Ecological processes on coral reefs commonly have limited spatial and temporal scales and may not be recorded in their long-term geological history. The widespread degradation of Caribbean coral reefs over the last 40 years therefore provides an opportunity to assess the impact of more significant ecological changes on the geological and geomorphic structure of reefs. Here, we document the changing ecology of communities in a coral reef seascape within the context of its geomorphic zonation. By comparing basic ecological indices between historical and modern data we show that in 35 years the reef-front zone was transformed from a complex coral assemblage with a three-dimensional structure, to a size-homogenized and flattened one that is quasi indistinguishable from the adjacent non-accretional coral-ground zone. Today coral assemblages at Punta Maroma are characterized by the dominance of opportunistic species which are either tolerant to adverse environmental conditions, including sedimentation, or are known to be the first scleractinian species to recruit on disturbed reefs, implying they reflect a post-hurricane stage of adjustment. Despite an increase in similarity in ecological indices, the reef-front and coral-ground geomorphic zones still retain significant differences in coral assemblages and benthic habitat and are not homogeneous. The partial convergence of coral assemblages certainly has important consequences for the ecology and geological viability of the reef and its role in coastal protection, but environmental physical drivers continue to exert a fundamental role in the character and zonation of benthic communities of this reef seascape.

## 13 ABSTRACT

14 Ecological processes on coral reefs commonly have limited spatial and temporal scales and may not be  
15 recorded in their long-term geological history. The widespread degradation of Caribbean coral reefs over  
16 the last 40 years therefore provides an opportunity to assess the impact of more significant ecological  
17 changes on the geological and geomorphic structure of reefs. Here, we document the changing ecology  
18 of communities in a coral reef seascape within the context of its geomorphic zonation. By comparing basic  
19 ecological indices between historical and modern data we show that in 35 years the reef-front zone was  
20 transformed from a complex coral assemblage with a three-dimensional structure, to a size-homogenized  
21 and flattened one that is quasi indistinguishable from the adjacent non-accretional coral-ground zone.  
22 Today coral assemblages at Punta Maroma are characterized by the dominance of opportunistic species  
23 which are either tolerant to adverse environmental conditions, including sedimentation, or are known to  
24 be the first scleractinian species to recruit on disturbed reefs, implying they reflect a post-hurricane stage  
25 of adjustment. Despite an increase in similarity in ecological indices, the reef-front and coral-ground  
26 geomorphic zones still retain significant differences in coral assemblages and benthic habitat and are not  
27 homogeneous. The partial convergence of coral assemblages certainly has important consequences  
28 for the ecology and geological viability of the reef and its role in coastal protection, but environmental  
29 physical drivers continue to exert a fundamental role in the character and zonation of benthic communities  
30 of this reef seascape.

## 31 INTRODUCTION

32 Coral reefs develop over geologic timescales through a complex process termed accretion (Perry and  
33 Hepburn, 2008; Pandolfi et al., 2011). Most consider this to involve a dynamic interplay between three  
34 ecological and sedimentological processes: framework growth, physical and biological erosion and  
35 internal sedimentation and cementation (Rasser and Riegl, 2002; Perry and Hepburn, 2008). Framework  
36 growth is accomplished primarily by scleractinian corals but with important contributions from calcifying  
37 encrusters, such as crustose coralline algae (Adey, 1975; Kikuchi and Leão, 1997). This growth is

38 balanced by biological, chemical and physical erosion and mediated by environmental gradients in  
39 wave-energy, light penetration, and sediment flux (Geister, 1977; Huston, 1985), and produces a layer of  
40 geomorphically zoned framework (Geister, 1977; Graus and Macintyre, 1989; Kennedy and Woodroffe,  
41 2002). Left undisturbed by storms and hurricanes, this framework has the potential to accrete vertically,  
42 as one corallgal cohort develops over another through time producing a geological reef deposit (Geister,  
43 1980; Done, 2011).

44 Vertical reef accretion is clearly dependent upon short-term ecological processes persisting over  
45 thousands of years and generating a positive balance of growth and accumulation over erosion and  
46 removal. And even in zones with a positive balance, that accretion should vary significantly depending  
47 on the size and growth rate of corals in assemblages dominating each zone. For example, analysis of  
48 cores drilled on Caribbean reefs protected from hurricanes has shown that frameworks dominated by  
49 branching Acroporid corals have undergone significant vertical accretion and produced large geological  
50 reef structures during the Holocene (Macintyre and Glynn, 1976). However, in more hurricane-prone  
51 areas, cores obtained from the same zones have shown that Holocene reef structures are biotritral  
52 consisting mostly of the fragmented remains of corals that once covered their surfaces (Blanchon et al.,  
53 1997, 2017). Furthermore, coral-grounds, have been reported from the extensive shelf zones both adjacent  
54 to and between the accretionary reef structures (Rodríguez-Martínez et al., 2011). Clearly the ecological  
55 seascape of reefs is complex and transient and surface coral assemblages may not always indicate how  
56 accretion occurs or even if it occurs at all.

