

Were early pterosaurs inept terrestrial locomotors?

Mark P Witton

Pterodactyloid pterosaurs are widely interpreted as terrestrially competent, erect-limbed quadrupeds, but the terrestrial capabilities of non-pterodactyloids are largely thought to have been poor. This is commonly justified by the absence of a non-pterodactyloid footprint record, suggestions that the expansive uropatagia common to early pterosaurs would restrict hindlimb motion in walking or running, and the presence of sprawling forelimbs in some species. Here, these arguments are re-visited and mostly found wanting. Restriction of limb mobility is not a problem faced by extant animals with extensive flight membranes, including species which routinely utilise terrestrial locomotion. The absence of non-pterodactyloid footprints is not necessarily tied to functional or biomechanical constraints. As with other fully terrestrial clades with poor ichnological records, biases in behaviour, preservation, sampling and interpretation likely contribute to the deficit of early pterosaur ichnites. Suggestions that non-pterodactyloids have slender, mechanically weak limbs are demonstrably countered by the proportionally long and robust limbs of many Triassic and Jurassic species. Novel assessments of pterosaur forelimb anatomies conflict with notions that all non-pterodactyloids were obligated to sprawling forelimb postures. Sprawling forelimbs seem appropriate for species with ventrally-restricted glenoid articulations (seemingly occurring in rhamphorhynchines and campylognathoidids). However, some early pterosaurs, such as *Dimorphodon macronyx* and wukongopterids, have glenoid arthrologies which are not ventrally restricted, and their distal humeral anatomy resembles those of pterodactyloids. It seems fully erect forelimb stances were possible in these pterosaurs, and may be probable given proposed links between pterodactyloid-like distal humeral morphology and forces incurred through erect forelimb postures. Further indications of terrestrial habits include antungual sesamoids, which occur in the manus and pes anatomy of many early pterosaur species, and only occur elsewhere in terrestrial reptiles, possibly developing through frequent interactions of large claws with firm substrates. It is argued that characteristics possibly associated with terrestriality are deeply nested within Pterosauria and not restricted to Pterodactyloidea as previously thought, and that pterodactyloid-like levels of terrestrial competency may have been possible in at least some early pterosaurs.

9 Abstract

10 Pterodactyloid pterosaurs are widely interpreted as terrestrially competent, erect-limbed
11 quadrupeds, but the terrestrial capabilities of non-pterodactyloids are largely thought to have
12 been poor. This is commonly justified by the absence of a non-pterodactyloid footprint record,
13 suggestions that the expansive uropatagia common to early pterosaurs would restrict hindlimb
14 motion in walking or running, and the presence of sprawling forelimbs in some species. Here,
15 these arguments are re-visited and mostly found wanting. Restriction of limb mobility is not a
16 problem faced by extant animals with extensive flight membranes, including species which
17 routinely utilise terrestrial locomotion. The absence of non-pterodactyloid footprints is not
18 necessarily tied to functional or biomechanical constraints. As with other fully terrestrial clades
19 with poor ichnological records, biases in behaviour, preservation, sampling and interpretation
20 likely contribute to the deficit of early pterosaur ichnites. Suggestions that non-pterodactyloids
21 have slender, mechanically weak limbs are demonstrably countered by the proportionally long
22 and robust limbs of many Triassic and Jurassic species. Novel assessments of pterosaur forelimb
23 anatomies conflict with notions that all non-pterodactyloids were obligated to sprawling forelimb
24 postures. Sprawling forelimbs seem appropriate for species with ventrally-restricted glenoid
25 articulations (seemingly occurring in rhamphorhynchines and campylognathoidids). However,
26 some early pterosaurs, such as *Dimorphodon macronyx* and wukongopterids, have glenoid
27 arthrologies which are not ventrally restricted, and their distal humeral anatomy resembles those
28 of pterodactyloids. It seems fully erect forelimb stances were possible in these pterosaurs, and
29 may be probable given proposed links between pterodactyloid-like humeral morphology and
30 forces incurred through erect forelimb postures. Further indications of terrestrial habits include
31 antungual sesamoids, which occur in the manus and pes anatomy of many early pterosaur
32 species, and only occur elsewhere in terrestrial reptiles, possibly developing through frequent

33 interactions of large claws with firm substrates. It is argued that characteristics possibly
34 associated with terrestriality are deeply nested within Pterosauria and not restricted to
35 Pterodactyloidea as previously thought, and that pterodactyloid-like levels of terrestrial
36 competency may have been possible in at least some early pterosaurs.

38

39 Introduction

40 The terrestrial competency of pterosaurs was keenly debated during the 1980s and 1990s, when
41 the utility of bipedal and quadrupedal gaits, orientation and posture of the extremities, as well as
42 overall terrestriality were discussed at length (Fig. 1, Padian 1983a, b; Padian and Olsen 1984;
43 Wellnhofer 1988; Unwin 1988, 1989, 1996a, 1999; Lockley et al. 1995; Bennett 1997a; Clark et
44 al. 1998; see Witton 2013 for a recent overview). The current consensus emerged when
45 *Pteraichnus* trackways, first identified by Stokes (1957) as pterosaurian, but argued to be of
46 crocodylomorph origin by Padian and Olsen (1984) and Unwin (1989), were convincingly
47 demonstrated as belonging to pterodactyloid pterosaurs (Lockley et al. 1995; Bennett 1997a;
48 Unwin 1996a, 1999; also see Kubo 2008). This reappraisal started the construction of a
49 compelling case for pterodactyloids as terrestrially competent quadrupeds with plantigrade feet
50 and parasagittal gaits, a hypothesis now strengthened by numerous trackway discoveries (e.g.
51 Mazin *et al.* 1995, 2003; Lockley and Wright 2003; Hwang et al. 2002; Padian 2003; Lockley et
52 al. 2008) but also functional analyses of pterosaur anatomy (e.g. Bennett 1997a; Clark et al.
53 1998; Sangster 2003; Wilkinson 2008; Witton and Naish 2008; Fujiwara and Hutchinson 2012;
54 Costa et al. 2013; Hyder et al. 2014).

55

56 Although it seems that the basic tenets of pterodactyloid terrestrial locomotion are understood,
57 the same cannot be said for non-pterodactyloids. Research into the terrestrial capacity of early
58 pterosaurs is entirely based on interpretations of their functional anatomy because their
59 trackways remain elusive (Unwin 2005; Lockley et al. 2008; Whyte and Romano 2014). Such
60 considerations are relatively few in number and have reached varying conclusions, either arguing
61 for non-pterodactyloids as terrestrially competent, digitigrade bird-like bipeds which could not
62 easily reach the substrate with their forelimbs (Fig. 1a; Padian 1983a, b, 1985, 2003, 2008); as
63 widely-sprawled quadrupeds, limited to rotatory gaits (as defined by Padian et al. 2010) and ill-

64 suited to movement on the ground, but possibly adept at climbing (Unwin 1987, 1988, 1989,
65 1999; 2005; Unwin and Bakhurina 1994); or as quadrupeds with erect hindlimbs, capable of
66 arboreal locomotion and powerful leaping (Bennett 1997b) or bipedal running (Padian 2008a, b,
67 c).

68

69 To some extent, discussions of non-pterodactyloid terrestriality have been intertwined with
70 debates over pterosaur bipedality, as many of the foundations of this hypothesis were set using
71 non-pterodactyloids (Padian 1983a, b). Pterosaur bipedality has always been controversial
72 (Bennett 1997a, p. 107) and has inspired numerous analyses. Most have suggested that habitual
73 bipedalism – either bird-like or otherwise – is unlikely for any pterosaur. Criticisms of this
74 concept include all pterosaurs having a centre of gravity situated towards the shoulders
75 (Wellnhofer 1988; Bennett 1997a; Sangster 2003; Wilkinson 2008); a pedal morphology ill-
76 suited to digitigrady (Bennett 1997a; Clark et al. 1998); lever arms of proximal hindlimb
77 musculature which perform poorly at postures imposed by bipedality (Fastnacht 2005; Costa et
78 al. 2013); an inability to neatly fold the forelimbs (Wilkinson 2008), and forelimb strength
79 scaling regimes contrasting with those of flying bipeds, but matching those of quadrupeds (Habib
80 2008). The inability of pterosaur forelimbs to reach the ground has also been disputed (Unwin
81 1996a; Bennett 1997a), although Padian (1983b, 2003a, b) maintains that the limb proportions of
82 some species, in concert with perceived limited limb motion at the shoulder, dictates facultative
83 bipedality for some pterosaurs. Functional evidence casting doubt on bipedal postures in
84 pterosaurs is consistent with a wealth of trackway data showing pterosaurs as quadrupedal
85 animals with plantigrade feet (e.g. Mazin *et al.* 1995, 2003; Lockley and Wright 2003; Hwang et
86 al. 2002; Padian 2003; Lockley et al. 2008), and is further bolstered by the unique fit of pterosaur
87 anatomy to these tracks (Lockley et al. 1995; Bennett 1997a; Unwin 1996a). Note that further
88 experimentation with extant crocodylian trackmakers has cast further doubt on perceived
89 similarities between *Pteraichnus* tracks and those of crocodylomorphs (Kubo 2008; contra.
90 Padian and Oslen 1984; Padian 2003).

