The size of the organs responsible of emitting and detecting sexual communication signals is affected by sexual and natural selection. Communication via bioluminescent signals in fireflies is an interesting model to test hypotheses regarding the effect of the size of signal emission and detection organs on reproductive success. We studied the synchronous firefly *Photinus palaciosi*, a species that during the mating season congregates in large numbers in forests of central Mexico, offering a magnificent natural show that attracts numerous tourists. *P. palaciosi* operational sex ratios are strongly male-biased and the females are brachypterous. Our field study tested the hypothesis that the operational sex ratios and short daily mating period result in strong male-male competition that selects for males with larger signal detection (eyes) and signal emission (lantern) organs, whereas female-female mate competition is absent and, thus, no selection on body and lantern size is expected. Supporting the hypothesis, we found that (a) lantern size was more than four times larger in males than in females, that (b) the size of lanterns, eyes and body in females has no effect on mating success and (c) an absence of assortative mating in the size of signal detection and signal emission organs or in body size. However, contrary to our predictions, we found that (d) females have larger eyes than males and that (e) the size of lanterns, eyes and body has no effect on male mating success. Discrepancies with our predictions could be due to trade-offs with pressures different from sexual selection, such as those imposed by predators, although larger eye size in females also could be a result of intersexual selection (female choice).

16 ABSTRACT

17 The size of the organs responsible of emitting and detecting sexual communication signals is
18 affected by sexual and natural selection. Communication via bioluminescent signals in fireflies is
19 an interesting model to test hypotheses regarding the effect of the size of signal emission and
20 detection organs on reproductive success. We studied the synchronous firefly *Photinus palaciosi*,
21 a species that during the mating season congregates in large numbers in forests of central
22 Mexico, offering a magnificent natural show that attracts numerous tourists. *P. palaciosi*
23 operational sex ratios are strongly male-biased and the females are brachypterous. Our field
24 study tested the hypothesis that the operational sex ratios and short daily mating period result in
25 strong male-male competition that selects for males with larger signal detection (eyes) and signal
26 emission (lantern) organs, whereas female-female mate competition is absent and, thus, no
27 selection on body and lantern size is expected. Supporting the hypothesis, we found that (a)
28 lantern size was more than four times larger in males than in females, that (b) the size of lanterns,
29 eyes and body in females has no effect on mating success and (c) an absence of assortative
30 mating in the size of signal detection and signal emission organs or in body size. However,
31 contrary to our predictions, we found that (d) females have larger eyes than males and that (e) the
32 size of lanterns, eyes and body has no effect on male mating success. Discrepancies with our
33 predictions could be due to trade-offs with pressures different from sexual selection, such as
34 those imposed by predators, although larger eye size in females also could be a result of
35 intersexual selection (female choice).

36

37 INTRODUCTION

38 Communication between males and females is a fundamental element of the mating biology of
39 most animals (*Darwin, 1871; Maynard Smith & Harper 2003; Rosenthal, 2017*). There is a great
40 variety of organs, newly evolved or specialized via sexual selection, for the emission and
41 reception of sexual signals (*Darwin, 1871; Rosenthal, 2017; Elgar et al., 2019*). A fascinating
42 example of sexual communication involving vision is that of nocturnal fireflies (*Lloyd, 1979;*
43 *Lewis, 2016*). In these insects, adults possess an organ specialized for the emission of light
44 known as lantern. Typically, males fly searching for females, emitting flashing patterns that are
45 species- and sex-specific and that are involved in mate choice, while females emit glows or
46 flashes in response (*Lloyd, 1979; Lewis & Cratsley, 2008; Lewis, 2016; Stanger-Hall et al.,*
47 *2018*). If a successful dialogue is established, the male alights, contacts the female and a close-
48 range courtship ensues (*Lewis & Cratsley, 2008; Stanger-Hall et al., 2018*). It is reasonable to
49 propose that the sizes of the lantern and of the eyes are among the traits influencing the
50 efficiency of sexual communication in fireflies (*Vencl & Carlson, 1998; Crastley & Lewis, 2003,*
51 *2005; Demary et al., 2006; Lau & Meyer-Rochow, 2006*). Somewhat surprisingly, studies of the
52 effect of signal-emission organ size on mating success in fireflies are scant and their results are
53 inconsistent. While some studies detected an effect of male lantern size on mating success and
54 female responses in two *Photinus* species (*Vencl & Carlson, 1998; Crastley & Lewis, 2003,*
55 *2005*), another study found that female mating decisions in a third *Photinus* species are not
56 influenced by lantern size (*Demary et al., 2006*). The effect of signal-detection organ (eyes) size
57 on the fitness of both sexes, and of signal emission organ size on female fitness components have
58 not been studied in fireflies (but see *Crastley & Lewis, 2005*).