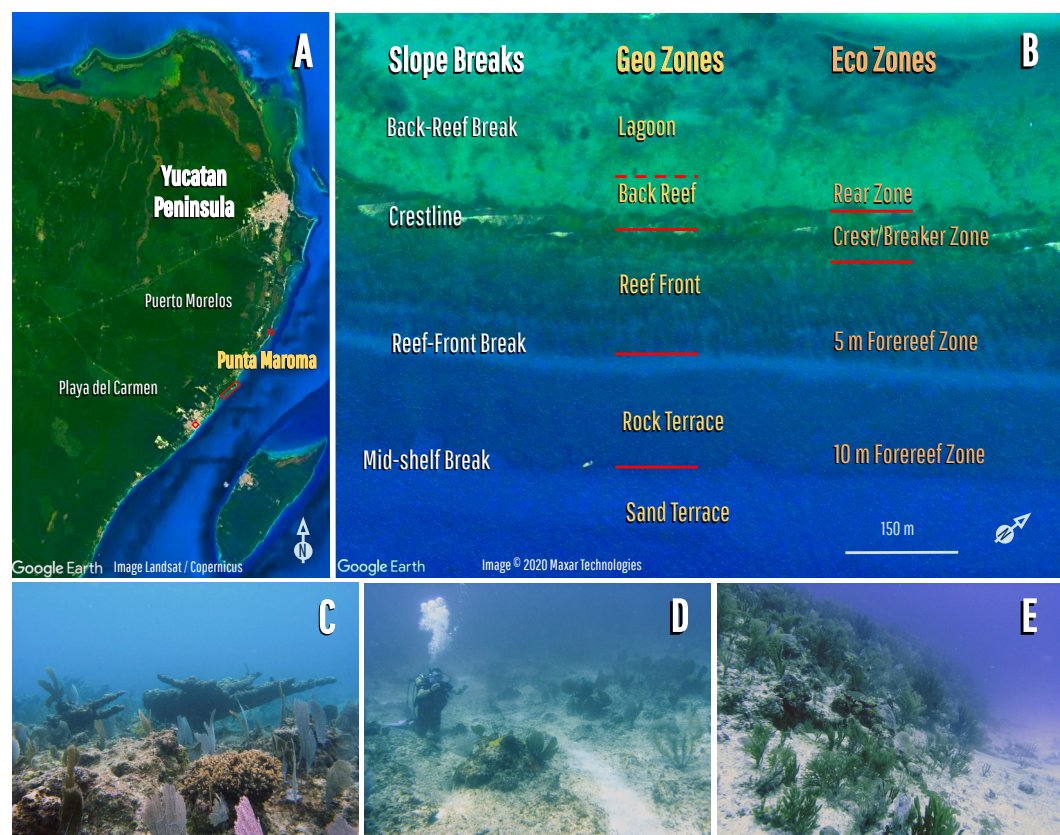

57 With the demise and deterioration of Caribbean reefs during the last 40 years, and the decimation of  
58 keystone Acroporids in particular (Gardner et al., 2005; Jackson et al., 2014), this complex ecological  
59 seascape is radically changing (Perry and Alvarez-Filip, 2019). Biodiversity loss and biotic homogeniza-  
60 tion are not only compromising the ecological functioning of reefs (Olden and Poff, 2003; Burman et al.,  
61 2012; Alvarez-Filip et al., 2013; Elliff and Silva, 2017) and their ability to provide local and regional  
62 services (Alvarez-Filip et al., 2009, 2011), but are predicted to reduce their potential for long-term  
63 accretion (Perry et al., 2013; Estrada-Saldívar et al., 2019). Assessing the accuracy and validity of these  
64 accretion predictions, however, is problematic for several reasons (Lange et al., 2020). First, biotic  
65 homogenization stemming from the loss of large reef-builders, like Acroporids, makes it difficult to  
66 locate geomorphic boundaries between accretionary fringing-reef zones and adjacent non-accretionary  
67 coral-ground zones that veneer the surrounding shelf. Combining such geomorphic zones would therefore  
68 give less representative accretion potentials for reef systems. Second, use of ecological ‘snapshots’ to  
69 estimate the accretion potential of entire reefs makes two questionable assumptions: that drivers which  
70 exist outside of ecological timescales are unimportant in the accretion process, and that accretion is  
71 uniform in space and time (Perry, 2011; Courtney et al., 2016; Manzello et al., 2018). In terms of drivers,  
72 we know that hurricanes have played an important role in Caribbean reef accretion during the Holocene  
73 (Blanchon et al., 2017). However, little is known about changes in accretion rates, although it seems  
74 unlikely that they would remain constant given that sea level and climate has varied during the Holocene  
75 (Blanchon and Shaw, 1995; Gischler, 2006; Toscano and Macintyre, 2006; Khan et al., 2017).

76 In this study, we assess if the homogenization has occurred between the two most conspicuous  
77 windward geomorphic zones along a reef at Punta Maroma, Mexico, where the long-term history of  
78 accretion is known from drilling (Blanchon et al., 2017). These geological records show the geomorphic  
79 zones have different accretion histories, and yet ecological studies commonly group them into a general  
80 ‘fore-reef’ zone. Although surveys indicate there has been some homogenization in the abundance, species  
81 composition, and size structure of coral assemblages in adjacent geomorphic zones, we find that coral  
82 communities continue to be statistically different.

# METHODS

## Study site

The study site is a 4.5 km-long fringing reef at Punta Maroma, in the northeastern Yucatan Peninsula, close to Playa del Carmen, Quintana Roo, Mexico (Fig. 1A). It has a typical tripartite geomorphic zonation, with a reef-front, crest, and back-reef, and is flanked by a shallow (< 6 m) lagoon on its landward side, and a deeper (> 8 m) coral-veneered rock terrace, on its seaward side (Fig. 1B). The geological structure of the reef front was reported by [Blanchon et al. \(2017\)](#) who showed that it consists of clast-dominated hurricane deposits, with a maximum age of 5.5 ka. Cores from this study also showed that the seaward coral-veneered rock terrace is a late Pleistocene extension of the coastal bedrock with no evidence of reef accretion during the Holocene.

**Figure 1.** Ecological seascape and zonation of the fringing reef at Punta Maroma. (A) Location of Punta Maroma; (B) Reef zonation and geomorphology showing: slope breaks and geomorphological zones (following [Blanchon et al., 2017](#)) and ecological seascape zones (following [Jordán-Dahlgren et al., 1981](#) and [Estrada-Saldívar et al., 2019](#)); (C) View of the Reef-Front zone (or Fore reef) at ~ 5 m; (D) View of the Rock-Terrace zone (or Fore reef) at ~ 10 m; (E) View of the Mid-shelf break (or Fore reef) between 10 to 15 m.

The combination of these geomorphic zones produces an extensive windward ecological seascape (> 2000 m<sup>2</sup>), which consists of a shallow accretionary reef-front zone (RF), from the crest down to ~ 6 meters depth (Fig. 1C), and a non-accretionary deeper coral-ground (CG) zone (Fig. 1D), extending from the limit of the RF out across the rock-terrace to a mid-shelf slope break (Fig. 1E) at ~ 10 m depth ([Rodríguez-Martínez et al., 2011](#); [Blanchon et al., 2017](#)). These zones have been collectively referred to as the ‘fore-reef’ in other studies (Fig. 1B).

## 99 Survey methodology and Historical analysis

100 To compare recent coral assemblages from the RF and CG zones at Punta Maroma reef, we surveyed  
 101 coral species abundance and size between March and June, 2019. The sampling effort consisted of ten  
 102 30 m-long belt transects (BT), randomly placed in an orientation roughly parallel to the crestline at ~ 5  
 103 m (RF) and ~ 10 m (CG). Sample size was determined based on historical cumulative species diversity  
 104 curves, empirically determined in previous studies (Jordan et al., 1981; Jordán-Dahlgren, 1989). All  
 105 scleractinian colonies with size  $\geq 4$  cm within one-metre-wide belt transects were sampled, including  
 106 those intercepted by the belt line, following Zvuloni et al. (2008). Other environmental data, including  
 107 depth, spatial position and distance to the mid-shelf edge, were also recorded. Scleractinian coral species  
 108 were classified based on their morphology and life history following Estrada-Saldívar et al. (2019).