91

92 Of the several interpretations of non-pterodactyloid terrestrial locomotion outlined above, the
93 proposal that they were relatively ineffective terrestrial quadrupeds has gained the largest
94 acceptance (e.g. Unwin 1987, 1988, 1989, 1999; 2005; Unwin and Bakhurina 1994; Ősi 2010;

95 Butler et al. 2013; Benson et al. 2014; Whyte and Romano 2014). The assumed contrast in
96 terrestrial abilities between non-pterodactyloids and pterodactyloids has influenced
97 considerations of not only non-pterodactyloid palaeobiology (e.g. lifestyle and diets – see Unwin
98 2005; Ósi 2010) but also the evolution of Pterosauria as a whole. Some recent workers have
99 considered the origin of pterodactyloids a ‘terrestrialisation’ of pterosaurs (Unwin 2005; Butler
100 et al. 2013), and a radical evolutionary departure from the primarily scansorial and volant habits
101 used by earlier members of the group.

102

103 The concept of grounded non-pterodactyloids as poor terrestrial locomotors relies on three oft-
104 repeated hypotheses. The first concerns the expansive uropatagium which extended between the
105 hindlimbs of non-pterodactyloids, supported distally by long fifth pedal digits (Fig. 2; Sharov
106 1971; Unwin and Bakhurina 1994; Wild 1994; Kellner et al. 2009). This is reasoned to have
107 restricted independent hindlimb motion and stride length, limited speed and agility, and hindered
108 movement through complex, vegetated environments (e.g. Unwin 1988, 1999; 2005; Ósi 2011).
109 The reduction of fifth toe length in pterodactyloids is interpreted as signifying the loss or
110 reduction of this membrane, as evidenced by a pterodactyloid specimen with reduced hindlimb
111 membranes lacking medial contact (Wellnhofer 1987). This ‘decoupling’ of the hindlimbs from
112 one another is thought to have permitted longer strides and more effective, faster terrestrial
113 locomotion in pterodactyloids, explaining their relative success in inland settings over their
114 ancestors (e.g. Unwin 1988, 1999, 2005; Ósi 2011).

115

116 The absence of pterosaur trackways from Triassic to Middle Jurassic rocks is a second piece of
117 evidence cited for non-pterodactyloid terrestrial incompetency. The pterosaur body fossil record
118 begins in at least the Norian but, to date, no definitively identified pterosaur trackways occur in
119 rocks pre-dating the Aalenian (Lockley et al. 2008; Whyte and Romano 2014). The oldest
120 occurrence of pterosaur tracks roughly coincides with the oldest evidence of pterodactyloids
121 (Andres et al. 2014; Whyte and Romano 2014) and is seen as evidence for pterosaurs becoming
122 ‘terrestrialised’, it being assumed that pterodactyloid anatomical nuances allowed exploitation of
123 settings such as tidal flats and lake margins, and creation of a track record (Unwin 2005; Butler
124 et al. 2012). Non-pterodactyloids, by contrast, are assumed so poorly adapted for walking and

125 running that they scarcely used such forms of locomotion, and thus rarely left footprints (Unwin
126 2005).

127

128 Both of these concepts are in keeping with a third hypothesis, that non-pterodactyls had
129 sprawling forelimbs, and perhaps hindlimbs as well (Wellnhofer 1975; Unwin 1988, 1999, 2005;
130 Padian 2008b). It has been argued that these would limit quadrupedal walking speeds and force
131 reliance on other forms of locomotion – bipedal running or flight – to move rapidly (Unwin
132 1988, 1999, 2005; Padian 2008b). Although some have argued that the hindlimbs of early
133 pterosaurs were erect and powerfully muscled (e.g. Padian 1983a, b, 2008b; Bennett 1997b;
134 Elgin et al. 2011), these observations have not influenced some considerations of non-
135 pterodactylid terrestrial locomotion (Unwin 1988, 2005). However, even among those
136 proposing erect hindlimbs, the terrestrial prospects of non-pterodactyls are not considered
137 highly. Padian (2008a, b) has suggested that a combination of erect hindlimbs and sprawled
138 forelimbs would incline early pterosaur torsos anteriorly, and, in concert with limited forelimb
139 reach, render them ill-suited to terrestrial locomotion – at least as quadrupeds (this is considered
140 one line of evidence for bipedal habits). In recent years, views that early pterosaurs were inept
141 terrestrial animals have been presented as established and important parts of the pterosaur
142 evolutionary history, and said to explain patterns within the pterosaur fossil record (Unwin 1999,
143 2005; Butler et al. 2012; Benson et al. 2014).

144

145 These assumptions have become established despite the low number of dedicated assessments
146 into non-pterodactylid locomotion. There have been considerably fewer studies into non-
147 pterodactylid functionality than there are for pterodactyls, and particularly so in recent years.
148 This probably reflects the larger amount of material available for studies into pterodactylid
149 mechanics: along with footprints and tracks, many pterodactyls are known from three-
150 dimensional material which lends itself better to functional studies than the mostly flattened and
151 fragmentary remains forming the non-pterodactylid record. Nevertheless, some non-
152 pterodactylid anatomies are well enough known to permit evaluation of arguments suggesting
153 poor terrestriality in these early forms. This is attempted here, with the three principle hypotheses
154 underlying most assessments of non-pterodactylid terrestriality being considered:

155

- 156 1. Did the large uropatagium of non-pterodactyloids restrict hindlimb function during
157 terrestrial locomotion?
158 2. Is the absence of non-pterodactyloids trackways related to their terrestrial capabilities?
159 3. Were the limbs of non-pterodactyloids sprawled during terrestrial locomotion?
160

171

172 **Materials and Methods**

173 *Systematic declaration*

174 Pterosaur systematics, and particularly those of early taxa, are currently highly controversial.
175 With so little agreement on multiple aspects of early pterosaur phylogeny including clade
176 content, group definitions, and appropriate nomenclature (e.g. Unwin 2003; Kellner 2003; Wang
177 et al. 2009; Kellner 2010; Dalla Vecchia 2009; Lü et al. 2010, 2012; Witton 2013; Andres and
178 Meyers 2013; Andres et al. 2014), accurate discussion of pterosaur systematics requires regular
179 citation of the specific taxonomy being followed (e.g. Andres and Meyers 2013) or frequent
180 mentions of conflicting phylogenies (e.g. Witton 2013). Neither approach is practical or makes
181 for compelling reading. Thus, unless otherwise stated, this paper uses the nomenclature and
182 taxonomy of the non-pterodactyloid phylogeny of Lü et al. (2012). Dalla Vecchia (2009), Wang
183 et al. (2010) and Andres and Meyers (2013) offer alternative contemporary schemes.

184

185 *Material*

186 A number of specimens inform the discussion provided here, but key material includes three-
187 dimensionally preserved remains of *Dimorphodon macronyx*, a well-known Sinemurian, Liassic
188 non-pterodactyloid from Dorset, UK. Observations were chiefly made on the holotype NHMUK
189 R1034, a partial skeleton, and the near complete skeleton NHMUK 41412-13. Both specimens,
190 although partially embedded in matrix, are largely three dimensionally preserved and sufficiently
191 prepared to appreciate most aspects of limb girdle and limb anatomy, especially when viewed in
192 concert with other, less complete *Dimorphodon* material in the Natural History Museum,
193 London. Additional study was made on a near-complete three-dimensional rhamphorhynchine
194 scapulocoracoid from the Callovian-Oxfordian Oxford Clay, UK, NHMUK R5672. Wellnhofer
195 (1975) referred this specimen to *Rhamphorhynchus* sp., but diagnostic characters for this genus
196 are presently only known in the skull anatomy and limb proportions of this genus (Bennett
197 1995). While undoubtedly *Rhamphorhynchus*-like, NHMUK R5672 is conservatively considered
198 an indeterminate rhamphorhynchine here, echoing taxonomic suggestions by Unwin (1996b).

199

200 Results

201 1. *Did the large uropatagium of non-pterodactyloids restrict hindlimb function during* 202 *terrestrial locomotion?*

203 The inference that relatively large uropatagia impeded early pterosaur terrestrial habits has
204 received no detailed evaluation, despite its confident presentation in some literature (“There can
205 be no doubt that this shackling of the limbs must have hindered pterosaurs as they sought to
206 move around on the ground” – Unwin 2005, p. 204). It might be presumed that attributes of
207 fossil pterosaur soft-tissues or observations on modern animals with similar membrane structures
208 support this assertion, but it is only the relatively large size of early pterosaur uropatagia which is
209 cited in favour of this idea (e.g. Unwin and Bakhurina 1994; Unwin 2005). While it is difficult to
210 evaluate the effects of soft-tissues on non-pterodactyloid hindlimb kinematics in the absence of
211 footprints, evidence from pterosaur body fossils, and the anatomy and behaviour of modern
212 animals, conflict with proposals that expansive uropatagia impeded early pterosaur terrestriality.

