slope of the first phase of the urban expressway
102 along the Xiazhou Avenue in Yichang, China. The test soil was collected from 0.3 m below the
103 surface, and the impurities in the soil were removed. The soil was air-dried, crushed and sieved
104 through a 2.0 mm sieve. The soil had a silt loam texture with 24.08% sand (0.05-2.00 mm),
105 55.91% silt (0.002-0.05 mm), and 20.01% clay (<0.002 mm) contents, a 1.38 g cm⁻³ bulk density,
106 a 14.37% natural moisture content, a 2.78% air-dried soil moisture content, and a pH of 6.2.

107 *Indigofera amblyantha*, used widely in slope greening projects, were the roots selected as the
108 reinforcing material. *Indigofera amblyantha* is a perennial deciduous shrub, and its growing
109 period is approximately 6 months; it possesses strong drought resistance and barren resistance.
110 These plants are the most common soil-water conservation plants in tropical and subtropical
111 regions.

112 *Indigofera amblyantha* has a horizontally developed root system, including many branches
113 and fibrous roots (Fig. 1), and the root diameter is mostly concentrated within 1.0-2.5 mm. In
114 this paper, 50 plants of *Indigofera amblyantha* were excavated by the whole excavation method.
115 Normal and straight roots were cut to lengths of 30 mm and 60 mm with scissors. The roots with
116 an average diameter of 1.4-1.6 mm were chosen, of which the average tensile resistance and the
117 average tensile strength were 62.10 N and 35.86 MPa, respectively.

118

119 Experimental methods

120 The density and moisture content of the soil-root composites were set according to the actual
121 situation of the test soil taken from the cutting slope (bulk density is 1.38 g cm⁻³, and natural
122 moisture content is 14.37%). The root contents (the ratio of the root mass to soil mass in the
123 specimens) were set to 0.25%, 0.50% and 0.75%.

124 The *Indigofera amblyantha* has a horizontally developed root system, resulting most of the
125 roots are in vertical stage on the slope. To evaluate the effect of root distribution patterns on the
126 shear strength of reinforced soil and ensure the vertical roots are much more than the horizontal
127 roots, the root distribution patterns were categorized into VR, HR and CR in this research (Fig.
128 2A, B, C). The first form (A) is VR with a root length of 60 mm; the second form (B) is HR with
129 the root length is 30 mm; the third form (C) is CR with the ratio of the horizontal to vertical roots
130 is 1:1 in mass (2:1 in number). In this paper, plant roots were organized in the centre of soil-root
131 composites in three forms.

132 As most *Indigofera amblyantha* roots are concentrated within 0.5 m below Earth's surface.
133 When the depth exceeds 0.5 m, the reinforcing effect of plant roots is not obvious because the
134 root content is low (Waldron & Dakessian, 1982). Therefore, to effectively evaluate the GECP
135 of plant roots in reinforced soil, three levels of confining pressure (50 kPa, 100 kPa and 150 kPa)
136 are tested in this paper.

137 Soil-root composites were remoulded in a circular loading box of $\Phi 39.1 \text{ mm} \times 80 \text{ mm}$ (Fig.
 138 2D), which matched with the TSZ-1 strain-controlled triaxial compression apparatus. First, a
 139 suitable amount of test soil was weighed and placed in a container that could be sealed, and an
 140 appropriate amount of water was sprayed on the soil to reach the moisture content required in
 141 this work. Second, the test soil and water were fully mixed, and then the container was sealed for
 142 24 h until the test soil was soaked completely. Third, the required amount of soil was taken from
 143 the sealed container and placed in the circular loading box mentioned above. Finally, plant roots
 144 were buried evenly in the soil, and the method of three-layer compaction was adopted to remould
 145 the soil-root composites in the circular loading box according to the standardized methods of soil
 146 mechanics test and specimen preparation. In addition, specimens of un-reinforced soil were also
 147 prepared, and the preparation processes for the reinforced and un-reinforced samples were
 148 consistent except that no roots were present in the un-reinforced specimens.

149 A prepared specimen was put into the pressure room on which 20 kPa of confining pressure
 150 was applied. Water entered the specimen base until it flowed from the upper surface, and the
 151 constant head was controlled at 1.2 m. The saturated specimens were obtained when the inflow
 152 water and the overflow water were equal.