109 To determine if coral assemblages from the RF and CG zones at Punta Maroma reef experienced  
 110 changes in the last few decades, we used ecological surveys taken in 1979 (Jordan et al., 1981) and in  
 111 1985 (Jordán-Dahlgren, 1989). These data were obtained from 20-m long line-intercept transects (LIT),  
 112 separated from each other by distances of 5-25 m. In these studies, the transects were delimited by plastic  
 113 chains (with 2.73 cm chain links) that followed the bottom topography. Transects were taken from three  
 114 zones, described as ‘rear-reef’, ‘breaker zone’ and ‘fore-reef’. In both surveys the ‘fore-reef’ transects  
 115 were placed perpendicular to the coast at two depths: 5 and 10 m. These three zones correspond to four  
 116 geomorphological zones described by Blanchon et al. (2017): the Back Reef (‘rear reef’), Reef Crest  
 117 (‘breaker zone’), Reef Front (‘forereef’ at 5 m) and Rock Terrace and Mid-shelf break (‘forereef’ at 10  
 118 m). In this study we refer to the ‘forereef’ at 10 m as the coral-ground. All scleractinian corals below  
 119 the chain were counted and measured using the chain link as the measurement unit. In 1979, the number  
 120 of transects per depth was five and in 1985 four. Additionally, in 1985 colonies were measured by their  
 121 maximum diameter. Every survey fulfilled the minimal sampling effort necessary to accurately describe  
 122 the coral communities according to cumulative species diversity curves (Gleason, 1922). Also, because in  
 123 the 1979 and 1985 *Montastrea annularis*, *Montastraea faveolata* and *M. franksi* were considered as part  
 124 of the same species complex (*M. annularis*), for our 2019 surveys we combined these three species in one  
 125 (*Orbicella* [formerly *Montastrea*] “*annularis*” complex).

## 126 Approach to accretion processes

127 Scleractinian corals are considered to be the principal builders of three-dimensional structures of tropical  
 128 coral reefs (Goreau, 1959). However, differences in skeleton stability, size and habitat distribution of coral  
 129 species, can lead to differences in their preservation potential in the geological record (Greenstein, 2007).  
 130 Therefore, we use a two-level classification of the role of coral species in the accretion process to reflect  
 131 the presence or species contribution the geological records. Levels were: a) key reef-building species ( key  
 132 spp.), consisting of large branching Acroporids and massive *Orbicella* [formerly *Montastrea*] “*annularis*”  
 133 complex, (Budd et al., 2012) which are considered to be the principal reef builders in the Caribbean  
 134 (Goreau, 1959; Lewis, 1984; Toth et al., 2019) and b) Less influential species like small massive, sub-  
 135 massive or encrusting, digitate and foliose morphologies with lower growth rates, which participate in the  
 136 accretion processes but are less represented in the geological records. This group includes some abundant  
 137 species in the contemporary coral communities like *Agaricia agaricites* and *Porites astreoides* (Aronson,  
 138 2006; González-Barrios and Álvarez Filip, 2018; Toth et al., 2019).

139 In addition to classifying their role in accretion, we also use a species Importance Value Index (IVI)  
 140 (Curtis and McIntosh, 1951; Finol Urdaneta, 1971) as a proxy to estimate the relative importance of each  
 141 species in the accretion processes within each geomorphic zone. The IVI of each species is calculated as  
 142  $IVI = (RA + RSD + RF)/3$ , where RA is relative abundance, calculated from the number of individuals  
 143 per species with respect to the number of individuals of all species found in the community; where RSD is  
 144 relative spatial dominance defined as the area covered by each species (using the colonies maximum and  
 145 minimum diameters and assuming a planar area for the 2019 data) with respect to the cover of all species;  
 146 and where RF is relative frequency, estimated as the proportion of transects where a species is present,  
 147 normalised to the frequency of all species in the community. The analysis of IVI was carried out because  
 148 different geomorphic zones within a reef have a heterogeneous accretion capacity as a consequence of the

149 composition of the coral community and external environmental gradients (Geister, 1977; Perry, 1999).

## 150 Method biases and uncertainties

151 Different benthic sampling protocols and probabilistic designs tend to produce somewhat different results  
152 and therefore, different measures and indices with their own particular bias (Vallès et al. (2019) and others).  
153 However, if the signal of change is strong enough, an appropriate approach can clearly differentiate the  
154 main changes of interest. Benthic survey methods are characterized by different spatial grain sizes of  
155 sampling units, and therefore the obtained abundance measurements could be described by different  
156 sampling distributions. However, Nadon and Stirling (2006) and Jokieli et al. (2015) concluded that the  
157 results from different benthic protocols, (including the two used to collect the data we analyze here),  
158 were virtually indistinguishable. By contrast, Vallès et al. (2019) recently claimed that switching between  
159 benthic methods and pooling data without accounting for method differences could obscure real tendencies,  
160 for example in coral coverage percentages. The actual impact of this important source of error in further  
161 analyses of data collected by distinct benthic methods depends on the specific question to be answered  
162 and how data are treated (Ohlhorst et al., 1988; Chiappone and Sullivan, 1991; Beenaerts and Berghe,  
163 2005). For instance, in our study, the comparative analysis was focused mostly in spatial and temporal  
164 changes in diversity composition and the correlation between species proportions by geomorphic zones,  
165 rather than in the estimation of temporal tendencies in any particular ecological index (e.g, coral cover).  
166 Yet, transect methods yield roughly the same estimates for coral genus diversity but tend to overestimate  
167 coral densities and coral coverage (Ohlhorst et al., 1988; Beenaerts and Berghe, 2005). Therefore, we  
168 consider our analysis to be more affected by an incomplete representation of the community composition  
169 rather than another method bias. We tackle the uncertainty related to the accurate representation of coral  
170 species within each geomorphic zone reaching the asymptotic zone of species accumulation curves in  
171 each zone. Ultimately, we are aware that ecological data, including abundance data, usually violate the  
172 assumptions of traditional parametric statistics, which has difficulties dealing with this using traditional  
173 univariate methods (Fieberg et al., 2020).