213

214 Many gliding and flying mammals possess large, hindlimb-spanning uropatagia comparable in
215 size to those of non-pterodactyloids (Fig. 2). A number of these species are terrestrially
216 proficient (e.g. Sollberger 1940; Nowark 1994; Stafford et al. 2003; Riskin et al. 2006; Meijaard

217 et al. 2006), some spending considerable amounts of time on the ground in pursuit of food or
218 refuge using fast, complex and sometimes strenuous behaviours (Sollberger 1940; Daniel 1976;
219 Nowark 1994; Pyare and Longland 2002; Riskin et al. 2006). These animals are not confined to
220 barren habitats, predator-free environments or the result of reduced competition from other
221 terrestrial creatures. Rather, they inhabit complex, predator-filled habitats and have persisted for
222 many millions of years in some regions (Hand et al. 2009). Examples include the New Zealand
223 lesser short-tailed bat, *Mystacina tuberculata*, which is reported as having “rodent-like agility on
224 the ground and on trunks, branches, and kiekie vines” by Daniel (1976; p. 397). Common
225 vampires, *Desmodus rotundus*, rely on their terrestrial skills to stealthily stalk hosts or quickly
226 evade danger using forelimb-propelled galloping (Nowark 1994; Riskin and Hermanson 2005;
227 Riskin et al. 2006). Flying squirrels, such as *Glaucomys* species, forage on the ground, are
228 capable of running, and have membranes resilient to frequent digging for fungal food sources
229 (Sollberger 1940). Similarly, membranes of *Mystacina* bats withstand crevice-crawling as well
230 as digging (Daniel 1979). Clearly, the grounded activities of these animals are not impeded by
231 their patagia, nor do their membranes snag on obstacles or become easily damaged. Presumably,
232 membrane elasticity plays a role in reducing impedance to terrestrial activity, both allowing the
233 limbs to move freely as well as drawing the membranes close to the body to prevent interference
234 with the environment or limb motion. The extent of such membrane shrinkage can be extreme,
235 rendering them almost indiscernible in some circumstances (Meijaard et al. 2006). Critically,
236 while some membrane-bound extant animals are poor terrestrial locomotors, this has not been
237 linked to membrane size or distribution, but instead to aspects of skeletal morphology, limb
238 strength or myology (Riskin et al. 2005).

239

240 Certain bats and flying squirrels show that large uropatagia do not rule out terrestrial potential in
241 volant mammals, but are they suitable models for pterosaurs? Fossils of pterosaur wing
242 membranes show some similarities to those of modern volant mammals in that they were likely
243 elastic in their proximal regions. Pterosaur brachiopatagia are stiffened by structural fibres
244 distally, but other membrane components – including the uropatagium – lack rigid structural
245 fibres and are widely considered to have been compliant (e.g. Padian and Rayner 1993; Unwin
246 and Bakhurina 1994; Bennett 2000; Frey et al. 2003). Unwin and Bakhurina (1994), describing
247 the uropatagium of *Sordes pilosus*, comment specifically on this, stating “...adjacent to the body

248 the [structural] fibres are shorter, more sinuous and loosely packed, indicating that the
249 propatagium, uropatagium and proximal regions of the cheiropatagium were somewhat softer
250 and more elastic” (p. 64). From this, it can be expected that all pterosaur membranes would
251 contract significantly when the limbs were not extended to flight position, as occurs in many
252 volant mammals, clearing them of obstacles and permitting stretching of the membranes during
253 walking or running. Some evidence for this contraction may be seen in pterosaur fossils with
254 preserved membranes (Elgin et al. 2011). Trackways made by running pterodactyls indirectly
255 demonstrate how elastic their proximal membranes must have been, allowing track makers to
256 take strides of considerable magnitude (Mazin et al. 2003) despite membranes stretching from
257 the distal hindlimb to their hands (Elgin et al. 2011). The expansion and contraction of
258 brachioptagia in running pterodactyls was probably no greater than that experienced by non-
259 pterodactyl uropatagia during terrestrial activity.

260

261 Even if the hindlimb strides of non-pterodactyls were restricted by membranes, pterosaurs
262 were likely capable of circumventing this issue by using asymmetrical, bounding gaits (Witton
263 and Habib 2010; Witton 2013; Hyder et al. 2014). Indeed, both the fore- and hindlimbs of
264 pterosaurs have been noted for their strength and leaping potential (Padian 1983a, Bennett
265 1997b; Habib 2008; Witton and Habib 2010), and there are obvious parallels between forelimb-
266 dominated *Desmodus* galloping and recent, compelling hypotheses concerning forelimb use in
267 pterosaur launch (Habib 2008). Pterosaurian bounding locomotion may be countered by
268 exclusive trackway evidence for symmetrical gaits in pterodactyls (e.g. Stokes 1957; Mazin *et*
269 *al.* 1995, 2003; Lockley and Wright 2003; Hwang et al. 2002), but it remains unclear if these
270 gaits were employed by all pterosaurs, all the time, nor is it clear if interpretations of these tracks
271 are applicable to non-pterodactyls. Bounding gaits are at least tenable from a functional and
272 biomechanical perspective.

273

274 In light of these observations, the proposal that early pterosaurs were terrestrially hindered by
275 their membranes is peculiar. It relies on the uncertain assumption that the uropatagium was
276 especially restrictive compared to other pterosaur wing membranes and behavioural restrictions –
277 membranes snagging on obstacles and limiting stride length – which have no precedent among
278 modern pterosaur analogues. Clear evidence demonstrating broad uropatagia were barriers to

279 early pterosaur terrestriality has yet to be presented, whereas what we know of pterosaur soft-
280 tissues and modern animals with similar anatomy indicates that their membranes likely had little,
281 if any, impact on terrestrial potential.

282

283 *2. Is the absence of non-pterodactyloids trackways related to terrestrial capabilities?*

284 The view that a lack of early pterosaur trackways must equate to their terrestrial ineptitude (e.g.
285 Unwin 2005; Butler et al. 2013) relies on a very literal interpretation of the pterosaur fossil
286 record and an assumption that we can distinguish genuine absences of fossil phenomena from
287 biases affecting fossil datasets. There are reasons to consider both these assertions uncertain.

288

289 The non-pterodactyloid body fossil record is not only poorer than that of pterodactyloids, but
290 also many contemporary terrestrial tetrapod groups (e.g. Benton and Spencer 1995; Kielan-
291 Jaworowska et al. 2004). It is particularly impoverished in terrestrial basins (Butler et al. 2013).
292 This is thought to reflect the general lack of inland or near-shore pterosaur-bearing Lagerstätten
293 before the Late Jurassic; the small body sizes and low preservation potential of early pterosaurs;
294 a possibly restricted distribution of the group in its early history; or perhaps existence of the first
295 pterosaurs in habitats unconducive to fossilisation and sediment accumulation - inland forests or
296 upland environments (Bennett 1997b; Unwin 2005; Witton 2013; Butler et al. 2013). Regardless
297 of the cause, recent studies have concluded that recorded patterns of Triassic and Jurassic
298 pterosaur diversity – the interval dominated by non-pterodactyloids – have little statistical
299 significance (e.g. Butler et al. 2013; Upchurch et al. 2014), and that our understanding of early
300 pterosaur history remains generally poor. This is difficult to reconcile with suggestions that the
301 lack of an early pterosaur fossils – specifically their track record - is somehow significant. If
302 understanding of the early pterosaur record is demonstrably limited, how can any apparent trends
303 or patterns in that data be confidently interpreted, and especially those reliant on an absence of
304 data?

305

306 It seems unwise to link the absence of a track record to a very specific cause, such as functional
307 anatomy (and especially so given the lack of detailed research into early pterosaur terrestriality)
308 when there are a number of reasons why non-pterodactyloids may not have an ichnological
309 record. If non-pterodactyloids were genuinely rare in terrestrial basins – as their record currently

310 indicates - their likelihood of creating traces must also be low. Likewise, it seems most early
311 pterosaurs were small, with wingspans of 1-2 m (O'Sullivan et al. 2013) and corresponding
312 masses of 0.55-3.26 kg (using data from Witton 2008). Their footprints would thus be small and
313 shallow, without substantial underprinting, and require exceptional conditions for impression,
314 fossilisation and discovery. In contrast, pterodactyloids are generally larger bodied than early
315 pterosaurs (Hone and Benton 2007; Benson et al. 2014), which may constitute creation of
316 deeper, longer-lasting tracks which are better suited to fossilisation and detection. A related
317 problem concerns our ability to distinguish the footprints of pterodactyloids from those expected
318 of non-pterodactyloids (Lockley et al. 2008): all pterosaurs have the same basic manus and pes
319 structure, the only exception being the longer fifth toe in non-pterodactyloids. Given the role of
320 this structure in supporting the uropatagium, it may have been held aloft when walking (Lockley
321 et al. 2008). If so, the tracks of all pterosaurs might look similar, and some alleged Jurassic
322 pterodactyloid ichnites may be misidentified.