59 Synchronous fireflies are good subjects to study the effects on mating success of the size
60 of the organs involved in sexual communication because in these species the density of signaling

61 males is very large and the operational sex ratio is male biased, resulting in intense competition
62 between males and ample opportunities for female choice (*Lloyd, 1979; Lewis, 2016*), two types
63 of selective pressures that could favor larger organs sizes. In this paper, we present the results of
64 a field study of the effect of signal emission (lantern) and signal detection (eyes) organ size on
65 the probability of being found in copula, in males and females of the synchronous Mexican
66 firefly *Photinus palaciosi* (*Zaragoza-Caballero, 2012; Zaragoza-Caballero et al., 2020*). *P.*
67 *palaciosi* lives in pine-oak-fir forests of central Mexico, in the states of Estado de México,
68 Puebla and Tlaxcala, and its reproductive season goes from June to the beginning of August.
69 Mate searching, courtship and mating occur during approximately ninety minutes every night
70 (heavy rainfall prevents mating activity), starting around 20:30 h. In the study site, the
71 municipality of Nanacamilpa de Mariano Arista (Tlaxcala), thousands of males congregate under
72 the canopy of the forest during this period, flying in search for females and frequently
73 synchronizing their flashing and providing a magnificent show that attracts numerous tourists
74 (*Acle Mena et al., 2018*). The females cannot fly because they are brachypterous (i.e. their wings
75 are extremely reduced) (*Zaragoza-Caballero, 2012*), and they remain stationary in herbs at
76 heights < 60 cm and glow infrequently during the mating period. The number of sexually
77 receptive females every night is much smaller than that of males and thus the operational sex
78 ratio (OSR) is male biased (personal observation).

79 In this research we aimed to test predictions derived from the following hypothesis:
80 Given that the operational sex ratios is male biased and the daily mating period is short, male-
81 male competition for mates is intense in *P. palaciosi* and, thus, selection favors males with larger
82 eyes that could improve the ability to detect the glows of the relatively scarce females, as well as
83 males with larger lanterns that increase signal emission capabilities. Larger eye size in females

84 could be advantageous if increases the ability to detect high quality males, but considering that
85 they are the limiting sex and have large numbers of potential mates every night, it would not
86 have an effect on their probability of mating. In contrast to males, females are selected to emit a
87 glow of just enough intensity to be perceived by the males, thus no selection for increased
88 lantern size is predicted. In fact, it is even possible that females are selected to produce less
89 intense glows not only to reduce emission costs, but as a female choice mechanism to increase
90 the probability of being detected by males that are particularly good at detecting females, an
91 ability they could inherit to their male offspring. We tested the following predictions of this
92 hypothesis: (1) There is male biased sexual dimorphism in lantern size. (2) Males with larger
93 eyes and lanterns have higher probability of mating, whereas female differences in the size of
94 eyes and lanterns have no effect on their mating probability. (3) Larger males have a higher
95 probability of mating as a consequence of correlative selection (for example, due to direct
96 selection on the correlated lantern size) or direct selection (for example, if larger male size is
97 advantageous in direct competition with other males and in female mate choice; *Thornhill &*
98 *Alcock, 1983*); in contrast, females differences in body size have no effect on their probability of
99 mating. Finally, (4) the lack of selection in favor of male mate choice, due to the highly
100 competitive conditions experienced by male synchronous fireflies, results in the absence of
101 assortative mating in the size of signal detection and signal emission organs or in body size.