## 174 Data transformation and Statistical analyses

175 To tackle the challenge of statistical analysis of empirical data collected with substantially different  
176 benthic methods, and where the sampling distribution is unknown, we selected a methodological approach  
177 based in multivariate analysis of abundance data. Although having some limitations, a multivariate  
178 approach has been recognized as more effective in dealing with ecological data (Beals, 1984; Fieberg  
179 et al., 2020). The approach includes several standard transformations of data and so the raw data were  
180 not compared. First, we standardized separately the relative abundances of species by its total in 2019 to  
181 reduce the differences in magnitude generated by the benthic method. Although the abundance data from  
182 1979 and 1985 were relative measurements (percentage of live coral coverage), we standardized values  
183 again by its total to reduce method-bias related to the effect of the former benthic scheme that included  
184 other benthic classes (Vallès et al., 2019). In addition, data were square-root transformed to reduce the  
185 differential between the largest and smallest non-zero value in the transformed matrix. The relativization  
186 process (percentage of the total sample) was followed by an ordination process where we constructing  
187 the correspondent Bray-Curtis matrix of similarities. Additionally, each data set was transformed into  
188 Presence/Absence data and generate correspondent Jaccard matrix. All subsequent multivariate statistical  
189 analyses were performed using Plymouth Routines in Multivariate Ecological Research (Primer-e version  
190 7.0.13, serial number 4901, (Clarke and Gorley, 2015). Each specific multivariate test demands its  
191 additional pre-treatment procedure for the best performance. Graphical outputs were constructed using  
192 the free software platform of R Core Team (2013) and Primer-e v7.0.13.

193 To determine the contribution of species to coral assemblages in each zone through time, we conducted  
194 a two-way similarity percentage analysis (SIMPER) for zones by time period, based on Bray-Curtis  
195 similarity measures of transformed square-root matrix of abundance data, making a 70% cut-off for  
196 low contributions (Clarke and Warwick, 1994; Clarke et al., 2014). To evaluate changes in diversity we  
197 conducted a PERMANOVA and PERMDISP tests on the basis of a Jaccard transformed data matrix using

previously transformed to Presence/Absence data. PERMDISP test on the basis of Jaccard matrix has been reported as a reliable test to identify changes in beta- diversity (Anderson, 2006; Anderson et al., 2006). Shade plots were created to visualize the relative contribution of all surveyed coral species to the assemblages of each geomorphic zone before the 1990s and in 2019.

To evaluate changes in coral communities of the two zones through time, we performed a two-way crossed permutational analysis (PERMANOVA) of the Bray-Curtis matrix under an orthogonal design of two fixed factors: time, with three levels (1979, 1985 and 2019), and zone, with two levels (RF and CG). Additionally, for the factor year, we designated two linear contrasts: C1 (1979 vs 1985) and C2 (1979 and 1985 vs 2019). Linear contrast is a statistical procedure that allows comparing different sub-sets of data, whereas other sub-sets can be excluded from the comparison. Search for the possibility of pooling the data subsets from 1979 and 1985 stemmed from the previous knowledge that the 1990's decade is considered a turnover moment for coral reefs worldwide, including Punta Maroma reef (Odériz et al., 2014). Therefore, we expected no differences between those data whereas the pooling process leads to a balanced design in further analysis of periods of interest. The test was done using permutation of residuals under a reduced model and Type III (partial Square Sums) in 9999 permutations (Anderson, 2001; Anderson and Braak, 2003; Anderson, 2017). To measure and test the homogeneity of multivariate dispersions of data, we performed a non-parametric permutational analysis of multivariate dispersions (PERMDISP), along with pairwise comparisons of Bray-Curtis matrix of similarities. PERMDISP was performed on the basis of distances to centroids, with P-values obtained using permutations (P(perm)) and 9999 permutations, giving the best overall results expected in terms of type I error and power (Anderson, 2006). The results are presented in a Principal coordinates analysis (PCO; (Torgerson, 1958; Gower, 1966)) constructed by calculating the distances between samples in a transformed Bray-Curtis similarity merged matrix, of previously standardized and square-root transformed relative abundances matrices, for both periods in time. Pearson correlation coefficients of selected taxa were superimposed over the PCO as vectors to indicate the taxa that most strongly contributed to reef community variation. The taxa selected were derived from a similarity percentage breakdown (SIMPER) analysis of the characteristic and distinguishing reef taxa.