153 Therefore, the un-reinforced and reinforced samples with root content (0.25%, 0.50%, and
 154 0.75%), root distribution pattern (HR, VR, and CR), confining pressure (50, 100, and 150 kPa),
 155 were performed at the different conditions of shearing rate ($0.012 \text{ mm min}^{-1}$ for CD, 0.12 mm
 156 min^{-1} for CU, and 0.9 mm min^{-1} for UU). The shear strengths of the soil-root composites and un-
 157 reinforced soil specimens were measured by triaxial testing with 15% of the axial strain (Zhang
 158 *et al.*, 2010). All conditions were repeated three times.

159

160 Generalized equivalent confining pressure (GECP)

161 The GECP was derived from the traditional equivalent confining pressure. Gray and Al-Refaei
 162 (1986) analysed the failure mechanism of reinforced sandy soil via a triaxial test and derived the
 163 expression of traditional equivalent confining pressure under drained conditions (Moroto, 1992;
 164 Li *et al.*, 2017):

$$165 \quad \Delta\sigma_{3t} = \sigma_3 \frac{\Delta\sigma_{1f}}{\sigma_{1f}} \quad (1)$$

166 where σ_3 and $\Delta\sigma_{3t}$ represent the confining pressure and traditional equivalent confining pressure,
 167 respectively, and $\Delta\sigma_{1f}$ represents the deviator of the failure principal stresses of reinforced and
 168 un-reinforced soil specimens under the same confining pressure of σ_3 .

$$169 \quad \Delta\sigma_{1f} = \sigma_{1fb} - \sigma_{1f} \quad (2)$$

170 where σ_{1f} is the failure principal stress of un-reinforced soil under a confining pressure of σ_3 and
 171 σ_{1fb} is the failure principal stress of reinforced soil under a confining pressure of σ_3 .

172 The expression of traditional equivalent confining pressure is proposed for sandy soil under
 173 drained conditions, in which cohesion has not been considered (the cohesion of the sandy soil is
 174 0). Meanwhile, the function of plant roots in reinforced soil is evaluated, which does not take the
 175 effect of the drained condition into account.

176 To avoid these limitations in the traditional equivalent confining pressure, *Huang et al. (2007)*
 177 proposed the GECP of cohesive soil and soil-root composites under different drainage conditions,
 178 considering that the Mohr-Coulomb strength theory is also obeyed in reinforced soil. GECP is
 179 the difference in confining pressure between the reinforced and un-reinforced soil specimens at
 180 the same shear strength (Fig. 3). The equation of GECP was derived based on cohesive soil and
 181 un-drained condition were comprehensively considered, the traditional equivalent confining
 182 pressure of sandy soil can also be realized in the equation of GECP when sandy soil be regarded
 183 as a special cohesive soil which with the cohesion is 0. Therefore, to distinguish the expression
 184 of traditional equivalent confining pressure, the GECP is expressed as $\Delta\sigma_{3g}$.

185 The limited balance equation of un-reinforced soil is as follows:

$$186 \quad \sigma_{1f} = \sigma_3 K_p + 2c\sqrt{K_p} \quad (3)$$

187 The limited balance equation of reinforced soil in terms of the difference in confining
 188 pressures between the reinforced and un-reinforced soil specimens at the same shear strength is
 189 as follows:

$$190 \quad \sigma_{1fb} = (\sigma_3 + \Delta\sigma_{3g})K_p + 2c\sqrt{K_p} = \sigma_{1f} + \Delta\sigma_{3g}K_p \quad (4)$$

191 where $\Delta\sigma_{3g}$ represents the generalized equivalent confining pressure; K_p is the passive earth
 192 pressure coefficient of cohesive soil, $K_p = \tan^2\left(45^\circ + \frac{\varphi}{2}\right)$; and c and φ represent shear strength
 193 indexes.

