Background: The genomic sequences of centromeres, as well as the set of proteins that recognize and interact with centromeres, are known to quickly diverge between lineages potentially contributing to post-zygotic reproductive isolation. However, the actual sequence of events and processes involved in the divergence of the kinetochore machinery is not known. The patterns of gene loss that occur during evolution concomitant with phenotypic changes have been used to understand the timing and order of molecular changes.

Methods: I screened the high-quality genomes of twenty budding yeast species for the presence of well-studied kinetochore genes. Based on the conserved gene order and complete genome assemblies, I identified gene loss events. Subsequently, I searched the intergenic regions to identify any un-annotated genes or gene remnants to obtain additional evidence of gene loss.

Results: My analysis identified the loss of four genes (NKP1, NKP2, CENPL/IML3, and CENPN/CHL4) of the inner kinetochore constitutive centromere-associated network (CCAN/also known as CTF19 complex in yeast) in both the *Naumovozyma* species for which genome assemblies are available. Surprisingly, this collective loss of four genes of the CCAN/CTF19 complex coincides with the emergence of unconventional centromeres in *N.castellii* and *N.dairenensis*. My study suggests a tentative link between the emergence of unconventional point centromeres and the turnover of kinetochore genes in budding yeast.

11
12 **Abstract**

13
14 **Background:** The genomic sequences of centromeres, as well as the set of proteins that
15 recognize and interact with centromeres, are known to quickly diverge between lineages
16 potentially contributing to post-zygotic reproductive isolation. However, the actual sequence of
17 events and processes involved in the divergence of the kinetochore machinery is not known. The
18 patterns of gene loss that occur during evolution concomitant with phenotypic changes have been
19 used to understand the timing and order of molecular changes.

20 **Methods:** I screened the high-quality genomes of twenty budding yeast species for the presence
21 of well-studied kinetochore genes. Based on the conserved gene order and complete genome
22 assemblies, I identified gene loss events. Subsequently, I searched the intergenic regions to
23 identify any un-annotated genes or gene remnants to obtain additional evidence of gene loss.

24 **Results:** My analysis identified the loss of four genes (NKP1, NKP2, CENPL/IML3, and
25 CENPN/CHL4) of the inner kinetochore constitutive centromere-associated network
26 (CCAN/also known as CTF19 complex in yeast) in both the *Naumovozyma* species for which
27 genome assemblies are available. Surprisingly, this collective loss of four genes of the
28 CCAN/CTF19 complex coincides with the emergence of unconventional centromeres in
29 *N.castellii* and *N.dairenensis*. My study suggests a tentative link between the emergence of
30 unconventional point centromeres and the turnover of kinetochore genes in budding yeast.

31
32 **Introduction**

33
34 The increasing availability of genomic datasets across diverse species has allowed the use of
35 comparative genomic approaches to study kinetochore evolution. Such comparative approaches

36 have led to interesting evolutionary insights from species with unique kinetochores (Drinnenberg
37 & Akiyoshi, 2017). The kinetochore is a complex of interacting proteins that have undergone
38 frequent changes in gene content and exhibits strong signatures of adaptive evolution (Malik &
39 Henikoff, 2001; Talbert, Bryson & Henikoff, 2004; Schueler et al., 2010; Drinnenberg, Henikoff
40 & Malik, 2016). Despite changes in gene content, the kinetochore in diverse species is known to
41 consist of the inner kinetochore which is assembled close to the centromere DNA as a
42 specialised form of histone (CENPA) and the outer kinetochore which interacts with
43 microtubules. The inner and outer kinetochores are known to consist of several interacting
44 protein complexes (see van Hooff et al., 2017 for more details). These kinetochore protein
45 complexes show patterns of co-evolution with interacting components through correlated gene
46 loss events (Tromer, 2017). The CCAN/CTF19 complex interfaces with both the inner and outer
47 kinetochore acting as a foundation for kinetochore formation (Hara & Fukagawa, 2017; Hinshaw
48 & Harrison, 2019). Surprisingly, large-scale systematic screening for kinetochore genes in the
49 genomes of numerous eukaryotes has shown that the majority of the components of the
50 CCAN/CTF19 complex are lost in many lineages (van Hooff et al., 2017). Another unexpected
51 observation was that the CENPA (CENH3 & CSE4 homolog) gene, which performs a central
52 role in kinetochore function, was lost in many insect species. This potentially recurrent loss of
53 the CENPA/CSE4 gene in insect species coincides with their transition to holocentricity
54 (Drinnenberg et al., 2014). Interestingly, it has been shown that *C.elegans* holocentromeres are
55 actually point centromeres that are dispersed at transcription factor hotspots (Steiner & Henikoff,
56 2014). Hence, it has been speculated that changes in the gene content of kinetochores might be
57 functionally related to transitions in the centromere type (Drinnenberg & Akiyoshi, 2017).

58
59 Centromere sequences in the vast majority of species are repeat-rich regions that are thought to
60 be defined epigenetically and/or through recognition of dyad rich regions with non-B-form DNA
61 structures (Kasinathan & Henikoff, 2018). Despite advances in genome sequencing and
62 assembly methods, the high repeat content of these centromeres makes it harder to assemble and
63 study them. Hence, as a proxy to the study of centromere regions, comparison of tandem repeats
64 across large phylogenetic distances have been performed to understand the evolution of
65 centromere sequences (Melters et al., 2013).