323

324 It should also not be assumed that early pterosaurs and pterodactyloids occupied ecologies with
325 similar track-making potential. The start of the pterosaur footprint record in the Middle Jurassic
326 roughly corresponds with the emergence of pterodactyloid clades predicted to be waders,
327 suspension-feeders and molluscivores (ctenochasmatoid and dsungaripterids - Unwin 2005;
328 Witton 2013). Such animals are expected to routinely patrol lake margins and other habitats
329 suitable to footprint preservation in search of food. Lockley et al. (2003, 2008) note that
330 pterodactyloid tracks are frequently associated with invertebrate traces and occasional feeding
331 marks, which may indicate foraging was a common factor in pterosaur ichnite creation, inferring
332 ecological influences on the delayed start of the pterosaur ichnological record. By contrast, non-
333 pterodactyloids are largely perceived as pelagic piscivores or insectivores (Wellnhofer 1975;
334 Wild 1978; Chatterjee and Templin 2004; Ósi 2010; Witton 2008, 2013), neither of which are
335 habits lending themselves to sustained terrestrial activity on mudflats, water margins or other
336 settings liable to preserving footprints.

337

338 Perhaps most importantly, early pterosaurs are not alone in having a very sparse track record.
339 The tracks and traces of many fully terrestrial Mesozoic clades are surprisingly poorly known –
340 examples include geographically widespread, long-lived lineages with good body fossil records,

341 such as Mesozoic Mammaliaformes, tyrannosaurids and ceratopsids (Lockley and Hunt 1995;
342 Kielan-Jaworowska et al. 2004; McCrea et al. 2014). Not only are the ichnological records of
343 these groups poor – restricted to single localities in some cases – but many ichnites referred to
344 them are controversially identified (Kielan-Jaworowska et al. 2004; McCrea et al. 2014). This
345 occurs despite these animals seemingly being abundant (as evidenced by their good body fossil
346 records) and fully terrestrial in their habits, thus potentially creating tracks in virtually all of their
347 activities (unlike pterosaurs, which, in being volant, avoided track creation much of the time). In
348 contrast to perceptions of the pterosaur track record however, the sparse trackways of Mesozoic
349 Mammaliaformes or certain dinosaur clades are not interpreted as signs terrestrial ineptitude, but
350 as biases of behaviour, ecology, preservation, sampling or interpretation.

351

352 Ultimately, while the absence of early pterosaur footprints is an intriguing phenomenon of the
353 pterosaur record, and one with possible implications for the development of terrestriality in
354 Pterosauria, its significance cannot be divorced from a number of factors unrelated to functional
355 morphology. As with any case supported by negative evidence, data deficits can only be
356 interpreted so far, especially when related datasets are demonstrably poor. Considering the
357 absence of early pterosaur tracks as significant requires ignorance of not only statistics on the
358 quality of the pterosaur fossil record, but also data concerning early pterosaur palaeobiology and
359 the broader ichnological record. Other sources of evidence should be pursued for more reliable
360 insights into the development of pterosaur terrestriality.

361

362 3. *Were the limbs of non-pterodactyloids sprawled during terrestrial locomotion?*

363 Postural sprawl and the use of rotatory limb mechanics has been proposed for grounded non-
364 pterodactyloids from assessments of their limb joint arthrology (e.g. Wellnhofer 1975; Unwin
365 1988, 1999; 2005; Padian 2008b). These suggestions have mostly applied to the forelimbs, but
366 some have suggested that both limbsets were constrained to sprawling stances (Unwin 1988,
367 1999, 2005). Unwin (1988) argued that the *Dimorphodon* femoral-pelvic joint projected the
368 femur anterolaterally and somewhat dorsally when ‘naturally articulated’, while the tibiotarsus
369 was capable of twisting medially at the knee, permitting the foot to face forwards. This is said to
370 allow for semi-erect or sprawling stances, which are in accordance with suggested similarities
371 between the pelves of *Dimorphodon* and the sprawling or semi-erect archosauriform *Euparkeria*

372 *capensis* (Unwin 1988). Computer modelling has also predicted entirely sprawling stances and
373 rotatory gaits for non-pterodactyloids through a digital model of *Rhamphorhynchus* (Fig. 1B;
374 Unwin 2005). The methodology behind this has not been presented, but the resultant digital non-
375 pterodactyloid model ‘Roborhamphus’ shows hindlimbs projecting entirely laterally from the
376 body, similarly-sprawling forelimbs, low clearance from the ground and slow walking speeds
377 (Unwin 2005). The latter is seemingly a consequence of the limited reach afforded by the
378 sprawling limbs.

379

380 There are several reasons to think that the non-pterodactyloid hindlimb did not sprawl. Firstly,
381 the assumption that a ‘natural articulation’ of the hindlimb can be determined from acetabulum
382 and femoral head morphology (Unwin 1988) is problematic. As evidenced by debates over
383 ‘osteological neutral pose’ in fossil animal necks (e.g. Stevens and Parrish 1999, Taylor et al.
384 2009; Taylor and Wedel 2013; Stevens 2013), attempts to determine ‘neutral’ or ‘natural’ poses
385 of animal joints rely on arbitrary assignments of optimal joint configurations which often have
386 little or no significance to typical animal postures (Taylor et al. 2009). It is probably unwise to
387 suggest the hindlimb of *Dimorphodon* sprawled based on acetabulum and femoral head
388 morphology alone.

389

390 Secondly, the pelves of *Dimorphodon* and other early pterosaurs are clearly distinguished from
391 those of *Euparkeria* and other sprawling animals in having a well-developed preacetabular
392 process (Unwin 1988; Hyder et al. 2014). In this respect, non-pterodactyloid pelves resemble
393 those of other ornithodirans – including pterodactyloids - and mammals. These taxa are
394 characterised by erect limbs, the preacetabular process anchoring large hip flexors for moving
395 the hindlimb forward in the parasagittal plane (Hyder et al. 2014), and assessments of pterosaur
396 hindlimb muscle mechanics seem to confirm that the pterosaur pelvic and femoral
397 musculoskeletal system is optimally configured for an erect stance (Fastnacht 2006; Costa et al.
398 2013). Furthermore, while arguments for bipedal, pronograde pterosaurs with parasagittal
399 hindlimbs and digitigrade pedes (Padian 1983a, 1985) have been largely criticised in recent years
400 (e.g. Wellnhofer 1988; Bennett 1997a; Clark et al. 1998; Fastnacht 2005 – also see above),
401 observations that their hip, knee and ankle articulations have hallmarks of upright limb

402 functionality have been borne out by further study (Bennett 1997b; Padian 2008a, b; Fastnacht
403 2005; Costa et al. 2013).

404

405 Thirdly, virtually all recent models of pterosaur evolution suggest taxa with erect hindlimbs
406 bracket non-pterodactyloids, with *Scleromochlus taylori* and non-pterosaurian ornithodirans on
407 one side, and pterodactyloids the other (Sereno 1991; Benton 1999, Hone and Benton 2008;
408 Nesbitt 2011; but also see Bennett 2013). This implicates erect hindlimb postures as probably
409 ancestral for Pterosauria and, given the similarity of their pelvic and hindlimb osteology to their
410 nearest probable relatives, there is little reason to assume non-pterodactyloids deviated from this
411 ancestral state (Bennett 1996b; Padian 2008a; Hyder et al. 2014). It seems that multiple lines of
412 evidence indicate erect hindlimbs across Pterosauria, including all known non-pterodactyloids.
413

414 Relatively little has been said on the stature of non-pterodactyloid forelimbs, however.

415 Traditionally, they have been reconstructed as sprawling. Wellnhofer (1975) observed that the
416 glenoid of *Rhamphorhynchus muensteri* projected laterally and permitted anterodorsal and
417 posteroventral motion of the humerus, but that anterior and posterior motion was limited, and
418 that the humerus could not be adducted below the level of the scapula. Padian (1983a) suggested
419 that the glenoid of *Dimorphodon* permitted a 90° arc of rotation, most of it dorsal to the glenoid,
420 also suggested the shoulder joint of *Dorygnathus* permitted little movement below the frontal
421 plane (Fig. 1C; Padian 2008b). This is said to limit *Dorygnathus* to a sprawling forelimb stance
422 during quadrupedal locomotion which could not match pace with the erect hindlimbs during
423 running, for which bipedality was employed (Padian 2008b). This configuration, which Padian
424 (2003, 2008a) considers typical of all ‘basal pterosaurs’ (presumably non-pterodactyloids), is
425 also thought to limit ventral reach of the forelimb to the extent that bipedal locomotion must be
426 used, as the pectoral region is depressed significantly below that of the hindlimb in a state
427 considered awkward for effective locomotion (Padian 1983b, 2003, 2008a, b). Unwin (2005)
428 showed the digital ‘Roborhamphus’ forelimbs in a sprawling fashion somewhat consistent with
429 these models (Fig. 1B).