194 Expression of GECP:

$$195 \quad \Delta\sigma_{3g} = \sigma_3 \frac{\Delta\sigma_{1f}}{\sigma_{1f} - 2c\sqrt{K_p}} \quad (5)$$

196 Expression (5) indicates that the GECP of the soil-root composite depends on the deviator of
 197 the failure principal stresses of the reinforced and un-reinforced soil specimens, the failure
 198 principal stress of the un-reinforced soil and the shear strength indexes of the un-reinforced soil.
 199 The expression of the traditional equivalent confining pressure is a special case when the
 200 cohesion is 0; then, expression (5) transforms into expression (1). That is, the expression of the
 201 traditional equivalent confining pressure proposed is for sandy soil, so sandy soil can be regarded
 202 as a cohesive soil when the cohesion is 0.

203

204 Data analyses

205 All statistical analyses were performed using by using SPSS with version of 21.0 and Excel
 206 with version of 2010. All the data used for further analysing (c , φ and *GECP*) is based on the
 207 mean value of the three replications for each condition. Therefore, no statistical test was applied
 208 when describe the results of c , φ and *GECP* in this research.

209 TEST RESULTS

210 Shear strength indexes of soil-root composites under different drainage conditions

211 The shear strength indexes, c and φ , characterized as different trend under different drainage
 212 conditions (Table 1). For the un-reinforced soil, the c values were 8.24, 6.83 and 15.74 and the φ
 213 values were 21.9°, 20.1° and 11.6° under the CD, CU and UU conditions, respectively. For the

214 reinforced soil, the c values varied under different drainage conditions and root contents, while
215 the ϕ values remain basically stable under different drainage conditions due to the root content,
216 which is different to the results of the un-reinforced soil.

217 Under the CD and CU conditions, the c values of the soil-root composites showed obviously
218 increase. The shear strength indexes of the soil-root composites increase the most under the CD
219 condition, with a 251.9% increase in c and a 45.2% increase in ϕ . Under the UU condition, the
220 difference is inconspicuous in the shear strength indexes of the soil-root composites when the
221 root distribution pattern changes. The c values present a complicated change trend, which mainly
222 depends on the root distribution pattern and root content. For example, for VR soil-root
223 composites, the c decreased from 15.35 kPa to 11.81 kPa as the root content increased from 0.25%
224 to 0.75%. However, for the HR and CR soil-root composites, the c decreases and then increases
225 with the increase in root content.

226 Under the same root content and drainage conditions, the c values ranked in order of lower to
227 higher were HR, VR and CR, suggesting the CR is the best at enhancing the soil shear strength.

228 **The GECP of *Indigofera amblyantha* roots in the reinforced soil varied by root contents**

229 The values of GECP in the reinforced soil increased with root content (Fig. 4). Under the CD and
230 CU conditions, when the root content is 0.75%, the GECP of the plant roots in the soil-root
231 composites is 1.5-2.0 times that of 0.50% and more than 5 times that of 0.25%. Taking the CD
232 condition as an example, when the soil-root composites are under 150 kPa of confining pressure
233 and the CR content is 0.75%, the GECP of the plant roots in the soil-root composites is 106.83
234 kPa (Table 2). Namely, the shear strength of the soil-root composites under these conditions is
235 equivalent to the strength of un-reinforced soil subjected to a confining pressure of 256.83 kPa.
236 For the UU condition, the GECP of the plant roots was mainly concentrated within the range of -
237 10 kPa to 10 kPa. The GECP of the plant roots increased as the root content increased, largely
238 mirroring the results for the drainage condition. For the CR reinforced soil, the GECP changes
239 from negative to positive as the root content increases, whereas the GECP is always negative
240 under the condition of HR.

241

242 **The GECP of *Indigofera amblyantha* roots in the reinforced soil varied by drainage 243 conditions and root distribution patterns**

244 The values of GECP are positive under the CD and CU conditions, while shows from negative to
245 positive under UU condition (Fig. 5). Generally, the values of GECP followed the sequence of
246 CD > CU > UU. The GECP of the plant roots under CU condition increased by 5.48-74.76 when
247 compared with those under UU condition. And the GECP of the plant roots under CD condition
248 increased by 0.63-46.15 when compared with those under CU condition. The effect of the root
249 distribution pattern on the GECP in reinforced soil followed the sequence of CR > VR > HR.
250 Under the CU and CD conditions, the GECP of CR is 1-2 times that of VR and 2-5 times that of
251 HR. The largest GECP of CR is 106.83 kPa, while it is only 21.26 kPa for HR (Table 2).