66

67 One of the most interesting transitions during centromere evolution was the emergence of
68 genetically defined point centromeres in budding yeasts (Malik & Henikoff, 2009). These
69 ~150bp long centromeres found in Saccharomycetaceae have been easier to study due to the lack
70 of repetitive regions, availability of complete high-quality genome assemblies for multiple
71 closely related species, gene knockout libraries and ease of experimental manipulation. Hence,
72 budding yeast species are a popular system to study the evolution of centromeres and the set of
73 proteins that interact with them (Roy & Sanyal, 2011).

74

75 In addition to changing their sequences, centromeres are also known to change their genomic
76 positions without any change in the karyotype (Montefalcone et al., 1999). However, centromere
77 evolution can also be accompanied by changes in the karyotype (O'Neill, Eldridge & Metcalfe,
78 2004). Within mammals, centromeres are known to have undergone multiple repositioning
79 events (Rocchi et al., 2012). Centromere repositioning events seem to be fairly common and
80 could have a role in driving speciation or, at the very least, have a non-negligible role in
81 affecting the local genomic selection landscape.

82

83 Recently, it has been shown that in *Naumovozya*, an unconventional centromere has come into
84 existence at a location that is largely distinct from that expected based on synteny with other
85 Saccharomycetaceae species (Kobayashi et al., 2015). The *Naumovozya* genus has been
86 suggested as a model for comparative genomics and study of adaptive evolution due to the
87 various phenotypic differences compared to other yeast species (Karademir Andersson & Cohn,
88 2017).

89

90 In this study, I first screened the genome assemblies of eight Pre-WGD and twelve Post-WGD
91 yeast species for the presence/absence of homologs of 67 kinetochore genes. I find evidence for
92 the concurrent loss of multiple genes from the CCAN/CTF19 protein complex in *Naumovozya*
93 species and corresponding sequence divergence of the N-terminus region of the CENPA/CSE4
94 gene that interacts with the CCAN/CTF19 complex. In contrast to this, I see high levels of
95 sequence conservation of the C-terminus region of the CENPA/CSE4 gene that mediates an
96 interaction between the kinetochore and centromere. My analysis finds an association between
97 gene loss events and the emergence of novel centromeres in *Naumovozya* species.

98

99 **Materials and Methods**

100

101 **Gene presence/absence screening**

102

103 I compiled a list of 67 kinetochore associated genes in the yeast *S. cerevisiae* by downloading
104 genes annotated with the GO term kinetochore (GO: 0000776) in Ensembl release 91. The
105 orthologs of these genes in all twenty yeast species were identified from the Yeast Gene Order
106 Browser (YGOB) (Byrne & Wolfe, 2005). I screened the genomes of all twenty yeast species for
107 the presence of all 67 genes and identified eight genes that are (both copies lost in post-WGD)
108 lost in at least one species (see **Supplementary Material S1**). Kinetochore genes are known to
109 evolve at a very fast rate, making it hard to identify orthologs of these genes even in closely
110 related species (van Hooff et al., 2017). It is possible that these genes have evolved at a very fast
111 rate making it unfeasible to establish homology of these genes. Fortunately, the YGOB provides
112 not only the order of the genes but also the intergenic sequences between genes. Based on
113 flanking genes with conserved synteny in other species, I identified the intergenic regions that
114 correspond to the location of the missing genes (see **Supplementary Material S2**). I checked
115 these intergenic sequences for the presence of open reading frames (ORFs) using the NCBI ORF
116 finder program with default settings. The ORFs that were found in the intergenic regions did not
117 show any homology (inferred using blastn and blastp search against NCBI's nucleotide
118 collection and non-redundant protein sequences, respectively) to the genes that I have inferred to
119 be lost. Based on the evidence from the identification of syntenic regions using YGOB and
120 additional screening of intergenic regions I am confident of these gene loss events. Nonetheless,
121 the presence of highly diverged copies of these genes in non-syntenic regions and genome
122 assembly errors cannot be ruled out.

123

124 **Multiple sequence alignments of CENPA/CSE4 gene**

125 The complete open reading frame of the CENPA (CENH3 & CSE4 homolog) gene was used for
126 multiple sequence alignment. To ensure that the results I see are not the result of alignment
127 artifacts, I performed the multiple sequence alignment at the nucleotide sequence level and
128 amino acid residue level using four different programs (Clustal omega (default settings in the
129 webserver), M-coffee (command used and alignment scores are provided in **Supplementary**
130 **Material S3**), MUSCLE (default settings in MEGA) and Guidance with PRANK as the aligner