430

431 Notions that non-pterodactyloid forelimbs were confined to sprawling stances by their glenoids
432 are based in part on the pectoral girdles of rhamphorhynchine pterosaurs (e.g. Wellnhofer 1975;

433 Padian 2008b). The glenoids of these animals are typified by the isolated, but well-preserved
434 scapulocoracoid of an Oxford Clay rhamphorhynchine, NHMUK R5672 (Fig. 3D-G, I). Here,
435 the glenoid is a laterally prominent structure with a long axis aligned with the base of the
436 scapula. The anterior and posterior ends are bordered by a prominent lower tubercle and
437 supraglenoidal buttress, respectively, between which occurs a deeply-curved, saddle-shaped
438 articular surface. This wraps almost 90° from the lateral face to the dorsal, suggesting ample
439 humeral motion lateral and dorsal to the glenoid. The articular face is anteroposteriorly broadest
440 in its dorsal region and most constrained laterally. The ventral extent of the glenoid is marked by
441 a laterally-projecting ridge between the posterior buttress and anterior tubercle. This ridge is
442 continuous with the lower extent of the scapula, supraglenoidal buttress and lower tubercle so
443 that the ventral face of the glenoid is a wide, flat surface instead of a saddle shaped-joint like that
444 of the dorsal region. As noted by previous authors (e.g. Wellnhofer 1975; Padian 2008a, b), such
445 glenoids clearly did not permit humeral adduction below the level of the scapula, and likely
446 limited fore- and aft-motion of the humerus at maximal adduction. Humeral motion was likely
447 less constrained dorsally, however. Given their marked dorsoventral asymmetry, these glenoids
448 are hereafter referred to as ‘asymmetric’.

449

450 A survey of non-pterodactyloid remains suggests asymmetric glenoids occur in a number of taxa,
451 including the Jurassic rhamphorhynchines *Rhamphorhynchus muensteri* (see numerous examples
452 in Wellnhofer 1975); the recently-named Kimmeridge Clay *Rhamphorhynchus etchesi* (MJML-
453 K1597, O’Sullivan and Martill, 2015); *Dorygnathus banthensis* (GPIT 1645/1, Padian 2008b);
454 and *Sericipterus wucaiwansensis* (IVPP V14725, Andres et al. 2010). They thus appear to be
455 typical for rhamphorhynchines, and further occurrences may occur within Campylognathoididae,
456 including the Triassic *Eudimorphodon ranzii* (MCSNB 2888, Wild 1978), and Jurassic
457 *Campylognathoides liasicus* (SMNS 11879, Padian 2008c). Asymmetric glenoids may be more
458 widely spread across non-pterodactyloids than this, but establishing their frequency is
459 complicated by a deficit of good preservation and frequently unmet requirements for particular
460 scapulocoracoid orientations in flattened specimens. Accordingly, the shape of the glenoid
461 cannot be established for many taxa which may otherwise be considered well-known, such as the
462 Anurognathidae.

463

464 Asymmetric glenoids are not the only shoulder morph of non-pterodactyloids, however: the well-
465 preserved glenoids on *Dimorphodon macronyx* specimens NHMUK R1034 and 41412-13 are
466 rather differently constructed (Fig. 3A-C, H). Although following the same basic configuration
467 as other non-pterodactyloids, these specimens have a larger supraglenoidal buttress which
468 projects further ventrally than the lower tubercle. The dorsal portion of the glenoid articular face
469 is similar to that described above, but the ventral portion wraps onto the underside of the glenoid
470 until it meets the scapula shaft, instead of terminating at an elevated scapular margin. This gives
471 the glenoid a spool- or hourglass-like appearance in lateral view, and presents no obvious
472 restriction to adducting the humerus to a subvertical position. As with the rest of the glenoid, the
473 ventral articular region is widely open anteroposteriorly (although not as much as the dorsal
474 region) and is estimated to permit 90° of anteroposterior humeral rotation beneath the body. This
475 observation contrasts with previous assessments of *Dimorphodon* glenoid morphology, which
476 suggested anatomy and arthrological range akin to the ‘asymmetric’ morph outlined above
477 (Padian 1983b, 2003, 2008b). As demonstrated in Fig. 3H-I, the ventral morphologies and likely
478 arthrological ranges of these glenoids are quite distinct.

479

480 Glenoids like those seen in *Dimorphodon* are hereafter referred to as ‘symmetric’, after their
481 relatively similar dorsal and ventral articular surfaces. It seems such glenoids were rare in non-
482 pterodactyloids: other than *Dimorphodon*, only the wukongopterids *Darwinopterus*
483 *linglongtaensis* (IVPP V16049, Wang et al. 2010) and *Darwinopterus robustodens* (HGM
484 41HIII-0309A; Lü et al. 2011) seem to possess them, although the caveats mentioned above
485 mean this assessment should not be considered definitive. It is notable that some aspects of
486 pterodactyloid glenoids are similar to this ‘symmetric’ condition, including the relatively large
487 supraglenoidal buttress, expansive articular face, and absence of an arthrologically prohibitive
488 ventral margin.

489

490 The two non-pterodactyloid glenoid morphologies identified here have different implications for
491 adoption of sprawling or erect postures. Asymmetric glenoids seem to obligate forelimb
492 sprawling, whereas symmetric glenoids could permit either sprawling or upright limb usage. As
493 noted above, relying on a single joint for insight into animal postures can be misleading, and
494 using only glenoid shape to infer forelimb postures in non-pterodactyloids may be unwise.

495 Additional insights on the stances of these animals are afforded by aspects of their distal humeri,
496 however. The morphology of distal humeri seems characteristic of stance in extant quadrupeds,
497 and has been used to predict sprawling or erect limb carriage in extinct animals (Fujiwara and
498 Hutchinson 2012). This is possible because the size of osteological correlates of wrist flexor and
499 extensor muscles, as well as those of elbow extensors, provide insights into primary mechanical
500 loads placed on the distal humerus and, therefore, an insight into habitual forelimb postures
501 (Fujiwara and Hutchinson 2012). This method, grounded and tested in a biometric dataset of 318
502 living taxa, has obvious utility for fossil species where interpreting limb posture based on
503 arthrology alone can be controversial. Fujiwara and Hutchinson (2012) have already applied
504 their technique to a pterodactyloid (*Anhanguera piscator*) humerus and found it met expectations
505 of animals using an upright posture, agreeing with other predictions made from limb bone
506 arthrology and trackway data for erect forelimb use in pterodactyloids (e.g. Unwin 1996a;
507 Bennett 1997a; Mazin et al. 2003). Fujiwara and Hutchinson (2012) note that their conclusions
508 likely apply to other pterodactyloids, implying that morphological similarity to *Anhanguera*
509 distal humeri (which are broadly similar to those of other pterodactyloids, even accounting for
510 body size, Fig. 4 G-F) in any pterosaurs might suggest similar forelimb use and stance.

511

512 A survey of non-pterodactyloid humeri shows variation in their distal ends that correlate with
513 distinctions in their glenoid shape (Fig. 4). The distal humeri of pterosaurs with asymmetric
514 glenoids possess markedly reduced medial and lateral epicondyles so that, in anterior view, their
515 distal humeri show relatively little expansion from the diaphyseal shafts. For this reason, the
516 palmar aspect of their distal humeri are dominated by the capitula and trochlea (Fig. 4 D-F). This
517 is seen in at least *Rhamphorhynchus* (Wellnhofer 1975) and *Dorygnathus* (SMNS 51827, SMNS
518 50164, see Padian 2008b), and perhaps also *Eudimorphodon* (MCSNB 2888) and
519 *Campylognathoides* (see examples in Padian 2008c), although the flattened, often oblique
520 preservation of humeri in specimens of the latter species prohibits full confidence in this
521 observation (Wild 1978; Padian 2008c). The lack of well-developed lateral and medial
522 epicondyles in these humeri contrasts with the pterodactyloid condition, in which these structures
523 are prominent and the distal humeri are expanded (Fig. 4 G-F). However, the distal humeri of
524 *Dimorphodon* (NHMUK 42016, YPM 350) and the probable wukongopterid
525 *Archaeoistiodactylus linglongtaensis* (JPM04-0008, see Sullivan et al. 2013 for comments on the

526 phylogenetic position of this species) are much more pterodactyloid-like. In these humeri, well-
527 developed lateral and medial epicondyles create a splayed distal termination much broader than
528 either the humeral diaphysis or the combined width of the capitulum and trochlea (Fig. 4 A-C,
529 Padian 1983a; Lü and Fucha 2010). In *Dimorphodon* at least, the medial condyle is also distally
530 displaced compared to the lateral. This results in the distal ends of *Dimorphodon* and
531 wukongopterid humeri being clearly different to those of rhamphorhynchines and
532 campylognathoidids, but morphologically very similar to those of pterodactyloids (Fig. 4 G-I).

533

534 The correlation between these humeral conditions and glenoid morphology is potentially
535 significant. The similarity of *Dimorphodon* and wukongopterid humeri to those of
536 pterodactyloids implies a similar mechanical regime being experienced at the elbow region
537 which, following Fujiwara and Hutchinson (2012) and other studies on pterodactyloid humeral
538 orientation when walking (e.g. Unwin 1996a; Bennett 1997a; Mazin et al. 2003), might indicate
539 the employment of upright stances. As noted above, portions of the symmetric glenoid articular
540 surface project ventrally in a manner expected for animals with erect forelimbs. The large, open
541 junction between the ventral articular surface, lower extent of the supraglenoidal buttress and the
542 lateral face of the scapula seems capable – perhaps even well-suited - to bolstering a fully
543 adducted forelimb for standing and walking. These anatomies raise the possibility of
544 wukongopterids and *Dimorphodon* being capable of erect forelimb postures. If, as noted by
545 Fujiwara and Hutchinson (2012), pterodactyloid-like distal humeri correlate with an upright
546 forelimb stance, such postures may even be likely. In any case, the assumption that sprawling
547 forelimbs were common to all non-pterodactyloids clearly warrants further investigation.