252

253 **The GECP of *Indigofera amblyantha* roots in the reinforced soil varied by confining**

254 **pressure**

255 The values of GECP increased as confining pressure increased under CD and CU conditions
256 while showed a complex change to the confining pressure under the UU condition (Fig. 6). The
257 GECP of the plant roots was increased when the confining pressure increased from 50 kPa to 150
258 kPa under CD and CU conditions. When the root content is 0.25% in the soil-root composite,
259 GECP is negative and diminishes as the confining pressure increases under the UU condition.
260 When the root content is 0.50%, the GECP of HR and VR is also negative, and the reduction in
261 GECP is small compared with the results with the 0.25% root content. However, the GECP of
262 CR changes to 0.41 kPa from -1.26 kPa due to the increase in confining pressure. For the root
263 content of 0.75%, the GECP of the plant roots gradually increases, with the exception that the
264 GECP of HR decreases from -0.03 kPa to -2.08 kPa (Table 2).

265 **DISCUSSION**

266 **The evaluation mechanism based on the GECP**

267 The soil-root composite is a composite system in which the plant roots have a high deformation
268 modulus but the soil is weak. When soil-root composites are destroyed under an external load,
269 dislocation occurs between soil and plant roots due to the tremendous difference in their
270 deformation moduli. The dislocation is constrained by the frictional resistance and interlocking
271 force between the soil particles and plant roots. Additionally, the root tensile strength and soil
272 compressive strength are effectively equilibrated by the friction of the soil-root interface; thus,
273 soil shear strength is improved (Waldron, 1977; Waldron & Dakessian, 1981; Wu et al., 1988;
274 Wu & Watson, 1998; Fan & Su, 2008).

275 The reinforcing effect of plant roots on soil is mainly manifested by the addition of cohesion
276 (Ali & Osman, 2007; Normaniza, Faisal & Barakbah, 2008), and the internal friction angle is
277 mainly related to the soil particle structure (De Baets & Poesen, 2006). The phenomenon that
278 plant roots affect the cohesion rather than the internal friction angle of the soil-root composites
279 can be explained by the fact that living plant roots are flexible (Huang et al., 2007). In addition,
280 the root content to soil mass ratio is small in the soil-root composite, although as the root content
281 increases, the soil structure does not greatly change, so the variation in the ϕ value is small
282 (Chegenizadeh & Nikraz, 2012).

283 Compared with the Wu-Waldron model, the evaluation mechanism based on the GECP
284 possesses the following merits: (1) different drainage conditions can be considered; (2) different
285 stress-strain characteristics of the cohesive soil and sandy soil can be simulated; (3) the effect of
286 drainage condition, root content and root morphology on the reinforced soil can be intuitively
287 mirrored by the GECP, accurately and reliably. There are some possible points to discuss: for
288 instance, Ingold (1983) showed that the shear strength of soil-root composites is worse under
289 undrained conditions than under other conditions, but the results from our specimens do not
290 agree.

291

292 **Effect of the root characteristics in the reinforced soil**

293 The c values of the soil-root composites showed obviously increase under the CD and CU

294 conditions, while it presents a complicated change trend under UU condition (Table 1). The
295 contact area increases gradually with the increase of the root content because the plant roots can
296 be fully in contact with the soil particles. Plant roots provide an effective lateral constraint on
297 soil: the lateral and axial deformation of soil-root composites is reduced and the shear strength is
298 increased compared with the results of un-reinforced soil (Tan et al., 2019). As an exception, the
299 stable reinforcing effect is not clearly produced when the root content is 0.25% because the low
300 plant root content has little effect on the shear deformation. In contrast, the bonding state of the
301 soil is destroyed when plant roots are placed in the preparation of the soil-root composites.

302 However, relevant studies have shown that the shear strength of soil-root composites increases
303 with root content until a peak value is achieved, and this peak corresponds to an optimal root
304 content (Tan et al., 2019). When the root content continues to increase, the plant roots are not
305 effectively connected with the soil particles, and plant roots come into contact. Therefore, the
306 lateral restraint of the root system in the soil is no longer strengthened. With root contents lower
307 than the optimal root content, the shear strength of the soil-root composites is reduced because
308 the relative displacement is exacerbated between plant roots. Clearly, the root content is
309 relatively low in this paper and represents the stage of soil reinforcing. The optimal root content
310 is not the focus of this paper, so no further discussion is provided on this topic.