## RESULTS

### Contemporary Assemblages

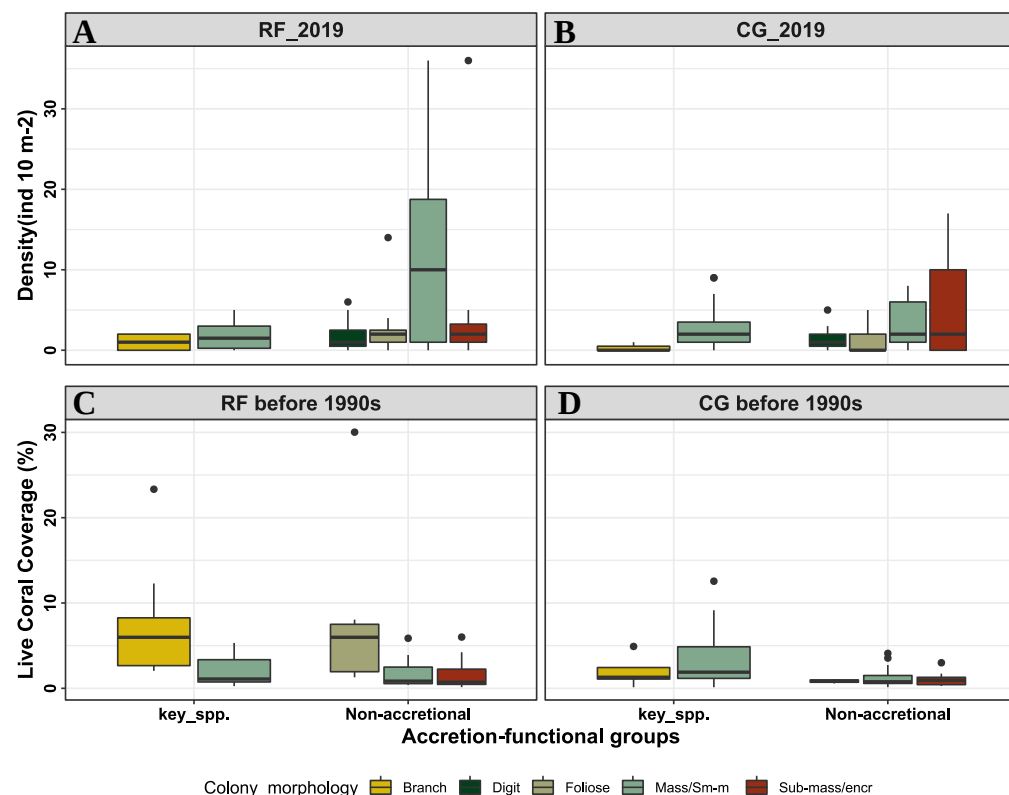

In 2019, we identified and measured 724 coral colonies in the RF zone and 732 colonies in the CG zone, resulting in coral densities of  $2.41 \pm 0.89$  and  $2.44 \pm 0.95$  col.  $m^{-2}$  respectively (Figure 2.A,B). In the RF zone, coral colonies belong to 23 species of 13 genera, and five species account for 89.4% of the colonies in the sample: *Porites astreoides* (55.7%), *Agaricia agaricites* (11.9%), *Siderastrea siderea* (9.4%), *Agaricia tenuifolia* (6.9%), and *Porites porites* (5.5%); the other 18 species represent the remaining 10.6% of the sample, with none representing over 5% (Table 1). In the CG zone, coral colonies belong to 23 species of 16 genera, and five species account for 81.5% of the sample: *A. agaricites* (32.5%), *P. astreoides* (15.8%), *Montastraea cavernosa* (10.2%), *S. siderea* (16.4%), and *P. porites* (6.4%). The coral species that are considered to contribute most to reef accretion (Acroporids and some massive forms) represent 35% of colonies in the non-accretionary CG zone, whereas they represent only 12.8% in the RF zone with the species *Acropora palmata* represented by a minimal number of individuals. In both zones combined, these 'key' reef builders represent 23.9% of all colonies.

Coral colony sizes in both the RF and CG zones are predominantly small, independent of their morphology (mean =  $17.9 \pm 14.7$  cm in the RF and  $19.3 \pm 15.4$  cm in the CG (Data S1.A,S1.B), with only 2.5% of them having diameters larger than 50 cm in both zones. Additionally, coral colonies of all morphologies have low heights in both zones (mean =  $6.5 \pm 8.0$  cm in the RF and  $10.8 \pm 11.1$  cm in the CG). Corals with massive and sub-massive encrusting morphologies dominate, both zones, contributing 83.8% of the colonies in the RF and 87.8% in the CG (Fig.2A), but the identity of the dominant species differs, with the small massive *P. astreoides* dominating in the RF zone and the sub-massive encruster *A. agaricites* in the CG zone. The SIMPER test shows the groups of species that co-occur between transects

(Data S2), and indicates that four species have a high degree of overlap within the CG zone: *A. agaricites*, *S. siderea*, *P. astreoides*, and *M. cavernosa* (Average similarity: 70.7), whereas in the RF zone three species overlap: *P. astreoides*, *A. agaricites* and *S. siderea* (Average similarity: 58.4).

## Historical Assemblages

Historically, all coral morphologies had higher coral coverage in the RF zone than in the CG zone; the RF zone showed a dominance of branching morphologies and the CG zone a dominance of massive ones (Table 1; Fig. 2C,D). The SIMPER test for historical data shows three species overlapped in the RF zone: *Ac. palmata*, *Acropora cervicornis*, and *Ag. tenuifolia* (Average similarity: 52.8) and five in the CG zone: *M. cavernosa*, *Dichocoenia stokesii*, *S. siderea*, *Ag. agaricites*, and *M. annularis* complex, (Average similarity: 42.6) (Data S1). In the RF zone, *Ag. tenuifolia* and *Ac. palmata* accounted for the largest live coral coverage (30.0% and 23.3% respectively), and in the CG zone the dominant species were *Orbicella* species and *M. cavernosa* (12.6% and 9.2% respectively, Table 1). In 1985, the average diameter maximum of coral colonies (mean =  $42.1 \pm 24.4$  cm) was more than double of those in 2019 (mean =  $18.6 \pm 3.2$  cm, Data S1.A).

**Figure 2.** Box Plots of Coral colony densities in reef-front (A) and coral-ground (B) zones in 2019. Box Plots (C) and (D) show Live coral coverage in reef front and coral-ground zones respectively before the 1990s, by accretion-functional groups, coral morphology and geomorphic zone in two reef zones at Punta Maroma reef. The bottom and top of the box are the first and third quartiles, respectively, the black line inside the box is the median. Whiskers are the lowest datum still within 1.5 times that of the lower quartile and the highest datum still within 1.5 times that of the upper quartile. RF: Reef front, or accretionary zone, CG: Coral-ground or non-accretionary zone; key\_spp.: key 'reef-building' species; Non-accretional: less influential species for accretion processes.

According to the Importance Value Index, the main species in the RF zone in 1985 were *P. astreoides*,

262 *Ag. tenuifolia* and *Ac. palmata* and in 2019 they were *P. astreoides*, *Acropora prolifera* and *Ac. palmata*.  
 263 The main species in the CG zone in 1985 were *Orbicella* species, *M. cavernosa*, *P. astreoides* and  
 264 *Pseudodiploria clivosa*, and in 2019 they were *Ag. agaricites*, *Colpophyllia natans* and *S. siderea*. So in  
 265 RF zone, the relative importance of *Ac. palmata* and *P. astreoides* increased in time whereas that of *Ag.*  
 266 *tenuifolia* decreased, and in CG zone the dominant species were replaced (Fig. 3, *Data S3*).

## 267 Comparative analysis of Coral Communities.

268 Coral assemblage of the CG zone underwent significant changes in beta diversity (PERMDISP, Jaccard  
 269 matrix,  $F_c: 4.59$ ,  $P(\text{perm}) < 0.01$ ; Table 2; *Data S4.A*), as shown in the shade plot (Fig. 4). Changes in the

**Table 1.** Coral species and number of colonies recorded in two geomorphic zones at Punta Maroma reef seascape before 1990s and in 2019. Coral species are classified according to their growth morphology (Darling et al., 2012). CG: Coral-ground zone, RF: Reef front zone of the fringing reef. Key reef-building spp.: large ‘reef-building’ species, Non-accretional Spp.: less influential species for accretion processes