102 MATERIALS AND METHODS

103 Sample collection

104 Samples of males and females found in copula or solitary were collected simultaneously by a
105 team of three researchers during the daily mating period (20:30 – 22:00 h) in the middle of the
106 2016 reproduction season (between June 27 and July 15). Signalling males were collected with

107 an entomological net and solitary females and mating couples by hand. Individual mating
108 couples and solitary individuals were kept in Eppendorf vials with absolute alcohol. Captures
109 were made in seventeen places (one per night) in the municipality of Nanacamilpa de Mariano
110 Arista, Tlaxcala state, México (Appendix 1). Our collection was made under the SEMARNAT
111 (Mexican Government) permit SGPA/DGVS/06292/16.

112 **Measurement of phenotypic traits**

113 We obtained three photographs of each firefly (dorsal view, ventral view and a close up of the
114 eyes) with a digital camera (Canon™ model T3i) mounted on a dissection microscope
115 (Olympus™ model SZH10). The phenotypic measurements were taken with the NIH ImageJ
116 open access software (National Institutes of Health USA, <http://rsb.info.nih.gov/ij/>). We
117 estimated lantern size by measuring the area covered by the lantern in the ventral-view
118 photographs. Eye size was estimated as the difference between maximum eyespan and
119 interocular space (*i.e.* approximately the sum of the maximum diameter of both eyes) in the eyes
120 close-up photographs. Body size was estimated, in the dorsal view photographs, as the area
121 covered by the elytra of the males, while in females was estimated as the area that would have
122 been covered by the elytra, had they not been reduced. The area covered by the reduced female
123 elytra was also measured to document quantitatively brachyptery.

124 **Statistical analyses**

125 Since all our predictions implied the comparison of morphological traits between two groups (all
126 males *vs.* all females for predictions 1 and 4, and males [or females] found in copula *vs.* males
127 [or females] found alone for predictions 2 and 3), we first calculated t tests for each
128 morphological trait as an exploratory measure. Because most morphological variables were
129 significantly correlated (Table 1) in the whole sample (Table 1A), as well as in females and

130 males separately (Tables 1B and 1C), we used principal component (PC) analysis to summarize
131 morphological variation. We then tested sexual dimorphism in morphological measurements
132 (Prediction 1) using a binomial generalized linear model with a logit link function, with the sex
133 of the individual as the binary response variable (0=male, 1=female) and the first two principal
134 components scores (PC1 and PC2) as explanatory variables. We evaluated separately for each
135 sex the effect of the size of morphological traits on the probability of mating success (probability
136 that an individual would be captured while copulating rather than alone) (Predictions 2 and 3).
137 We constructed a separate binomial generalized linear model with logit link for each sex, using
138 mating status (0=captured alone, 1=captured mating) as the binary response variable and PC1
139 and PC2 scores as the explanatory variables. We simplified the models using backwards stepwise
140 simplification, removing each explanatory variable in order of increasing significance and testing
141 the effect of removing that variable with a chi-squared likelihood ratio test until only terms
142 whose removal leads to worsening of the model remained (*Crawley, 2013*). We carried out these
143 analyses in R software, version 3.5.3 (*R Core Team, 2019*) using the RStudio interface (*R Studio*
144 *Team, 2016*). We tested assortative mating by calculating correlations between morphological
145 trait of males and females found in copula.

146 **RESULTS**

147 **General observations**

148 We sampled 114 females (63 solitary and 51 in copula) and 156 males (105 solitary and 51 in
149 copula). Two copulating females were not included in the analyses because the posture they had
150 after fixation in alcohol prevented obtaining correct measurements.