311 Among the three root distribution types (HR, VR and CR), CR is the best at enhancing the
312 soil shear strength (Table 2). HR does not effectively reinforce soil when the root content is low
313 because the soil integrity is destroyed and there is a smaller contact area between soil particles
314 and the root system. However, when the root system is decussately placed in specimens, the root
315 system bears some of the horizontal shear force and limits soil lateral deformation because of the
316 interaction between the soil particles and the root system. Meanwhile, the rigid modulus of the
317 soil-root composites is notably improved, which is mainly reflected in the increase in the
318 compression modulus of the specimens, and the soil deformation is effectively restrained (Lewis,
319 1956).

320

321 **Effect of the different drainage conditions in the reinforced soil**

322 Generally, specimens are consolidated to obtain different void ratios and left undrained to keep
323 the void ratio constant (Mun et al., 2016). For soil-root composites, the initial porosity of
324 specimens is small under consolidated conditions, and the concave-convex structure of the root
325 surface is in contact with some soil particles. When specimens are loaded, more energy is
326 required to overcome the interlocking force between the soil particles and plant roots. Therefore,
327 the curve describing the relationship between the large principal stress difference and the axial
328 strain in the soil-root composites is steeper than that for the unconsolidated specimens (Cazzuffi
329 & Crippa, 2005).

330 In the UU triaxial test, the soil moisture content and initial porosity are high in the specimens.
331 On the one hand, the decrease in electrolyte concentration greatly thickened the water film
332 around the soil particles, which increased the space of the soil-root interface. Furthermore, the
333 effective surface area of the root-soil interface decreases so that the interlocking force of the soil

334 particles on the root system is reduced. On the other hand, the lubrication effect of water reduces
335 the friction between soil particles and the root system, and then a soft sliding surface is formed at
336 the soil-root interface (*Fan & Su, 2008*). In addition, the confining pressure applied to the
337 specimens is offset by the pore water pressure based on the assumption that the volume of the
338 specimens does not vary. The effective stresses of the specimens remain stable, so the strength
339 envelope is relatively flat, therefore, the value of ϕ is not obviously changed (*Operstein &*
340 *Frydman, 2000*).

341

342 **Effect of the different confining pressure in the reinforced soil**

343 The values of GECP in the reinforced soil increased with root content (*Fig. 4*). The density of the
344 soil-root composites increased as the confining pressure increased, resulting in an increase in the
345 soil quality per unit volume and a reduce in the soil particle gap. And the plant roots could
346 interlock with soil particles more tightness because of the reducing in the soil particle gap, which
347 limits the lateral deformation of soil. On the other hand, an increase in the specimen density
348 increases the number of soil particles in contact with the root surfaces, resulting in a larger
349 contact area and presumably a higher cohesion in soil-root composites (*De Baets et al., 2008;*
350 *Abernethy & Rutherford, 2010*).

351 The values of GECP are positive under the CD and CU conditions, while shows from negative
352 to positive under UU condition (*Fig. 5*). The phenomenon that the GECP varies from a negative
353 value to a positive value occurs as the root content increases (*Fig. 4 and Fig. 5*). This
354 phenomenon can be explained by the fact that fewer plant roots enhance the water transport and
355 the lubrication of the soil-root interfaces. The soil shear strength is mainly borne by soil skeleton,
356 which is formed by the free arranging and binding of soil particles, and the biting force and
357 bonding force between soil particles are sensitive to water when the root content is low. However
358 large porosity exists between the interfaces of soil-root, high confining pressure accelerates soil
359 particles gap is filled and the organic calcium of soil particles is dissolved, and the deformation
360 resistance of soil skeleton is reduced (*Pierret et al. 2007*). Thus, fewer plant roots enhance the
361 water transport and the lubrication of the soil-root interfaces. Inversely, high root content can
362 limit soil lateral deformation and effectively reduce soil compression deformation, which is
363 conducive to the dissipation of excess pore water pressure, which delayed change of pore water
364 pressure and increased soil effective stress. However, the reinforcing effect of root distribution
365 patterns based on different confining pressures has yet to be studied.