548 Moreover, the possibility that some early pterosaurs could fully adduct their humeri suggests that
549 reaching the ground in a quadrupedal stance may not have been difficult, as has been proposed
550 (Padian 1983b; 2008a, b).

551

552 The humeral morphology in rhamphorhynchine and campylognathoidid non-pterodactyloids
553 differs from those seen in erect-limbed pterodactyloids (Fujiwara and Hutchinson 2012) and also
554 suits their glenoid morphology. Asymmetric glenoids seem to prohibit humeral adduction into an
555 erect stance, and it would be predicted that correlates for a different set of forelimb muscles –
556 likely those suited to sprawling - would be emphasised at the distal humerus compared to those

557 seen in pterodactyloids. Lack of indications of erect poses suggests these pterosaurs fit
558 ‘traditional’ models of sprawling forelimbs in non-pterodactyloids (e.g. Wellnhofer 1975; Unwin
559 2005; Padian 2008b). It might be predicted that their stance and walking gaits required relatively
560 little wrist motion, as evidenced by their weakly developed epicondyles for muscle attachment
561 related to carpal operation.

562

563 Discussion

564 *Other indications of terrestrial competency in non-pterodactyloids*

565 The possibility that some non-pterodactyloids were capable of fully upright stances, and
566 unconstrained during terrestrial locomotion by their membranes, might have broad implications
567 for our perception of their palaeobiology and role in pterosaur evolutionary history. Note,
568 however, that these are not the only aspects of early pterosaur anatomy indicating greater
569 terrestrial potential than previously anticipated.

570

571 It has been suggested that non-pterodactyloid limbs are too short and slender for effective
572 terrestrial locomotion (Fig. 5, Ósi 2011). This is probably an over-generalisation: early pterosaur
573 anatomy is quite disparate in many respects (Witton 2013). Several well-known taxa do possess
574 short and/or slender limbs (e.g. Fig. 5E-F), but Triassic and Jurassic taxa such as *Dimorphodon*,
575 anurognathids and *Preondactylus bufarinii* possess long, robust, and near-equally sized limbs
576 with well-developed extremities (Fig. 5A-D; Owen 1870; Dalla Vecchia 1998; Bennett 2007;
577 Padian 2008a). Indeed, the limbs of some non-pterodactyloids are more substantially developed
578 and proportionate than those of seemingly terrestrially-competent pterodactyloids, such as
579 azhdarchids (Witton and Naish 2008). It has been noted that several early pterosaur hindlimb
580 skeletons possess features of subcursoriality (Padian 1983b; 2003, 2008a, b), and this is also true
581 of their forelimbs. Subcursorial features include long limbs relative to their bodies, joints with
582 hinge-like mobility, short and massive propodia, slender and distally reduced/fused fibulae,
583 digitigrade manus and elongate metapodia (see Coombs 1978, p. 399 and 402). It bears repeating
584 that the limbs of pterosaurs – including those of non-pterodactyloids - have been frequently
585 identified as powerfully muscled and strongly built for leaping and flying (Padian 1983a, b,
586 2003; 2008a, b; Bennett 1997b; Fastnacht 2005; Habib 2008; Witton and Habib 2010), and were
587 therefore likely capable of supporting some grounded activity, perhaps even sustained and

588 energetic terrestrial behaviours. It is likely that the slender, disproportionate limbs of some better
589 known non-pterodactyloids such as *Rhamphorhynchus* have biased opinions on the terrestrial
590 ability non-pterodactyloids as a whole: considered independently, the long, proportionate and
591 robust limbs of genera such as *Dimorphodon*, anurognathids and *Preondactylus* might be
592 considered well-suited to terrestrial locomotion.

593

594 The digits of several non-pterodactyloid species are also adorned with features which may betray
595 routine terrestrial habits: antungual sesamoids (Fig. 6). These small, round bones are situated on
596 the dorsal surfaces of the penultimate manual phalanges of many Triassic and Lower Jurassic
597 pterosaur specimens, including the Triassic taxa *Eudimorphodon ranzii* (MCSNB 2888),
598 *Carniadactylus rosenfeldi* (MFSN 1797), *Peteinosaurus zambellii* (MCSNB 2887), the
599 “*Eudimorphodon*” specimen MCSNB 8950, the “*Peteinosaurus*” specimen MCSNB 3359 (Wild
600 1978, 1994; Dalla Vecchia 2009) as well as the Jurassic pterosaurs *Dorygnathus* (e.g. Fig. 6C,
601 BSP 1938 I 49; see also Padian 2008b) and *Dimorphodon* (Fig. 6A, NHMUK 41212; NHMUK
602 R1034; see Padian 1983a, Unwin 1988). *Dimorphodon* is unusual in also bearing pedal
603 antungual sesamoids, spreading their distribution across all clawed digits (Fig. 6B, GSM 1546;
604 Unwin 1988). Antungual sesamoids are present in an osteologically immature specimen of
605 *Eudimorphodon* (MPUM 6009; Wild 1978), suggesting they are not just confined to gerontic,
606 well-ossified adults.

607

608 Pterosaur antungual sesamoids are consistently preserved dorsally adjacent to the articular
609 condyles of penultimate phalanges and were presumably situated within the tendons of the digit
610 extensors (Bennett 2008). Their function has not been explored in detail, but two studies (Unwin
611 1988 and Bennett 1997b) cite them as part of a suite of characters important to pterosaur
612 grasping and climbing capabilities. Anatomies related to grasping and climbing are relatively
613 well explored (see Sustaita et al. 2013 for a recent review) but, to this author’s knowledge,
614 extension of the ungual is not generally associated with this behaviour. An exception might be
615 climbing geckos, which retract adhesive pads situated on the distal ends of their digits before
616 each step (Zaaf et al. 1999; Russel and Higham 2009). However, these geckos famously adhere
617 themselves to substrates via manipulation of molecular forces, not with claws, and their climbing
618 methods are unlikely to mirror those used by pterosaurs.

619

620 Antungual sesamoids are currently only known from three tetrapod groups: pterosaurs, and
621 terrestrial reptiles: several squamate lineages (Haines 1969; Jerez et al. 2009; Otero and Hoyos
622 2013) and the semiaquatic ‘bottom walking’ Triassic turtle *Proganochelys* (Gaffney 1990).
623 Gaffney (1990) proposed that antungual sesamoids confer functions typical of other reptile
624 sesamoids: increasing tendon moment arm lengths around joints, ensuring nutrient delivery to
625 tendons by limiting strain or pressure on joints articulated to their extremes (Haines 1969), or
626 strengthening tendons (Nussbaum 1982). High mechanical stresses on the dorsal side of
627 phalangeal-ungual joints seem to be the most likely catalyst for antungual sesamoid
628 development. Perhaps the only shared functional attributes between pterosaurs, squamates and
629 *Proganochelys* are large unguals and the potential to walk on firm substrates. It may be that these
630 two factors alone can account for antungual sesamoid development. One possibility is that
631 deflection of large, curving unguals by hard surfaces induce pressure on the extensor tendon,
632 promoting the development of a sesamoid to maintain tendon nutrient flow during sustained
633 bouts of standing and walking (Fig. 6Dii). Alternatively, deliberate hyperextension of claws may
634 promote antungual sesamoid development as means to increase the extensor tendon moment
635 arm, and thus improve efficiency of claw retraction (Fig. 6Diii). It is notable that pterosaurs with
636 antungual sesamoids possess expanded, deeply grooved penultimate phalangeal terminations and
637 large ungual extensor tubercles (Fig. 6A-C), similar to the phalanges of animals with
638 hyperextensible digits, such as cats, dromaeosaurids and schizotherine chalicotheres (Coombs
639 1983; Gonyea and Ashworth 1975; Parsons and Parsons 2009). By contrast, pterosaurs lacking
640 antungual sesamoids have relatively small, weakly developed phalangeal-ungual joints (e.g.
641 Wellnhofer 1975; Clark et al. 1998), suggesting limited potential for hyperextension. Ungual
642 hyperextension has evolved repeatedly within terrestrial tetrapods to avoid claw blunting (e.g.
643 Gonyea and Ashworth 1975; Coombs 1983) or to release strong grips, as demonstrated by many
644 modern geckos which, when walking, retract the ends of their digits before each step (Zaaf et al.
645 1999; Russel and Higham 2009): the possibility it occurred in pterosaurs is not unreasonable.
646 Indeed, claw retraction has been proposed as an explanation for the lack of ungual traces in some
647 pterodactyloid ichnites (Frey et al. 2003).

648

649 These hypotheses share frequent ungual interaction with hard substrates as the chief adaptive
650 pressure for antungual sesamoid development. Sustained activity in terrestrial settings is perhaps
651 the most likely cause of this interaction, and congruent with the seemingly-exclusive
652 development of antungual sesamoids in terrestrialised taxa such as squamates and
653 *Proganochelys*. If antungual sesamoids do represent such adaptations, their development in non-
654 pterodactyloids may represent further evidence of terrestrial habits in early pterosaurs.