151 **Sexual dimorphism**

152 Separate variance t tests showed that the area covered by the lantern, as expected from Prediction
153 1, was more than four times larger in males than in females (Table 2). Body size was also larger
154 (1.5x) in males, but eye size was smaller (Table 2). As expected in a species with brachypterous
155 females, the area covered by elytra and hindwings was strongly reduced in females to about one
156 sixth of that of males (Table 2).

157 The first two PC explained 94% of the whole variance (Table 3). Factor loadings
158 indicated that PC1 was mainly influenced by body size and lantern size, while PC2 was mainly
159 influenced by eye size (Table 3). Results of the binomial generalized linear model comparing
160 females and males are presented in Table 4A. There is sexual dimorphism in PC1, a difference
161 associated to the fact that males have larger body and, as expected from Prediction 1, larger
162 lantern size than females (Table 2). Females and males are clearly separated along PC1, even
163 though there is considerable variation within sexes (Table 2; Fig. 1).

164 **Effect of phenotypic traits on mating success**

165 We measured the effect of phenotypic traits on the probability of being collected in copula
166 separately for males and females. We compared 63 females collected alone with 49 females
167 collected in copula, and 105 males collected alone with 51 males collected in copula. The t tests
168 indicated that none of the morphological traits measured differed significantly between females
169 collected in copula or alone (Table 5A) or between males collected in copula or alone (Table
170 5B). These observations were confirmed by the results of the two independent binomial
171 generalized linear models comparing females collected in copula with females collected alone
172 (Table 4B) and males collected in copula with males collected alone (Table 4C). None of the
173 female and male traits summarized by PC1 and PC2 affected the probability of being collected in
174 copula (Table 4B and 4C; Figs. 2A y 2B). Thus, our results provide no support to our

175 expectations of a higher probability of mating for males with larger eyes and lanterns (Prediction
176 2) and larger body size (Prediction 3), although are consistent with the expectations of no-effect
177 in the case of females.

178 **Assortative mating**

179 Consistent with Prediction 4, we found no evidence of assortative mating in any of the three
180 morphological traits measured (Table 6).

181

182 **DISCUSSION**

183 In this paper we tested the hypothesis that in synchronous fireflies the male biased operational
184 sex ratios and the short daily mating period result in strong male-male competition that selects
185 for males with larger signal detection (eyes) and signal emission (lantern) organs, as well as
186 larger body sizes. On the other hand, in these fireflies female-female competition for mates is
187 apparently absent, and thus no selection on body and lantern size is expected in females,
188 although intersexual selection (female choice) could favor females with larger signal detection
189 organs (eyes).

190 In agreement with our hypothesis, males of *P. palaciosi* have larger lanterns (Prediction
191 1; Table 4A and Figure 1) and larger body sizes than females (Table 4A and Figure 1). Thus, our
192 data support the idea that strong intrasexual selection in males causes sexual dimorphism in
193 lantern and body size. On the other side, the observation that females evolved larger eyes than
194 males suggests that also intersexual selection (female choice) could affect sexual dimorphism,
195 although we do not know if larger eyes evolved to improve mate detection and assessment or if
196 other pressures, such as predator detection, were also involved (see below). Anyway, this last

197 result is intriguing because males of other *Photinus* species have larger eyes than females, a fact
198 considered evidence of selection favoring males with improved ability to detect females (*Lloyd,*
199 *1966; Demary et al., 2006*).