366 The GECP of the plant roots decreased and increased as confining pressure increased under
367 smaller and higher root contents, respectively (*Fig. 6*). When specimens are subjected to high
368 confining pressures, the soil particles become highly compacted. A smaller number of plant roots
369 placed in the specimens has little influence on the density of the soil particles and the soil-root
370 contact area. Therefore, the greater the confining pressure is, the smaller the reinforcing effect of
371 plant roots in reinforced soil. However, for higher root contents, a high confining pressure will
372 make the redundant plant roots fully contact the soil particles in the specimens. The soil particles
373 at the root-soil interface will rearrange until the reinforcing effect of the plant roots is effectively

374 exerted. Therefore, the contribution of plant roots to soil strength under a high confining pressure
375 is greater than that under a low confining pressure.

376 CONCLUSION

377 An evaluation based on the GECP is applied to assess the reinforcing effect of *Indigofera*
378 *amblyantha* roots on soil. The results reflect that the main function of plant roots in reinforced
379 soil is to change the soil cohesion but not to change the internal friction angle under different
380 drainage conditions. The c values of the soil-root composites showed obviously increase under
381 the CD and CU conditions, while it presents a complicated change trend under UU condition.
382 Under the CD and CU conditions, the c values of the soil-root composites showed obviously
383 increase. The reinforcing effect of the root content in reinforced soil followed the sequence of
384 $0.75\% > 0.50\% > 0.25\%$, and the c values ranked in order of lower to higher were HR, VR and
385 CR.

386 The values of GECP in the reinforced soil increased with root content, and it is positive under
387 the CD and CU conditions, while shows from negative to positive under UU condition with an
388 sequence of $CD > CU > UU$. The values of GECP increased as confining pressure increased
389 under CD and CU conditions while showed a complex change to the confining pressure under
390 the UU condition. Therefore, the GECP can be used as an intuitive and credible indicator to
391 quantitatively evaluate the reinforcing effect of plant roots on soil and helps to explain the soil
392 reinforcement mechanism of plant roots.

393 The results in this research are based on experiments on one soil type with the *Indigofera*
394 *amblyantha* root. However, the soil characteristics (e.g., texture) and the root of different plant
395 species have great influence on the shear strength of reinforced soil, which of course affect the
396 influence of root contents on the shear strength of reinforced soil. Therefore, more researches
397 under different soil characteristics with different root should be investigated in the future to
398 verify the results obtained in this research.

399 ADDITIONAL INFORMATION AND DECLARATION

400 Funding

401 This study was financially supported by the National Key Research & Development Plan of
402 China (2017YFC0504902), Research Fund for Excellent Dissertation of China Three Gorges
403 University (2020BSPY003), the National Natural Science Foundation of China (41807068), the
404 CRSRI Open Research Program (CKWV2018488/KY), and the open fund of Key Laboratory of
405 Geological Hazards on Three Gorges Reservoir Area, Ministry of Education (China Three
406 Gorges University) (2018KDZ06).

3 **Notes:** CD denotes the consolidation drained condition; CU denotes the consolidation undrained condition;
4 UU denotes the unconsolidated undrained condition; HR is horizontal root; VR is vertical root; CR is complex
5 root.
6

Table 2 (on next page)

Generalized equivalent confining pressure (GECP) of *Indigofera amblyantha* roots in the reinforced soil.

Notes: CD denotes the consolidation drained condition; CU denotes the consolidation undrained condition; UU denotes the unconsolidated undrained condition; HR is horizontal root; VR is vertical root; CR is complex root.

1 **Table 2:**
 2 **Generalized equivalent confining pressure (GECP) of *Indigofera amblyantha* roots in the**
 3 **reinforced soil.**

Confining pressure (kPa)	Root content (%)	CD			CU			UU		
		HR	VR	CR	HR	VR	CR	HR	VR	CR
50	0.25	3.61	11.23	21.01	1.61	6.35	13.72	-3.97	-4.10	-4.14