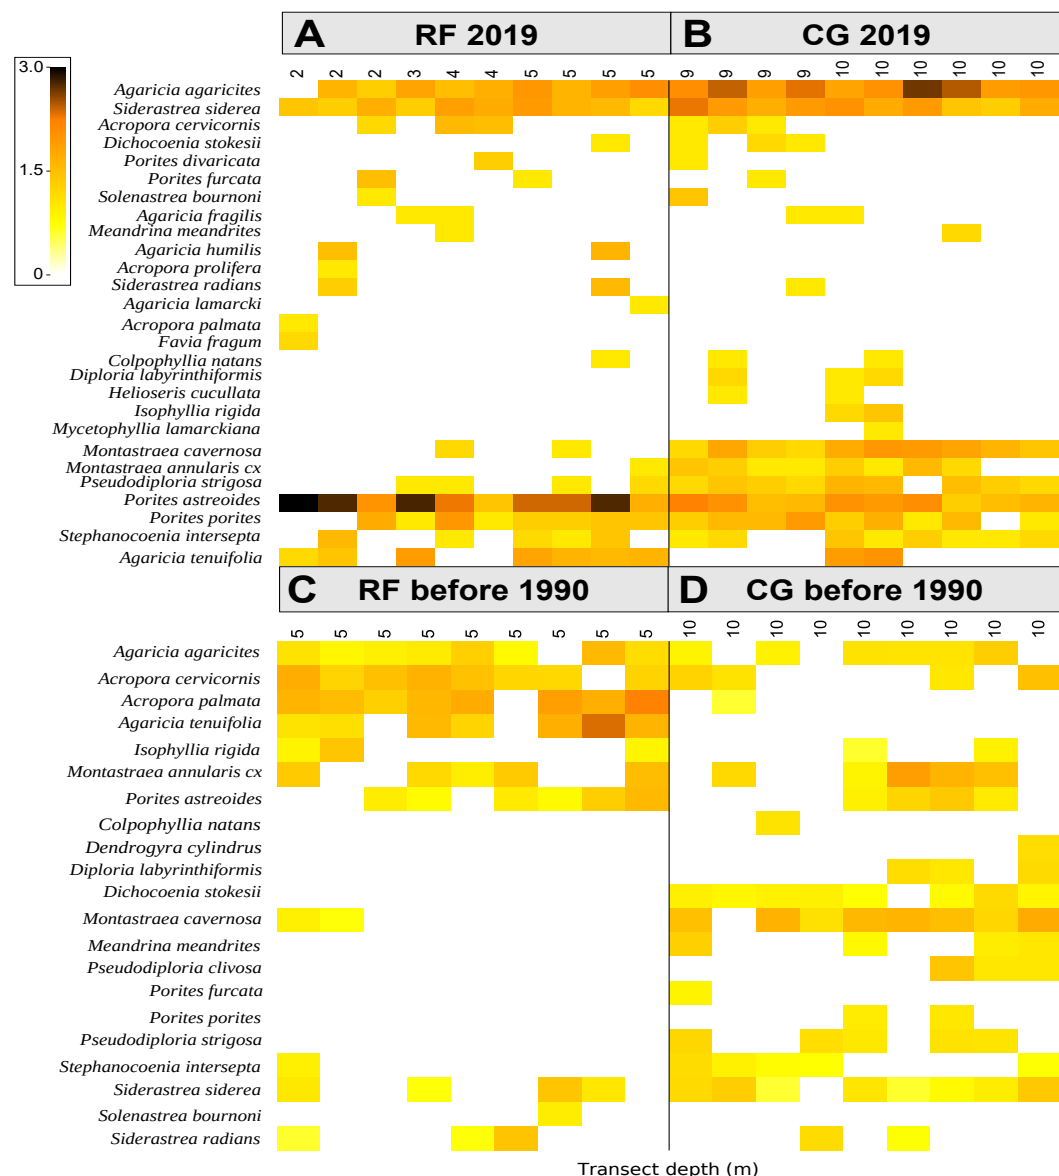

coral community composition of two zones and heterogeneity in species distribution were analyzed using a two-way crossed (orthogonal) PERMANOVA. This shows strong effect of zone- and time-factors over coral assemblages ( $P < 0.001$  for each test), with the zone-factor being slightly more important (Pseudo-F = 19.85 and 10.63 respectively, Table 2). The test indicates a statistically significant interaction in the effects of zone and time ( $P < 0.001$ ), although the combined effect was lower (Pseudo-F = 3.18). Linear contrasts indicate that the effect of time was relevant when comparing 2019 vs before 1990s although there was an effect of zonation. *A posteriori* PERMANOVA pairwise test for both zone- and time-factors versus the zone factor, shows that the average similarity between FR and CG groups is 52.6 (Table 2; Data S4.B).

These differences in abundance and composition of coral assemblages for the two zones through time are mirrored in a Principal Coordinates Analysis (PCO) ordination procedure (Fig. 5), which shows that *A. agaricites*, *S. siderea*, *M. cavernosa*, and *P. astreoides* have a strong negative relationship with the PCO1 axis (indicative of 2019 sites), while *Ag. agaricites*, *S. siderea* and *Ac. cervicornis* are neutrally related to the PCO2 axis. However, the main reef builders (acroporids and orbicellids) are strongly and positively related to the PCO1 axis (indicative of the period before 1990s), with *A. palmata* being positively related to RF zone before 1990s, whereas species of *M. annularis* spp. complex are related to CG zone (Fig. 5). Other species, such as *M. cavernosa*, *D. stokesii*, and *P. strigosa*, have strong negative relationships with negative sections of both axes (indicative of the CG zone).