131 (command used is provided in **Supplementary Material S3**). All the nucleotide and amino acid
132 sequence alignments are provided as **Supplementary Material S3**. I investigated the multiple
133 sequence alignments for evidence of lineage-specific patterns of selection in *Naumovozyma*
134 species using the programs (RELAX, MEME, FEL and BUSTED) available in the HYPHY
135 package (Kosakovsky Pond, Frost & Muse, 2005). The output files of these are also provided in
136 **Supplementary Material S3**. The presence of additional sequences in the genus *Naumovozyma*
137 was seen in all of the multiple sequence alignments that I have analysed. It is possible that longer
138 ORF's have been incorrectly annotated as the CDS for both *Naumovozyma* species. However,
139 the second methionine codon in the CDS occurs at the 226th and 40th residue from the currently
140 annotated start codon in *N. castellii* & *N. dairenensis*, respectively. If the second methionine is
141 the correct start codon, the *N. castellii* protein would be just 39 residues. This suggests that the
142 correct ORF is annotated in *Naumovozyma* species. To further rule out the possibility of
143 erroneous annotation of shorter ORF's in non-*naumovozyma* species I extracted the genomic
144 sequence found between genes flanking CENPA (CENH3 & CSE4 homolog) and searched them
145 for ORF's using the NCBI ORF finder program with default settings (see **Supplementary**
146 **Material S4**). I found that the longest ORF that could be identified in this sequence was the
147 currently annotated ORF itself. This further supports the validity of the annotation and multiple
148 sequence alignments generated by me. I used the amino acid alignment generated by MUSCLE
149 aligner to calculate the sequence conservation score using the al2co program (Pei & Grishin,
150 2001) with default settings along with the -a flag to calculate nine measures of sequence
151 conservation. Per base measures of sequence conservation are provided as **Supplementary**
152 **Material S5**.

153

154 **Calculation of dyad density**

155 Centromere sequences of the two *Naumovozyma* species were obtained from NCBI and YGOB
156 browser for the remaining 18 species. The intergenic regions in *Naumovozyma* species
157 orthologous to the old centromeres were extracted from YGOB. All these sequences and their
158 locations are provided in **Supplementary Material S6**. The program *palindrome* from the
159 EMBOSS package (Rice, Longden & Bleasby, 2000) was used to identify dyad symmetry (i.e.,
160 DNA sequences with base pairs that are inverted repeats of each other). The following settings
161 were used for running the program "-minpallen 5 -maxpallen 100 -gaplimit 20 -overlap". All the

162 palindromes identified for each of the sequences is provided as **Supplementary Material S7**.
163 The dyad density for each centromere sequence was calculated as the fraction of bases that are
164 part of a dyad. GC content for each sequence was calculated as the fraction of GC bases. GC
165 content and dyad density for each of the centromere sequences are provided in **Supplementary**
166 **Material S8**.

167 **Results**

168

169 **Patterns of kinetochore gene loss**

170

171 My study system consists of eight Pre-WGD and twelve Post-WGD yeast species at varying
172 evolutionary distances (see **Fig. 1, phylogeny based on** (Gordon, Byrne & Wolfe, 2011; Feng et
173 al., 2017)). Based on screening of twenty yeast genomes for the presence of kinetochore genes I
174 identified that eight genes (NKP1, NKP2, CENPL/IML3, CENPN/CHL4, CENPT/CNN1,
175 CENPW/WIP1, FIN1 and BIR1) are lost at least once (see **Fig. 1** and **Supplementary Material**
176 **S1**). Intriguingly, five of the eight genes (i.e., NKP1, NKP2, CENPL/IML3, BIR1 and WIP1)
177 that have lost both their copies in the Post-WGD species are also the ones that are lost in the Pre-
178 WGD species (see **Fig. 1**). This hints at the dispensability of these genes over the course of
179 evolution. In this study, I focus on the set of four genes (NKP1, NKP2, CENPL/IML3, and
180 CENPN/CHL4) that are lost in *Naumovozyma* (a genus known to have novel point centromeres).
181 As the name suggests, the Non-essential Kinetochore Protein genes NKP1 & NKP2 produce
182 proteins that localise to kinetochores and when deleted produce viable single gene mutants
183 (Cheeseman et al., 2002). However, both single gene mutants are known to show elevated rates
184 of chromosome loss (Fernius & Marston, 2009). Knockout of both NKP1 and NKP2 only shows
185 a moderate increase in chromosome loss (Tirupataiah et al., 2014). Despite being non-essential
186 genes, at least one copy of both of these genes is found in 15 of the 20 yeast species screened in
187 this study. A broader phylogenetic search for homologs of these genes has shown the repeated
188 loss of these two genes in various taxa (Tromer, 2017). While it was known that NKP1 and
189 NKP2 bind to COMA complex (Hornung et al., 2014), recent work has shown that NKP1 and
190 NKP2 are positioned at the bottom of the CTF19 complex and form a four-chain helical coil
191 along with OKP1 and AME1 at their c-terminus (Hinshaw & Harrison, 2019). The main function
192 of the NKP1 and NKP2 heterodimer is thought to be the stabilisation of the COMA complex

193 (Schmitzberger et al., 2017). The COMA complex is known to interact directly with the
194 CENPA/CSE4 protein (Fischböck-Halwachs et al., 2019).