200 We did not find evidence for an effect on mating success of any of the morphological
201 traits measured, either in females or males (Tables 4B and 4C and Figure 2). Thus, there is no
202 evidence of an advantage for males with larger lanterns and eyes (Prediction 2) or body size
203 (Prediction 3). As expected (Prediction 4), we did not detect assortative mating in any of the
204 phenotypic traits studied. Perhaps the best species to compare our results is *P. pyralis* (*Vencl &*
205 *Carlson, 1998*), a species resembling *P. palaciosi* in that there is “intense competitiveness:
206 aggregations of males regularly attain very high densities”, sometimes resulting in several males
207 attempting to mate with the same female (*Vencl & Carlson, 1998*), as we have observed in *P.*
208 *palaciosi* (personal observations). In contrast to our findings, in *P. pyralis* the body size (elytral
209 length) and lantern area of males affected the probability of being found in copula. Interestingly,
210 in this species larger males and males with larger lanterns were more successful when single
211 males courted females (the most common case: 70% of all matings), however smaller males had
212 an advantage when four or more males simultaneously courted a female “on foot” on her perch
213 (12% of all matings). According to the authors, these contrasting effects “obscured” the global
214 effect of elytral and lantern length on male mating success (*Vencl & Carlson, 1998*). When we
215 collected many of the copulating pairs there was at least one additional male close to the
216 copulating pair, unfortunately we did not make a record of this fact, thus a trade-off similar to
217 that proposed by *Vencl & Carlson (1998)* is conceivable and could explain the lack of effects of
218 morphological measures on male mating success.

219 Our results, on the other hand, are similar to those obtained in the non-synchronous *P.*
220 *greeni*, where the size of lanterns, eyes and body had no effect on the probability of males being
221 found alone or in copula (Demary *et al.*, 2006). In this species, as well as in other *Photinus*
222 species (Branham & Greenfield, 1996; Crastley & Lewis, 2003; Demary *et al.*, 2006; Lewis,
223 2016), elements of the flashing pattern are important in determining male mating success.
224 However, elements of the flashing pattern are also important in *Photinus ignites*, a non-
225 synchronous firefly in which also a significant effect of lantern size and body size on mating
226 success has been observed (Crastley & Lewis, 2003, 2005). A study of the effect of the flashing
227 pattern, and its possible interaction with lantern size, on the mating success of males and females
228 would be very interesting in *P. paaciosi*.

229 In the specific case of the signal detection organs (eyes), we did not find an effect of eye
230 size on male or female mating success. This fact could be explained if other selective pressures
231 also affect eye size. The morphology, physiology and behavior of signal detection and emission
232 organs are frequently influenced by selective pressures not related to the sexual communication
233 function (Niven & Laghling, 2008; Stöckl *et al.*, 2013; Elgar *et al.*, 2019). For example, the
234 detection and assessment of visual signals of mate quality (Lewis, 2016; Rosenthal, 2017; Elgar
235 *et al.*, 2019; Stanger-Hall *et al.*, 2018) suggests that the structure and function of the eyes has
236 evolved influenced by intersexual selection (mate choice). However, the eyes are also used to
237 detect other resources (food, shelter, etc.) or natural enemies and, thus, its evolution is also
238 affected by natural selection (Elgar *et al.*, 2019). In *P. palaciosi*, we have detected several
239 predators of males (e.g., orb-webbing spiders and grasshoppers) during the mating period that
240 could be a significant selective pressure (personal observations). Interestingly, eye size was
241 smaller in males than in females, suggesting that in females selection pressures derived from, for

242 example, processes such as female choice, predator avoidance, prey searching (which usually
243 occurs in the ground; Lewis, 2016) and the choice of perch for mate location, have been (and
244 are) important to understand the evolution of eye size.

245 In contrast to the eyes, the lantern originally evolved as a sexual signal-emission organ,
246 which subsequently could have been affected also by natural selection (*Branham & Wenzel,*
247 *2003; Woods et al., 2007; Lewis & Cratsley, 2008; Stanger-Hall et al., 2018*). For example, a
248 study of two *Photinus* species determined that flashing increases dramatically predation risk and
249 increases the metabolic rate 37% with respect to the basal metabolic rate (even though the
250 experimental setting excluded flight) (*Woods et al., 2007*). In *P. palaciosi* it is not known if some
251 predator exerts a similar pressure on signaling fireflies and if this possible effect is, in turn,
252 affected by lantern size. For orb-webbing spiders—predators of *P. palaciosi* that are relatively
253 abundant in the study area—light emission seems irrelevant.