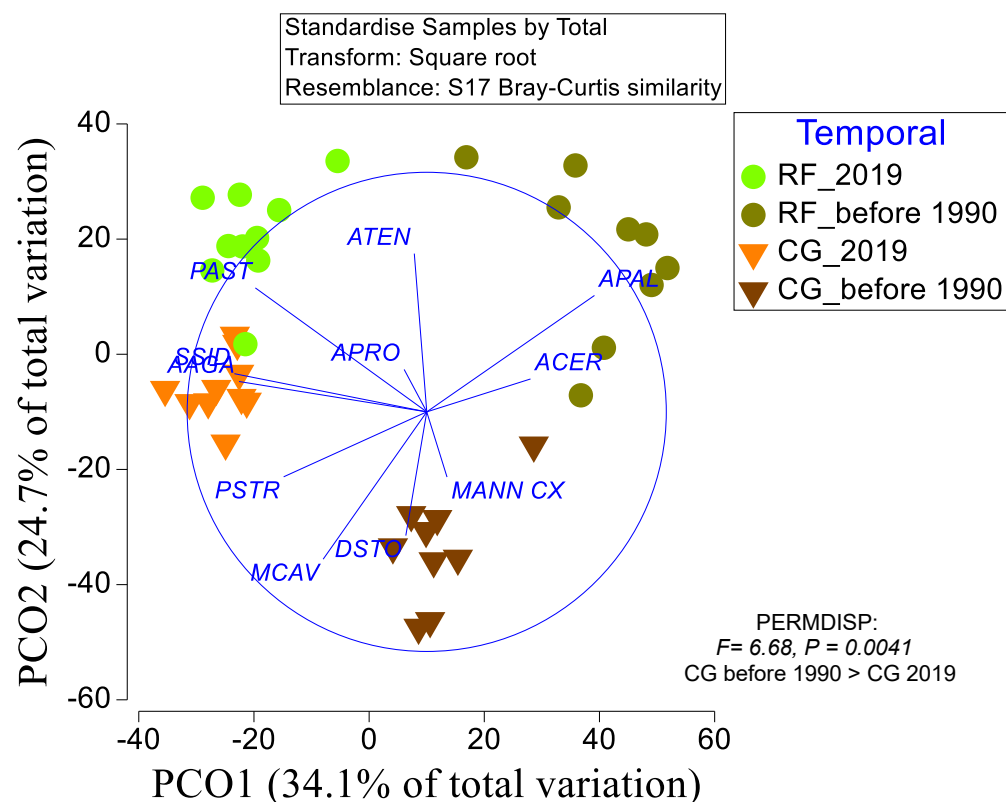

*A posteriori* pairwise PERMDISP test highlights that the RF zone conserve a homogeneous dispersion in variances before 1990s and 2019 data, whereas the CG zone shows heterogeneity in variance of data (P(tables): 0.59 and  $< 0.01$  respectively; Data S4.C). Therefore, the analyses indicate changes between period before 1990s and 2019 in the composition of both zones (PERMANOVA) and in the variance of sample distribution (PERMDISP) in the CG zone.

**Figure 3.** Ecological Importance Value Index of coral species by geomorphic zones in Punta Maroma reef before 1990s (based on 1985 data) and in 2019. The index is based on the relative abundance, frequency and spatial contribution of each species with respect to the coral assemblage. The x axis represent the importance value index (IVI) in percentages and the y axis list the coral species by it scientific accepted names. RF: Reef front, CG: coral-ground.

**Figure 4.** Comparison of the contemporary and historical abundance for each species at transect level. Color shaded plots of four root transformed species abundance (rows) by transect (columns) and zone (A, B: reef front RF and coral-ground,CG respectively for contemporary (2019) and C, D: reef front,RF and coral-ground,CG for historical (before 1990s) data). (A) The (ribbon) colored scale is shown in the key with back-transformed counts where white squares indicate zero counts or species accounting for 5% or less of the total abundance. The x axis represent the transect depth (in meters) of n- samples. The y axis represent coral species

**Figure 5.** Principal Component Analysis (PCO) derived from the Bray–Curtis similarity matrix constructed using a fourth root transformed matrix of standardized abundances of scleractinian coral species in two sampling zones at Punta Maroma reef seascape before 1990s and in 2019: a frontal zone of a fringing reef (RF) and a coral-ground (CG) zone. Vectors visualize, through Pearson correlation coefficient, the potential monotonic relationship between the species accounting for 70% of total abundances and ordination axes a PCO. **Table 2.** Results of PERMANOVA and PERMDISP tests. A synthesis of data transformation and pre-treatment procedure is presented for abundance and diversity data analyses. Additionally had been identified the benthic methods that originate raw abundance data. Where there is a pooled data analysis of abundance data using different benthic methods, a warning in interpretation of results is advised due to the possibility of method-bias. LIT: line intercept transect, BT: belt transect, CG: Coral-ground zone, RF: Reef front zone of the fringing reef; (\*) see section "Method biases and uncertainties" and "Discussion".

# DISCUSSION

Regrettably, like in other Caribbean reefs, coral assemblages covering the reefal seascape at Punta Maroma have declined in the past 35 years. Prior to the 1990's, there was a clear differentiation of coral assemblages between the shallow reef front (RF) and the deeper coral-ground (CG), with the former having higher presence of *Acropora* spp. and *Ag. tenuifolia*, and the latter with higher presence of small massive species such as *M. cavernosa*, *S. siderea*, *D. stokesii* and *Ag. agaricites*. These coral assemblages had become more homogeneous in abundance and species composition, with similarity among zones rising from 21.9%, before the 1990's, to 52.6%, by 2019. Furthermore, by 2019, both the accretionary RF and the non accretionary CG community had the same coral species richness ( $S = 23$ ), roughly the same colony density (2.4 per  $m^2$ ) and were dominated by small colonies ( $< 20$  cm) of *S. siderea*, *P. astreoides*, *Ag. agaricites*, and *P. porites*. However, according to the Index Value of Importance (IVI), reef builders like *Ac. palmata* conserved its high ecological value in the RF zone, despite its reduction in abundance through time, and the *Orbicella* (formerly *Montastrea*) reef-building group has a high value in the CG zone through time, despite the fact that this is a non-accretionary zone.

Reductions of live coral cover and decline in the abundance of large key reef-building species have been reported from other Caribbean reefs, together with the increase in the similarity of the coral assemblages and concomitant decrease in the visual difference amongst shallow adjacent coral-reef zones (Gardner et al., 2003; Jackson et al., 2014). Although the boundaries between these reef communities have often been defined by both biological and geological characteristics, these definitions have been inconsistent (e.g., ecozones in Fig.1b). For example, Estrada-Saldívar et al. (2019) recently reported that similar ecological changes led to functional convergence and homogenization between back-reef and fore-reef sites along the north-east Yucatan, including the one at Punta Maroma. However they considered the RF and CG zones as a single 'fore-reef' zone. A similar approach was followed by Jordan et al. (1981) to describe the windward zone of the entire Mexican Caribbean. Our findings show, however, that on a more detailed scale this ecological homogenization is incomplete and that each geomorphic zone still retains differences. In particular, the statistical analysis highlights differences in the ecological significance of adaptive distribution patterns of coral species in response to long-term environmental drivers (e.g., light, wave exposure). And although PERMANOVA results based on abundance data could be affected by uncertainties related to the method bias, the sibling test based on presence-absence data is more reliable. Thus, we show that changes in beta-biodiversity identified by biodiversity analysis are responsible for the main temporal differences. It may be that this 'partial' homogenization results from a convergence in species succession within each geomorphic zone, as reported on other Caribbean reefs (e.g. (Curran et al., 1995; Aronson and Precht, 1997)

The ecological differences in species distribution and their relative importance between adjacent geomorphic zones may be related to the interaction between environmental processes and geomorphic substrate over long time-scales. Despite changes in community structure, the RF zone still has an irregular substrate, with stumps of dead *A. palmata* and several acroporid spur-and-groove sets that slope up to the crest, and the CG zone is still a flat undulating rocky terrace crossed by shallow furrows and coral veneered ridges. These conditions favour the persistence of sediment-tolerant species, like *M. cavernosa*, *A. agaricites* (Lasker, 1980; Erftemeijer et al., 2012) and *S. siderea* in the CG zone, whereas in the RF zone the higher dominance of *P. astreoides*, which colonized space vacated by *A. palmata* may be a successional stage following disturbance. If this interpretation is correct then it highlights the importance of long-term adaptive responses of coral species to geomorphic substrates.