195

196 The CENPN/CHL4 (CHromosome Loss 4) single-gene knockouts are also viable but are known
197 to show increased levels of chromosome loss, miss-segregation, and abnormal kinetochores (Roy
198 et al., 1997). However, based on the chromatin state CENPN/CHL4 mutant cells are known to
199 show two distinct (high and low) levels of mitotic mobility (Roy & Sanyal, 2011). This suggests
200 that CENPN/CHL4 mutants can be compensated through changes in the chromatin state.
201 CENPL/IML3 (Increased Minichromosome Loss) protein forms a stable heterodimer with
202 CENPN/CHL4 protein (Hinshaw & Harrison, 2013). Although CENPL/IML3 and
203 CENPN/CHL4 are known interactors, the phylogenetic distribution of CENPL/IML3 seems to be
204 more restricted than that of CENPN/CHL4. The association of cohesin with the pericentromeric
205 regions is ensured by the action of CENPL/IML3 and CENPN/CHL4. The lack of these two
206 genes leads to reduced cohesin binding at the pericentromere that results in the miss-segregation
207 of chromosomes (Fernius & Marston, 2009).

208

209 The function of the genes lost in *Naumovozyma* may be performed by genes that are found in
210 *Naumovozyma* but are absent in *S. cerevisiae*. *Naumovozyma* species have 46 genes that are
211 absent in the other 18 species analysed in this study. To evaluate whether any of these genus
212 specific genes could have taken over the role performed by the four missing genes, I identified
213 homologs of each of these genes by performing blastp search against the non-redundant protein
214 database with an e-value cut-off of 10^{-3} . None of the identified homologs had a characterised role
215 related to the kinetochore machinery. However, profile-versus-profile search based comparisons
216 have identified that NKP1 and NKP2 are extremely similar to Mis12 and Nnf1 (Tromer et al.,
217 2019). Since, one copy (NCAS0H00450 & NDAI0K02740) of the Nnf1 gene is present in each
218 of the *Naumovozyma* species; it is possible that the functions of NKP1/2 are compensated.

219

220

221 **N-terminus divergence of CENPA/CSE4 gene in *Naumovozyma***

222

223 The detailed study of the interactions between kinetochore proteins in *S. cerevisiae* has led to a
224 better understanding of their roles (Measday et al., 2005; Baetz, Measday & Andrews, 2006).
225 However, the evolution of the kinetochore network across Eukaryotes has been shown to be a
226 complex process that requires further investigation (van Hooff et al., 2017). In the current study,
227 I have focussed on well-studied genetic interactions of the selected genes that have lost both
228 copies in Post-WGD yeast species. Chromatin Immuno-Precipitation (ChIP) of CENPA/CSE4
229 protein followed by sequencing of DNA fragments was used by Kobayashi et al. (2015) to
230 identify all the CENPA/CSE4 binding sites in the *N. castellii* genome. Based on this
231 experimental data for CENPA/CSE4 along with similar ChIP-seq data for the NDC10, NDC80,
232 and CEP3 proteins the locations of the new centromeres in *N. castellii* have been validated
233 (Kobayashi et al., 2015). The multiple sequence alignment of amino-acid sequences across the
234 study species (see **Supplementary Material S3**) shows that the CENPA/CSE4 genes of *N.*
235 *castellii* and *N. dairenensis* have a stretch of approximately ten amino acid residues at the very
236 beginning of the CENPA/CSE4 gene that is absent in other species. It is known that the C-
237 terminus of the CENPA/CSE4 protein binds to the centromeric DNA sequence, and the N-
238 terminus interacts with the CCAN/CTF19 complex (Chen et al., 2000). The N-terminus region
239 has overall reduced sequence conservation across all species compared to the C-terminus region
240 (see **Fig. 2**). I also find evidence of significant relaxed selection in the *N. castellii* and *N.*
241 *dairrenensis* lineages using the hypothesis testing framework available in the RELAX program
242 (version 2.1) on the multiple sequence alignments generated by MUSCLE. However, when the
243 alignments generated using guidance with PRANK as aligner was used, the relaxed selection in
244 the *N. castellii* lineage was not found to be statistically significant (see **Supplementary**
245 **Material S3**). These differences in the inferences based on the multiple sequence aligner used
246 are known to occur when the sequences are highly diverged (Blackburne & Whelan, 2013). I
247 have shown earlier that genes can experience relaxed selection when the c-terminal end is
248 increased in length due to change in the position of the stop codon (Shinde et al., 2019). Hence,
249 the relaxed selection detected in the CENPA/CSE4 gene could simply be a result of drastic
250 change in the length of the n-terminal sequence.

251

252 The N-terminus of the CENPA/CSE4 protein has been shown to play a role in the ubiquitin-
253 mediated proteolysis of the CENPA/CSE4 protein (Au et al., 2013). More recently, sumoylation

254 and ubiquitination of the N-terminus have been shown to be required to prevent the
255 mislocalization of CENPA/CSE4 to non-centromeric chromatin (Ohkuni et al., 2018). The lysine
256 65 residue (K65) in the CENPA/CSE4 gene has been identified as the residue important for
257 proper localisation. Changes in the N-terminus region of CENPA/CSE4 gene could have led to
258 changes in the post-translational modifications resulting in changes in the localisation patterns
259 and subsequent movement of centromeres in *Naumovozya*.