254 Firefly populations worldwide are declining and threatening factors vary in importance
255 for different species and regions (*Lewis et al., 2020*). Light pollution and tourism are considered
256 important threats for the charismatic synchronous species, such as *P. palaciosi*, and these factors
257 have their main impact during the mating period. Unfortunately, the mating system of only a
258 handful of species (out of the about 2,000 described) has been studied. Conservation measures
259 and regulation of touristic activities in fireflies “sanctuaries” need to be based on solid scientific
260 information.

261

262 **CONCLUSIONS**

263 Communication during sexual interactions requires signal emission and signal detection organs.
264 Sexual selection and other selection pressures affect the size of these organs. Our study of the
265 size of signal emission (lanterns) and signal detection (eyes) organs in the synchronous firefly *P.*
266 *palaciosi* tested the hypothesis that the male-biased operational sex ratios and the short nightly
267 mating period result in strong male-male competition, that selects for males with larger eyes and
268 lanterns, in contrast to females where mate competition is absent. In support of the hypothesis,
269 we found that lantern size was more than four times larger in males than in females, that in
270 females the size of lanterns, eyes and body has no effect on mating success, and an absence of
271 assortative mating for any of these traits. On the other hand, contrary to our predictions, we
272 found that in males the size of lanterns, eyes and body has no effect on their mating success. In
273 contrast to other fireflies, in *P. palaciosi* females have larger eyes than males. Discrepancies with
274 our predictions could be due to trade-offs with pressures different from sexual selection, such as
275 those imposed by predators, although larger eye size in females also could be a result of
276 intersexual selection (female choice).

Table 1 (on next page)

Morphological correlation matrices

Morphological correlation matrices for (A) males and females together, (B) females and (C) males of the firefly *Photinus palaciosi*. In males the area covered by elytra was used as a measure of Body size; since females have reduced wings, Body size was estimated as the area of the body that in males is covered by the elytra. Significant correlations are in italics.

1

A) Males + Females	Lantern (mm ²)	Eyes (mm)	Body size (mm ²)
Eyes (mm)	$r = -0.43$ $P = 1.53 \times 10^{-13}$	1	
Body size (mm ²)	$r = 0.84$ $P = < 2.2 \times 10^{-16}$	$r = -0.29$ $P = 1.71 \times 10^{-6}$	1
Elytra (mm ²)	$r = 0.97$ $P = < 2.2 \times 10^{-16}$	$r = -0.44$ $P = 3.22 \times 10^{-14}$	$r = 0.85$ $P = < 2.2 \times 10^{-16}$
B) Females			
Eyes (mm)	$r = 0.03$ $P = 0.77$	1	
Body size (mm ²)	$r = 0.60$ $P = 2.38 \times 10^{-12}$	$r = 0.05$ $P = 0.59$	1
Elytra (mm ²)	$r = 0.59$ $P = 7.73 \times 10^{-12}$	$r = -.0003$ $P = 0.99$	$r = 0.76$ $P = < 2.2 \times 10^{-16}$
C) Males			
Eyes (mm)	$r = 0.01$ $P = 0.90$	1	
Body size (mm ²)	$r = 0.85$ $P = < 2.2 \times 10^{-16}$	$r = 0.04$ $P = 0.62$	1

Table 2 (on next page)

Statistical summary and comparison of morphological measures of males and females

Comparison of the morphological measurements of male and female *Photinus palaciosi* fireflies. Average (Q_{25%}–Q_{75%}) [minimum value–maximum value] are given for each trait.

Results of independent variances t tests are given in the last column as follows: P value (t value) [degrees of freedom]. * The body size of males was estimated with the area covered by the elytra.