655

656 *The terrestrial proficiency of early pterosaurs*

657 The considerations of early pterosaur limb and limb girdle functions offered here suggest views
658 of non-pterodactyloid palaeobiology may warrant more detailed consideration. Existing models
659 of pterosaur locomotory mechanics, where pterodactyloids are adaptable, ‘terrestrialised’
660 pterosaurs and their forebears were confined to climbing and flying, are perhaps over-simplistic.
661 Not only are common arguments for terrestrially-inept early pterosaurs problematic, but
662 anatomies consistent with fully erect stances and other possible hallmarks of competent
663 terrestriality seem to be deeply nested within Pterosauria. These findings are the latest in a series
664 showing that pterosaur palaeobiology is much richer, more diverse and complex than previously
665 anticipated (see Witton 2013 for an overview).

666

667 Assessing the evolutionary pathways of the anatomies described here is complicated by the lack
668 of consensus over non-pterodactyloid phylogeny (Unwin 2003; Kellner 2003; Wang et al. 2009;
669 Kellner 2010; Dalla Vecchia 2009; Lü et al. 2010, 2012; Witton 2013; Andres and Meyers 2013;
670 Andres et al. 2014). Some tentative conclusions may be drawn, however. The distribution of
671 glenoid and humeral morphologies identified above is complicated, with no set of features
672 limited to specific clades or ‘grades’ of pterosaurs (Fig. 7). Potential signatures of erect postures
673 appear early in pterosaur evolution: *Dimorphodon* indicates that symmetric glenoids and
674 pterodactyloid-like humeral features had developed by the Sinemurian at the latest, and
675 pterosaurs with elongate, robust limbs (e.g. *Peteinosaurus*, “*Eudimorphodon*” specimen MCSNB
676 3359, *Preondactylus*) represent some of the oldest known pterosaurs (Carnian/Norian). Given
677 that likely pterosaur outgroups such as dinosauromorphs and *Scleromochlus* bore strong, erect
678 limbs (e.g. Sereno 1991; Benton 1999), it is possible that these early pterosaurs retained
679 characteristics of efficient terrestriality from immediate pterosaur ancestors. This might be in

680 keeping with models of pterosaurs evolving from terrestrially- or scansorially-adapted ancestors
681 in inland environments (Padian 1985, 2008a; Bennett 1997b; Witton 2013; Andres et al. 2014),
682 before spreading to marine habitats (Andres et al. 2014). Taxa likely utilising sprawling
683 forelimbs tend to occur further from the pterosaur root however, suggesting this ‘traditional’
684 stance might be a derived feature of clades such as Rhamphorhynchinae and
685 Campylognathoididae, and perhaps associated with the development of increasingly pelagic
686 lifestyles (see below).

687

688 How the development of these features relates to possible evidence for fully erect limbs in the
689 pterodactyloid sister group, Wukongopteridae, is intriguing. Their Callovian/Oxfordian (Lü et al.
690 2010) appearance in the fossil record approximates the appearance of pterosaur footprints as well
691 as the first pterodactyloids (Andres et al. 2014), making questions about distinguishing
692 pterodactyloid tracks from those of non-pterodactyloids all the more pertinent (Lockley et al.
693 2008). Were wukongopterids involved in an upper Jurassic ‘terrestrial radiation’ of pterosaurs,
694 and was this part of a separate ‘terrestrialisation event’ to that potentially indicated by earlier,
695 *Dimorphodon*-like pterosaurs? Do wukongopterids represent a lineage of pterosaurs which
696 retained plesiomorphic glenoid and humeral morphologies from much earlier pterosaurs, or were
697 these reversed from sprawling ancestors? Future discoveries of Jurassic and Triassic pterosaurs
698 in terrestrial basins and further resolution on the phylogeny of early pterosaurs may shed light on
699 these questions.

700

701 Concerning the specifics of terrestrial locomotion in different non-pterodactyloid taxa: the view
702 of early pterosaurs as forelimb-sprawling terrestrial locomotors (e.g. Wellnhofer 1975; Padian
703 2008b) seems appropriate for at least rhamphorhynchines and campylognathoidids (Fig. 8A),
704 although how limiting their sprawled or crouched forelimbs were to walking and running
705 remains to be determined. Padian’s (1983b, 2008a, b) suggestion that the torsos of quadrupedal
706 pterosaurs with sprawling forelimbs would be anteriorly inclined, and thus ill-suited to terrestrial
707 locomotion, is questionable. As demonstrated by the alternative reconstructions of such
708 pterosaurs provided in Fig. 5, torso inclination seems reliant on assumptions made when
709 restoring pterosaur skeletons – such as enhancement of hindlimb height through elevated
710 (digitigrade) ankles (compare Fig. 5E-F with Padian’s 2008b *Dorygnathus* illustration in Fig.

711 1C). In any case, the fact that numerous fossil and extant quadrupedal animals have anteriorly-
712 sloping backs and variable limb girdle heights when standing and walking (examples include
713 protorosaurs, modern and fossil crocodylomorphs, several dinosaur clades (diplodocoids,
714 stegosaurids, ceratopsids), and many small mammals lagomorphs, rodents, certain bats)
715 questions what significance this observation has on terrestriality. Other views that sprawling
716 gaits are inherently ‘primitive’ or inferior to erect ones, or somehow limit movement speed
717 (Unwin 2005) are problematic, as demonstrated by the tremendous success of sprawling
718 tetrapods both today and in Deep Time (Russell and Bels 2001). Although perhaps ill-suited to
719 sustained terrestrial locomotion, sprawling can be an effective, perhaps superior locomotory
720 kinematic for rapid acceleration, sprinting and climbing (Russell and Bels 2001). Indeed,
721 specialist lifestyles promote the retention or development of sprawling limbs in many species
722 (McElroy et al. 2008). Thus, the sprawling forelimbs of rhamphorhynchines and
723 campylognathoidids are not necessarily means to assume low terrestrial competency, and
724 arguments that sprawling pterosaurs would be limited to slow, ponderous locomotion do not
725 reflect the sometimes explosive and powerful abilities of modern sprawling amphibians, reptiles
726 and mammals (contra. Unwin 2005, Padian 2008b). Note that the limbs of galloping vampire
727 bats are sprawled (Riskin et al. 2006), a fact worth considering when arguing that
728 rhamphorhynchines and campylognathoidids required bipedal stances for rapid terrestrial
729 movement (e.g. Padian 2008b, c).

730

731 Nevertheless, because sustained terrestrial locomotion seems better served by erect limbs, the
732 indication that rhamphorhynchines and campylognathoidids had sprawling forelimbs might be
733 consistent with predictions that these pterosaurs were relatively flight-reliant, seabird-like
734 species (see functional and palaeoecological evidence discussed by Wellnhofer 1975; Wild 1978;
735 Chatterjee and Templin 2004; Witton 2008, 2013, etc.). Like some seabirds, these pterosaurs
736 may have relied on flight for long-distance movement rather than terrestrial locomotion, and
737 their anatomy may reflect adaptive biases towards the former (e.g. Kaiser 2007; Abourachid and
738 Höfling 2012). For instance, parallels may be drawn between the restricted shoulder arthrology
739 of asymmetric glenoids and the energy-saving arthrological ‘locks’ found in the shoulders of
740 modern soaring birds (e.g. Meyers and Stakebake 2005). If antungual sesamoids are, as proposed
741 here, indicators of routine claw interaction with the ground, their presence in *Dorygnathus*,

742 *Carniadactylus* and *Eudimorphodon* still suggest frequent terrestrial activities however. It may
743 be that these pterosaurs routinely landed to forage or roost but performed only limited walking or
744 running activities when grounded, while other habits – perhaps hanging or climbing –
745 necessitated large, trenchant claws and associated sesamoids. The sprawling stance of their
746 forelimbs is well suited to climbing behaviour (Russell and Nels 2001), as are the particularly
747 large and robust third manual digits of *Dorygnathus* (Fig. 6C; Padian 2008b)

748

749 With symmetrical glenoids and pterodactyloid-like distal humeri, it is possible *Dimorphodon* and
750 wukongopterids could utilise fully upright gaits and had pterodactyloid-like terrestrial
751 capabilities. *Dimorphodon* particularly embodies many ‘subcursorial’ features (long, robust
752 limbs; stout propodia, reduced fibulae, etc.) and it may have been capable of not only sustained,
753 but also relatively fast terrestrial activity (Fig. 8B). Especially well-developed appendages and
754 possession of antungual sesamoids on all clawed digits might signify that *Dimorphodon* was not
755 unduly reliant on flight, as do data suggesting it was particularly heavy for its wingspan and a
756 relatively ineffective, perhaps short-distance flier (Brower and Veinus 1980; Witton 2008, 2013,
757 in prep.; Henderson 2010). Scansorial features of the *Dimorphodon* skeleton (e.g. elongate
758 penultimate phalanges, asymmetrical pes structure, claw curvature – see Unwin 1988, Clark et
759 al. 1998; Witton 2013) marry with conclusions drawn here to present it as a terrestrial generalist,
760 capable of running, walking and climbing as well as flight. Many extant terrestrial animals with
761 mobile limb joints and long limbs - such as rodents, bovids, carnivorans, etc. – are as adept at
762 climbing as they are walking and running, to the extent that some measures of their
763 ecomorphospace overlap significantly with scansorial animals (e.g. Samuels et al. 2013): the
764 identification of climbing adaptations in some early pterosaurs does preclude terrestrial
765 proficiency. The suggested diet of insects and small vertebrates for *Dimorphodon*, based on its
766 skull morphology, tooth shape and dental wear patterns (Ösi 2010), is concordant with generally
767 terrestrial habits (Fig. 8B). Wukongopterid pterosaurs may have also been capable terrestrial
768 locomotors, although their limbs are not as powerfully built as those of *Dimorphodon* and some
769 aspects of their flight anatomy, such as their pteroids, are more substantially developed (Witton
770 2013). Like many small modern birds, wukongopterids may have been proficient enough to
771 move through terrestrial settings without flight – perhaps in search of insect prey (Lü et al. 2011;
772 Witton 2013) – but seem more aerially capable and flight-ready than the heavyset *Dimorphodon*.