260

261 **Dyad density at point centromeres**

262

263 Dyad symmetry refers to the presence of inverted repeats or palindromes in the sequence. The
264 inverted repeats identified on the centromere of *S. cerevisiae* are provided in **Fig. 3** as an
265 example. It has been shown that centromere regions are defined by the presence of Non-B-form
266 DNA structures resulting from the presence of dyad symmetry in the nucleotide sequence
267 (Kasinathan & Henikoff, 2018). While the new *Naumovozya* centromeres are enriched for
268 dyad symmetries and non-B-form DNA, the dyad symmetry was less and the SIST DNA melting
269 and cruciform extrusion scores were lower in *Naumovozya* (sensu lato, demarcated by a red
270 box in **Fig. 1**) compared to sensu strictu species (demarcated by a blue box in **Fig. 1** (Pulvirenti
271 et al., 2000)). However, they utilised the contrast of sensu stricto vs sensu lato and ignore other
272 species that have been phylogenetically placed closer to the sensu strictu species. Using a larger
273 sample size (centromeres from various budding yeast species) I show that the GC content shows
274 a significant negative correlation (Kendall's rank correlation coefficient tau of -0.59, p-value <
275 2.2e-16) with dyad density (see **Fig. 4A**). This correlation is reflective of the genome-wide
276 pattern seen in *S. cerevisiae* (Lisnić et al., 2005).

277

278 The unconventional centromeres in the yeast species *N. castellii* and *N. dairenensis* are in most
279 cases located at a different genomic locus compared to the point centromeres found in other
280 budding yeast species such as *S. cerevisiae* (Kobayashi et al., 2015). This movement of
281 centromeres has partly been attributed to chromosomal re-arrangements. I show that the GC
282 content of the intergenic regions corresponding to the older (*S. cerevisiae* like) centromeres is
283 very high and dyad density is low (see **Fig. 4A**; red coloured circles). On the other hand the new
284 unconventional centromeres that have been identified in *Naumovozya* (see **Fig. 4A**; blue
285 coloured circles) are having higher dyad densities and lower GC content. I note that the pattern is

286 the same for both *Naumovozya* species (see **Fig. 4A**; filled circles for *N. castellii* and unfilled
287 circles for *N. dairenensis*). The new (mean: 25.80, median: 24.77, min: 20.00 & max: 35.16)
288 centromeres in *N. dairenensis* have a lower GC content than the older regions (mean: 31.58,
289 median: 32.90, min: 22.03 & max: 37.32). Similarly, the new (mean: 21.36, median: 20.91, min:
290 18.18 & max: 24.55) centromeres in *N. castellii* have a lower GC content than the older regions
291 (mean: 30.15, median: 30.35, min: 21.82 & max: 36.47). I used a pair-wise wilcoxon test with
292 holm multiple testing correction (also see **Fig. 4B**) to compare the GC content of the old and new
293 centromere regions and find a difference in both *N. castellii* (q-value: 0.0067) and *N. dairenensis*
294 (q-value: 0.0778). This change in dyad density and GC content probably reflects a divergence
295 that occurred after the change in the location of the centromere.

296 **Discussion**

297

298

299 Nucleotide sequence divergence at the centromeres themselves as well as in the coding sequence
300 of proteins that recognise and bind to centromeres have been proposed as potential mechanisms
301 for the build-up of post-zygotic reproductive isolation (Borodin et al., 2001). The paradoxical
302 behaviour of centromeres to evolve rapidly while still being inherited stably makes them good
303 candidates for loci that contribute to the process of speciation (Henikoff, Ahmad & Malik, 2001).
304 However, the observation that *Drosophila* species produce fertile offspring despite the extensive
305 divergence of the sequence of centromere binding proteins seems to contradict this idea (Sainz et
306 al. 2003; but see Thomae et al. 2013). Computational identification and functional
307 characterisation of the effects of sequence divergence, loss, and duplication of the kinetochore
308 genes in diverse species will help clarify the role of the centromere in facilitating reproductive
309 isolation.

310

311 In this study, I provide evidence that suggests that both copies of four genes of the
312 CCAN/CTF19 complex are lost in *Naumovozya* budding yeast species that have transitioned to
313 unconventional centromeres (Kobayashi et al., 2015). The loss of these CCAN/CTF19 complex
314 genes is potentially mediated by changes in the N-terminus region of the CENPA/CSE4 gene
315 (see **Fig. 3B**). Although I have no experimental data to suggest that the changes in the N-
316 terminus region of the CENPA/CSE4 gene are a consequence of changes in the sequence of the
317 centromere being bound by the C-terminus region, it is one potential scenario that could explain

318 the observed association between gene loss and transition to unconventional centromeres. In
319 contrast to the well-studied case of loss of CENH3 (CENPA/CSE4 homolog) gene in multiple
320 insect lineages (Drinnenberg et al., 2014) and the multiple cases of exon gain and loss (Fan et al.,
321 2013), I show that transition to a new centromere sequence might be sufficient for the loss of
322 CCAN/CTF19 complex genes. Understanding the sequence of events involved in the loss of the
323 CCAN/CTF19 complex genes and the emergence of the unconventional centromere in budding
324 yeast species would help understand the loss of CCAN/CTF19 complex genes in various
325 eukaryotic lineages (van Hooff et al., 2017). The CENPA/CSE4 gene has additional sequence in
326 *Naumovozyma* compared to other species suggesting that the unconventional centromeres might
327 potentially be remnants of the ancestral state of point centromeres. I discuss a few other potential
328 scenarios for the sequence of events that could have led to the association observed.