1

	Females	Males	t test
Lantern (mm ²)	0.79 (0.66–0.91) [0.41–2.04]	3.54 (2.86–4.19) [1.65–6.08]	$P < 2.2 \times 10^{-16}$ (-38.728) [180.21]
Eyes (mm)	1.77 (1.56–1.99) [0.74–2.96]	1.32 (0.99–1.51) [0.49– 2.64]	$P < 2.2 \times 10^{-16}$ (9.252) [257.11]
Body size (mm ²)	20.48 (17.26–23.41) [11.34–40.69]	30.73 (25.68–35.41) [17.27–53.64] *	$P < 2.2 \times 10^{-16}$ (-14.641) [264.35]
Elytra (mm ²)	4.86 (4.17–5.47) [3.13–4.43]	30.73 (25.68–35.41) [17.27–53.641] *	$P < 2.2 \times 10^{-16}$ (-49.231) [166.32]

2

Table 3(on next page)

Principal components of morphological measurements.

Summary of principal components analysis of morphological traits of the synchronous firefly *Photinus palaciosi*. The data presented are the factor loading coefficients for each morphological trait and the percentage of variation explained by the first two PC. Sample size is 268 (112 females and 156 males).

1

	PC1	PC2
Lantern size (mm ²)	0.651	-0.186
Body size (mm ²)	0.612	0.445
Eye size (mm)	-0.449	-0.876
Eigenvalue	2.073	0.751
% variation	69.12	25.03

2

Table 4(on next page)

Generalized Linear Models results.

Results of models evaluating (A) sexual dimorphism (probability that an individual will be male versus female), and probability of being encountered copulating rather than alone in females (B) and males (C), in relation to the scores of the first two principal components of body measurements of the synchronous firefly *Photinus palaciosi*. Variables indicated in bold were significant, and therefore included in the minimum adequate model.

1

2

Fixed Effects	$\beta \pm SE^*$	Z^*	P_Z^*	$P_{\chi^2}^\S$
A) Sexual Dimorphism				
PC1	1.634 \pm 0.408	4.001	6.3 x 10⁻⁰⁵	3.112 x 10⁻⁰⁵
PC2	-0.510 \pm 0.279	-1.828	0.068	0.045
B) Female probability of mating				
PC1	-0.0893 \pm 0.565	-0.158	0.874	0.06
PC2	-0.752 \pm 0.513	1.466	0.143	0.874
C) Male probability of mating				
PC1	-0.219 \pm 0.601	-0.363	0.716	0.714
PC2	-0.504 \pm 0.353	-1.426	0.154	0.131

4 **Notes:**

5 *Parameters from initial (full) model

6 $\S P$ -value resulting from χ^2 nested model comparisons following removal of each variable during backwards stepwise
7 simplification

8

Table 5 (on next page)

Morphological measures of males and females found alone or in copula.

Comparison of the morphological measurements of (A) females found in copula vs. females found solitary, and (B) males found in copula vs. males found solitary, in *Photinus palaciosi* fireflies. Average ($Q_{25\%}$ – $Q_{75\%}$) [minimum value–maximum value] are given for each trait. In the last column, results of independent variances t tests are given as follows: P value (t value) [degrees of freedom].

1

	Solitary	In copula	t test
A) Females			
Lantern (mm ²)	0.80 (0.66–0.97) [0.53–1.25]	0.78 (0.645 – 0.865) [0.413–2.04]	P = 0.65 (-0.46) [89.34]
Eyes (mm)	1.79 (1.56–2.01) [1.05–2.71]	1.75 (1.562 – 1.963) [0.738–2.961]	P = 0.61 (-0.52) [94.70]
Body size (mm ²)	20.09 (16.60– 23.11) [11.66–32.11]	20.99 (17.48–21.11) [11.36–40.69]	P = 0.37 (0.90) [84.05]
Elytra (mm ²)	4.79 (4.15–5.33) [3.20–7.34]	4.95 (4.20– 5.53) [3.13–9.43]	P = 0.45 (0.76) [81.92]
B) Males			
Lantern (mm ²)	3.5 (2.84– 4.15) 2.05–5.52	3.62 (2.96–4.24) 1.65–6.08	P = 0.44 (0.77) 84.32
Eyes (mm)	1.30 (0.97–1.5) 0.49–2.64	1.34 (1.09–1.58) 0.82–2.48	P = 0.53 (0.62) 116.44
Body size (mm ²)	30.67 (25.89–35.25) 17.95–47.71	30.84 (25.57–36.35) 17.27–53.64	P = 0.88 (0.15) 89.38