Although retaining some of their geomorphic character, these once easy to differentiate geomorphic zones are now more difficult to separate based on coral cover or other ecological indices. This difficulty stems from the functional loss of major reef builders such as Acroporids (e.g., *A. palmata*, *A. cervicornis*) which are largely responsible for long-term accretion in shallow Caribbean reefs (Macintyre and Glynn, 1976; Blanchon et al., 2017; Toth et al., 2019). These losses were likely driven by multiple strikes from major Hurricanes that crossed the study area (Allen in 1980, Gilbert in 1988, Emily in 2005 and Wilma in 2005), and their coincident timing with white band/pox epidemics that were decimating acroporids elsewhere (Gladfelter, 1982; Lewis, 1984; Aronson and Precht, 2001; Bruckner, 2002). Although there is

debate over the proximate cause (hurricanes vs disease outbreaks) the result was the same: a convergence of shallow coral communities with a concomitant structural deterioration (Jackson et al., 2014; Elliff and Silva, 2017). At Punta Maroma the largest decline in Acropids had taken place by the mid-1980s, and no additional evidence of large-scale species succession has been reported since, although disturbances have not decreased (Nyström et al., 2000; Schutte et al., 2010; Graham et al., 2011; Rioja-Nieto and Álvarez-Filip, 2019). This rapid decline at Punta Maroma is likely related to a regional species succession reported by Aronson and Precht (2001).

The rapid transition to a partially homogenized coral community at Punta Maroma today is inconsistent with the reef's Holocene record, implying the importance of these changes for the future accretion potential of the reef. But assessing the contribution of key reef-building species, such as *A. palmata*, in this accretion process based on their current ecological condition is a challenging exercise which depends on the type of ecological indicator used. Analysis of changes in species abundance and composition on a relatively short time-scale indicates a reduction in its contribution and an inferred loss in accretion potential. However, more complex measures than relative abundance, like the IVI analysis, indicates that some acroporids have retained their relative importance, highlighting the important contribution of this species to reef accretion. This is because the IVI includes other data such as colony size in addition to species abundances, and so gives a more complete picture. Nevertheless, such indices may still not provide an accurate picture of which species is important for accretion. For example, relative abundance data indicate that the CG zone now has more reef-building species, implying a higher accretion potential, despite the fact that CG zone has been repeatedly reported as non-accretional one (Rodríguez-Martínez et al., 2011; Blanchon et al., 2017). As a consequence, even the best-suited ecological indices of reef-accretion potential may not give accurate estimates unless the geomorphic context of coral communities is considered in more detail. Furthermore, although ecological studies may provide a detailed snapshot of historical timescales, they may not be fully representative of the long-term development in complex geomorphologically zoned reef structures (Aronson and Precht, 1997; Bellwood et al., 2004; Bruckner, 2012). For example, Vallès et al. (2019) recently demonstrate that each reef type has its own pattern of coral coverage and that between reef types there are differences not related to method bias. As we have shown here, intrinsic ecological patterns can also be identified with a more detailed scrutiny of geomorphic zones within each reef type, not just coral coverage.

Finally, the ecological dynamics of reef-building communities raises an interesting question about how they create geological structures over thousands of years. Ecological assessments assume that reef accretion potential is a function of the carbonate production rate of the site (gross production of primary and secondary producers less gross erosion of bioeroders (Perry and Morgan, 2017), and therefore this balance defines the persistence of reef structure. Whereas those core processes undoubtedly lead to accretion, other processes are poorly represented, like physical erosion and transport of coral skeletons by storm swell or hurricane, and the patchiness and species zonation inherent to biological processes (Perry, 1999; Purkis and Kohler, 2008). Although it is challenging to incorporate physical erosion within the accretion potential estimates, geomorphic zonation is a more predictable factor with definable boundaries (Blanchon, 2011). Furthermore, the assumptions that reefs were always covered by dense coral thickets or inhabited the same contemporary reef areas is questionable and ignores processes that exist outside of ecological timescales, for example, changes in sea level and the related processes of retrogradation or progradation of the reef structure (Graus and Macintyre, 1989). Indeed, little is known about the patterns of long-term accretion because geological reconstructions are largely two dimensional, deriving data from single drill holes or drill transects, and therefore assume accretion is a homogeneous process in space and time. It may be, for example, that accretion is heterogeneous in space and time and that some sections of a reef develop at different intervals, in different areas through time. In this case, some ecological conditions may not be representative of geological trends (Jackson, 1992).

## CONCLUSIONS

Over the last 40 years coral assemblage data show that the two main windward geomorphic zones at Punta Maroma have maintained ecologic and benthic differences, implying that physical environmental

drivers continue to exert a fundamental control on this reefal seascape. These data also indicate there has been a partial homogenization of coral assemblages over that interval involving the loss of important key reef building species, which has raised concern about future accretion potential and the long-term role of reef structures and services they provide. However, by considering the more detailed changes between geomorphic zones, our data do not rule out the possibility that this may be a successional stage prolonged by recruitment failure and that accretion may in-fact be heterogeneous in space and time. As a consequence, we suggest that a consideration of geomorphic zonation is a fundamental prerequisite for determining the accretion potential of entire reef systems.

## ACKNOWLEDGMENTS

We are grateful with E. Perez-Cervantes and N. Estrada-Saldívar who participated in the coral surveys of 2019, and with L.M. Guzmán, A. González de la Parra and M. Sánchez who assisted in the survey of 1979 and 1985. I. Ortega, E.G. Islas Domínguez and F. Medellín assisted with data collection and logistics. Edlin Guerra Castro assisted greatly with multivariate statistical data analysis.

## ADDITIONAL INFORMATION AND DECLARATIONS

**Alexis E. Medina-Valmaseda** conceived and designed the experiments, performed the experiments, analyzed the data, prepared figures and/or tables, helped write and review drafts of the paper, and approved the final draft.

**Rosa E. Rodríguez-Martínez** helped write and review drafts of the paper, and approved the final draft.

**Lorenzo Álvarez-Filip** performed the experiments, helped write, reviewed drafts of the paper, and approved the final draft.

**Eric Jordán-Dahlgren** helped write and review drafts of the paper, statistically analyzed the data, and approved the final draft.

**Paul Blanchon** helped design the experiment, prepared figures, helped write, review drafts of the paper and approved the final draft.