329 The dispensability of the genes that are lost in *Naumovozyma* is supported by the viability of *S.*
330 *cerevisiae* knockouts and independent loss in the two Pre-WGD *Eremothecium* species. It is
331 possible that initially, these genes were sequentially lost, and the emergence of novel
332 centromeres was an adaptive response to compensate for the lost genes. Yet, the loss of three out
333 of these four genes in *Eremothecium* species (*E. gossypii* and *E. cymbalariae*) does not seem to
334 be associated with any noticeable changes in centromere type. The evolution of novel
335 centromeres could just be one possible solution to the loss of these genes from the CCAN/CTF19
336 complex, and *Eremothecium* species might have come up with a different solution. Further
337 phenotypic characterisation of *Eremothecium* species might shed light on this.

338
339 It has been shown that loss of RNAi leads to a shortening of the centromeres and is an important
340 determinant of centromere evolution in fungi (Yadav et al., 2018). The *N. castellii* species in
341 addition to having unconventional point centromeres, have also been shown to have a functional
342 RNA interference pathway (Drinnenberg et al., 2009). Despite having a role in fission yeast
343 heterochromatin specification at the centromeres, siRNA's have not been found to have any
344 centromere-specific role in *N. castellii* (Kobayashi et al., 2015). Nonetheless, it would be
345 interesting to know what role the presence of RNAi machinery in *Naumovozyma* might have had
346 in the loss of CCAN/CTF19 complex genes. The Drinnenberg et al. study (2009) reports the
347 gene expression fold change of ago1 knockout and dcr1 knockout in *N. castellii* compared to the

348 wild type. However, none of the genes showing a fold-change greater than two are part of the
349 kinetochore gene set.

350

351 The current study does not perform any experimental characterisation of phenotypes across the
352 twenty yeast species that would be caused by knocking out the genes that I identify as lost.
353 However, kinetochore genes have been studied extensively in *S. cerevisiae*. Single and double
354 gene knockouts have been phenotypically characterised in great detail (Measday et al., 2005).
355 This functional data from *S. cerevisiae* can be extrapolated to other species by supplementing it
356 with computational predictions. Such extrapolation would, of course, have to be experimentally
357 verified by subsequent studies in the focal species. Hence, our study is merely focussed on
358 demonstrating strong patterns of associations that suggest kinetochore network rewiring in
359 *Naumovozyma*.

360

361 Stable separation of chromosomes into daughter cells requires proper functioning of the
362 kinetochore machinery. Reduced efficiency in such segregation of chromosomes would result in
363 reduced fertility. The high levels of gene turnover seen in kinetochore genes suggest frequent
364 changes in the interactome of kinetochore. Such frequent changes in gene content could lead to
365 differences in the interactome of closely related species. These differences in the interactome can
366 have a prominent role in mediating speciation through reproductive isolation. Reconstruction of
367 the sequence of events leading to the turnover of kinetochore machinery and centromere
368 sequence at the molecular level in budding yeast species might serve as a good test case for
369 understanding its role in speciation.

370

371 **Conclusions**

372 Rapid changes in the genomic sequence of centromeres and associated kinetochore proteins
373 between closely related species are thought to have an important role in speciation. Yet, it is not
374 conclusively known whether the centromere sequence divergence occurs first or kinetochore
375 proteins evolve to use a different centromere sequence. I look at patterns of kinetochore gene
376 loss in twenty species of yeast to identify major lineage-specific events. Interestingly, the loss of
377 four genes of the CCAN/CTF19 complex coincides with the emergence of unconventional
378 centromeres in *N.castellii* and *N.dairenensis*. I speculate that loss of these genes might have

379 occurred subsequent to the divergence of the centromere sequences as their role might have been
380 taken over by other genes. While our results cannot establish the sequence of events, the
381 identified lineage-specific loss of kinetochores genes that are known to functionally interact
382 serves as a molecular footprint of genetic changes that contribute to reproductive isolation
383 between species.

530 **Figure 1: Observed loss of kinetochore genes in budding yeast species.** Gene loss events have
531 been mapped onto the widely accepted tree topology obtained from (Gordon, Byrne &
532 Wolfe, 2011). The whole genome duplication event separating the Pre-WGD and Post-
533 WGD species is denoted by a star. Point centromeres are common to all twenty budding
534 yeast species and their emergence is depicted by a dark blue dot. Emergence of
535 unconventional point centromere in *Naumovozyma* is depicted by a light blue dot. *Sensu*
536 *strictu* yeast species are demarcated by a blue box and *sensu lato* species with neo-
537 centromeres are demarcated by a red box.

538 **Figure 2: Conserved c-terminus of CENPA/CSE4 contrasts with the diverse n-terminus.**
539 Sequence conservation (unweighted entropy measure) along the length of the
540 CENPA/CSE4 gene calculated using the al2co program is shown for each amino acid
541 position. While the c-terminus is highly conserved, the n-terminus has very little sequence
542 conservation. Refer to **Supplementary Material 3** for actual multiple sequence alignments.