2

Table 6 (on next page)

Correlation matrix of males and females found in copula.

Correlation matrix of the morphological traits of males and females found in copula in *Photinus palaciosi* fireflies. No significant correlations were found (N = 49)

1

Females	Males		
	Lantern size (mm ²)	Body size (mm ²)	Eye size (mm)
Lantern size (mm ²)	r = 0.21 P = 0.16	r = 0.11 P = 0.45	r = -0.06 P = 0.68
Body size (mm ²)	r = 0.09 P = 0.52	r = 0.05 P = 0.74	r = 0.04 P = 0.78
Eye size (mm)	r = 0.05 P = 0.75	r = 0.01 P = 0.94	r = 0.12 P = 0.41

2

Figure 1

Sexual dimorphism of *Photinus palaciosi*.

First two principal components summarizing the morphological traits measured in females and males of the synchronous firefly *P. palaciosi*.

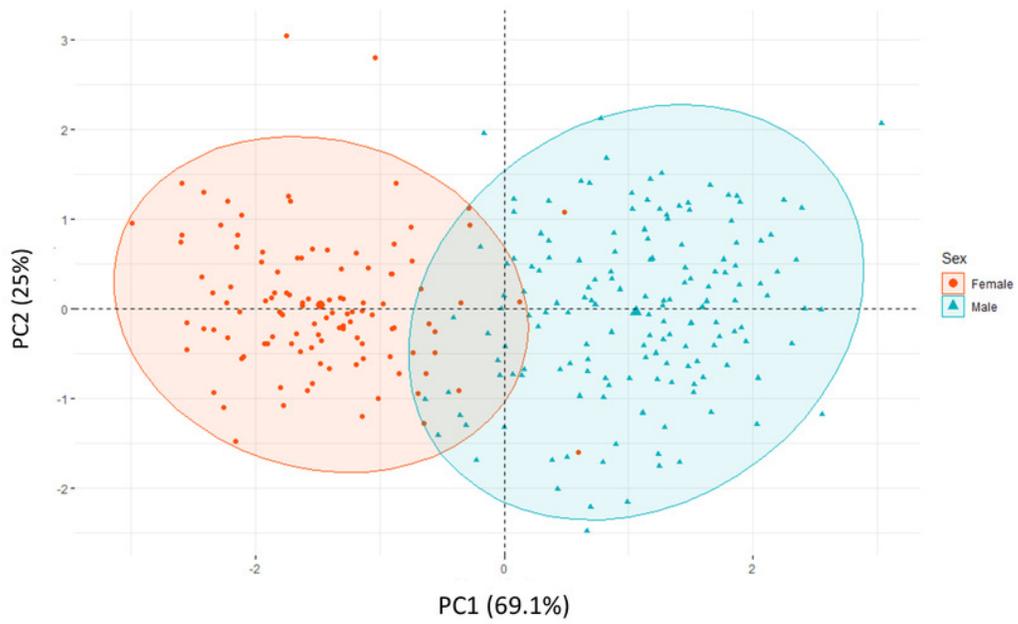

Figure 2

Comparison of morphological measurements of *P. palaciosi* fireflies collected alone or in copula.

Principal components comparison of individuals collected alone or in copula in (A) females and (B) males of the synchronous firefly *P. palaciosi*.