543 **Figure 3: Dyads identified in the *S. cerevisiae* centromere CEN1.** Inverted repeats were
544 identified by the program palindrome from the emboss package. Each of the lines has the
545 118 bp sequence of CEN1 and the dyad region is highlighted in red colour. The last line in
546 the figure shows the regions (coloured green) that are covered by at least one dyad. Dyad
547 density is calculated as the fraction of bases that are covered by a dyad.

548
549 **Figure 4: Dyad density and GC content at the centromere regions. (A) Negative correlation**

550 **between GC content and dyad density at the point centromeres across budding yeast**
551 **species.** The filled circles represent *N. castellii* and unfilled circles show *N. dairenensis*.
552 Red colour is used for the intergenic regions corresponding to the older (*S. cerevisiae* like)
553 centromeres. Blue colour is used for the new unconventional centromeres that have been
554 identified in *Naumovozyma*. Centromeres of the remaining budding species have the *
555 shape and are coloured black. (B) **Boxplots comparing the GC content of old and new**
556 **centromeres in *N. castellii* and *N. dairenensis*.** The new (mean: 25.80, median: 24.77, min:
557 20.00 & max: 35.16) centromeres in *N. dairenensis* have a lower GC content than the older
558 regions (mean: 31.58, median: 32.90, min: 22.03 & max: 37.32). Similarly, the new (mean:
559 21.36, median: 20.91, min: 18.18 & max: 24.55) centromeres in *N. castellii* have a lower
560 GC content than the older regions (mean: 30.15, median: 30.35, min: 21.82 & max: 36.47).
561 Pair-wise Wilcoxon test is used to compare the GC content of the old and new centromeres.
562 The q-values are obtained based on holm multiple testing correction.
563

Figure 1

Observed loss of kinetochore genes in budding yeast species.

Gene loss events have been mapped onto the widely accepted tree topology obtained from (Gordon, Byrne & Wolfe, 2011). The whole genome duplication event separating the Pre-WGD and Post-WGD species is denoted by a star. Point centromeres are common to all twenty budding yeast species and their emergence is depicted by a dark blue dot. Emergence of unconventional point centromere in *Naumovozyma* is depicted by a light blue dot. Sensu strictu yeast species are demarcated by a blue box and sensu lato species with neo-centromeres are demarcated by a red box.

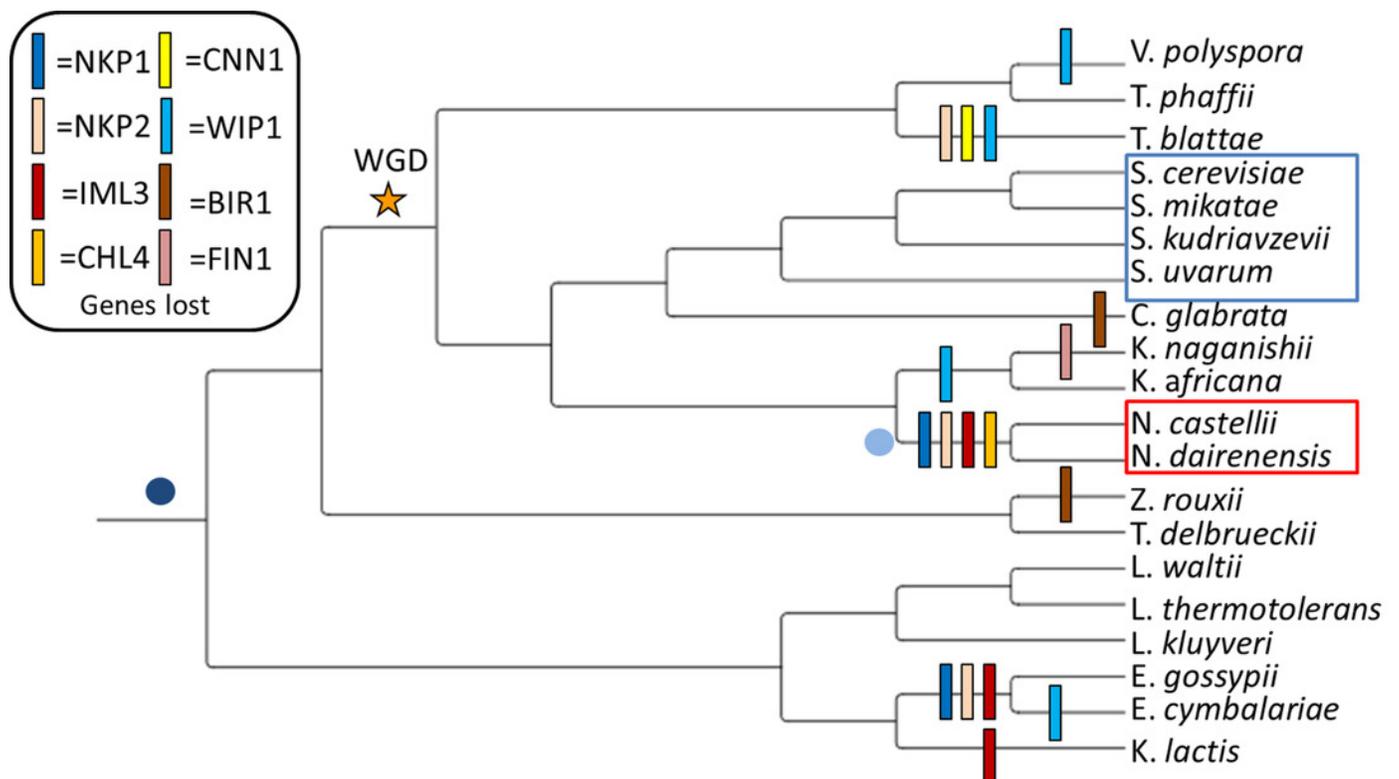

Figure 2

Conserved c-terminus of CENPA/CSE4 contrasts with the diverse n-terminus

Sequence conservation (unweighted entropy measure) along the length of the CENPA/CSE4 gene calculated using the al2co program is shown for each amino acid position. While the c-terminus is highly conserved, the n-terminus has very little sequence conservation. Refer to **Supplementary Material 3** for actual multiple sequence alignments.

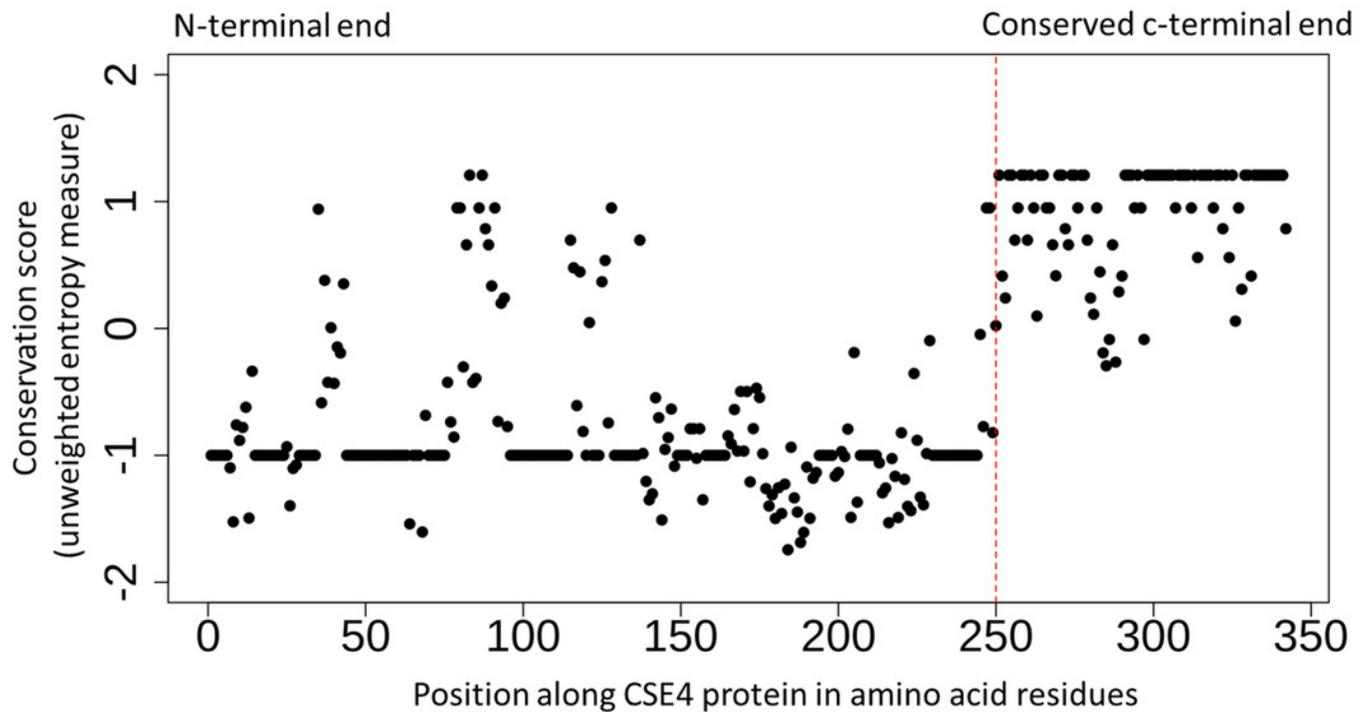

Figure 4

Dyad density and GC content at the centromere regions.

(A) Negative correlation between GC content and dyad density at the point centromeres across budding yeast species. The filled circles represent *N. castellii* and unfilled circles show *N. dairenensis*. Red colour is used for the intergenic regions corresponding to the older (*S. cerevisiae* like) centromeres. Blue colour is used for the new unconventional centromeres that have been identified in *Naumovozyma*. Centromeres of the remaining budding species have the * shape and are coloured black. **(B) Boxplots comparing the GC content of old and new centromeres in *N. castellii* and *N. dairenensis*.** The new (mean: 25.80, median: 24.77, min: 20.00 & max: 35.16) centromeres in *N. dairenensis* have a lower GC content than the older regions (mean: 31.58, median: 32.90, min: 22.03 & max: 37.32). Similarly, the new (mean: 21.36, median: 20.91, min: 18.18 & max: 24.55) centromeres in *N. castellii* have a lower GC content than the older regions (mean: 30.15, median: 30.35, min: 21.82 & max: 36.47). Pair-wise Wilcoxon test is used to compare the GC content of the old and new centromeres. The q-values are obtained based on holm multiple testing correction.