773

774 Concluding remarks

775 The assessment of non-pterodactyloid terrestrial locomotion offered here demonstrates that our
776 understanding of functionality and locomotory mechanics in early pterosaurs is limited to the
777 extent that basic differences in limb skeleton construction have yet to be noted in detail. It is
778 hoped this work will inspire further investigation into the functionality of these animals. As here,
779 such studies will likely be hampered by the quality of non-pterodactyloid fossils, where even
780 complete specimens can be too extensively crushed or poorly preserved to show the anatomies
781 needed for functional interpretation. However, there is clearly greater potential for understanding
782 early pterosaur functionality than currently realised and, until this has been researched more
783 thoroughly, caution is urged against making generalisations about the terrestrial competency of
784 non-pterodactyloids, and its role in the evolution of Pterosauria.

785

786 Acknowledgements

787 Lorna Steel and Sandra Chapman are thanked for repeated access to specimens in their care and
788 for assistance obtaining literature. Michael Habib, Luis Chiappe and an anonymous referee are
789 thanked for providing comments on this work, as are Hans Thewissen, Peter Binfield and Matt
790 Wedel for their editorial contributions. David Martill, Liz Martin and Michael O'Sullivan are
791 thanked for discussions of early pterosaur functionality. David Hone, Ross Elgin, David Unwin
792 and Calum Davies are thanked for sharing excellent photographs of German and Chinese
793 pterosaur specimens.

1091 Figure 1. Select hypotheses for non-pterodactyloid poses made in the last 35 years. A, Padian's
 1092 (1983a) bipedal *Dimorphodon macronyx*; B, redrawn lateral view of the 'Roborhamphus' model
 1093 discussed by Unwin (2005); C, quadrupedal *Dorygnathus banthensis* with sprawling forelimbs,
 1094 reversed from Padian (2008b).

1095
 1096 Figure 2. Pterosaur and bat uroptagia compared. A, line drawing of hindlimb region of *Sordes*
 1097 *pilosus* specimen PIN 2885/3, showing extensive, toe-supported uroptagium (dark shading) and
 1098 associated brachiopatagia (light shading); B, skeletal reconstruction of *Rhamphorhynchus*
 1099 *muensteri* showing distribution of membranes in non-pterodactyloid pterosaurs based on fossil
 1100 remains (see Elgin et al. 2011); C, line drawing of hanging common vampire bat *Desmodus*
 1101 *rotundus*, a terrestrially-competent species with an extensive uroptagium analogous to those of
 1102 non-pterodactyloid pterosaurs. Note *Desmodus* has a small uroptagium compared to other,
 1103 terrestrially-adept bat species. Scale bar of A represents 10 mm, other images not to scale.

1104 Abbreviations: Brachio, brachiopatagium; CV, caudal vertebrae; Ep, epiphysis, Fem, femur; Fib,
 1105 fibula; Pel, pelvis; Pro, propatagium; Ta, tarsals; Tib, tibia; Uro, uroptagium; WP, wing phalanx
 1106 (numerals denote phalanx number); i-v denote pedal digit numbers. A, modified from Unwin and
 1107 Bakhurina 1994; B, modified from Witton 2013; C, redrawn from photograph in Nowark 1994.

1108

1109 Figure 3. Non-pterodactyloid glenoid morphology. A-C, line drawings of NHMUK R1034
 1110 *Dimorphodon macronyx* left scapulocoracoid in anterodorsal (A), lateral (B) and ventrolateral
 1111 (C) aspect; D-G, NHMUK R5672, indeterminate rhamphorhynchine right scapulocoracoid in
 1112 dorsal (D), ventral (E), lateral (F) and anterior (G) aspects; H, photograph of the NHMUK R1034
 1113 glenoid ('symmetric' morph), in posteroventral aspect; I, photograph of NHMUK R5672
 1114 ('asymmetric' morph) in posteroventral aspect; J, schematic reconstruction of a non-
 1115 pterodactyloid torso with a symmetric (i) and asymmetric (ii) glenoid conditions, where green
 1116 shading approximates articulatory range of the humerus in the vertical plane based on extent of
 1117 articular surface. Scapulocoracoids in J reconstructed based on specimens illustrated herein and
 1118 models of pectoral anatomy presented for other early pterosaurs (Wellnhofer 1975; 1991;
 1119 Bennett 2003). Note this is only approximate for *Dimorphodon* because its sternum remains
 1120 unknown. ac, acromion process; ar, articular face of glenoid; cor, coracoid, lt, lower tubercle; sc,

1121 scapula; sb, supraglenoidal buttress. Scale bars represent 10 mm. J, modified from Wellnhofer
1122 (1991).

1123

1124 Figure 4. Pterosaur humeri in anterior view, showing development of lateral and medial
1125 epicondyles adjacent to the capitula and trochleae (shaded grey) in non-pterodactyls (A-F)
1126 and pterodactyls (G-I). A, NHMUK 42016, *Dimorphodon macronyx*; B, YPM 350 F, *Di.*
1127 *macronyx*; C, JPM04-0008, *Archaeoistiodactylus linglongtaensis*; D, Wellnhofer's (1975)
1128 *Rhamphorhynchus muensteri* humerus; E, SMNS 51827, *Dorygnathus banthensis*; F, SMNS
1129 50164, *Do. banthensis*; G, YPM 1164, *Pteranodon* sp; H, MOR 691, *Montanazhdarcho minor*; I,
1130 IVPP V.2777, *Dsungaripterus weii*. Note the relatively poorly developed epicondyles in D-F,
1131 and how the distal humeri of A-C resemble those of pterodactyls more than other non-
1132 pterodactyls. Ca, capitulum; LE, lateral epicondyle; ME, medial epicondyle; Tr, trochlea.
1133 Scale bars represent 10 mm, except for G and H, which equal 50 mm. B, after Padian (1983a); D,
1134 after Wellnhofer (1975); E, after Padian (2008b); G, modified from Bennett (2001); H, after
1135 McGowen et al. (2002); I, after Young (1964). D, E and H are reversed from their sources to
1136 enhance comparability.

1137

1138 Figure 5. Are non-pterodactyls ubiquitously equipped with short, slender limbs? Skeletal
1139 reconstructions of taxa such as *Preondactylus bufarini* (A), *Dimorphodon macronyx* (B) and
1140 *Anurognathus ammoni* (C and D, in erect and crouched poses respectively, acknowledging the
1141 poorly known glenoid condition of anurognathids) show they have proportionally long, robust
1142 limbs. Only some non-pterodactyls, including the Early Jurassic campylognathoidid
1143 *Campylognathoides liasicus* (E) and Late Jurassic rhamphorhynchine *Rhamphorhynchus*
1144 *muensteri* (F) have proportionally short and slender hindlimbs. *Preondactylus* has been
1145 reconstructed with erect forelimbs based on its grossly similar humeral morphology to
1146 *Dimorphodon*, although it remains to be established that this similarity extends to more detailed
1147 forelimb anatomy. Scale bars represent 100 mm, except for C and D, which represent 50 mm.
1148 Skeletal reconstructions modified from Witton (2013).

1149

1150 Figure 6. Antungual sesamoids in pterosaurs. A, manus and pes of NHMUK 41212
1151 *Dimorphodon macronyx*; B, partial pes skeleton of GSM 1546 *Di. macronyx*; C, manus of BSP

1152 1938 I 49 *Dorygnathus banthensis*; D, proposed interactions of pterosaur unguals with hard
1153 substrates, and utilisation of antungual sesamoids (extensor tendon shown in grey shading). Di,
1154 terminal phalanges of *Dimorphodon* manual digit 2 show as resting on a hard substrate without
1155 loading; Dii, passive hyperextension of the ungual, where pulling or depressing the phalanges
1156 (force vectors shown with arrows) retract the ungual to contact the sesamoid; Diii, active
1157 hyperextension of the ungual, where the extensor tendon is pulled to clear the ungual tip of the
1158 ground using the additional lever arm length afforded by the sesamoid. A-C, shading and
1159 numbers denote identification of clawed digits (Arabic numerals for manual digits, unary for
1160 pedal). Some skeletal elements present on the illustrated specimens are omitted for clarity. mc1-
1161 3, metacarpals 1-3; mt1-4, metatarsals 1-4; mt5, metatarsal 5; pd v, pedal digit 5; r, dorsal rib; s,
1162 sesamoids; wmc, wing metacarpal; wp, wing finger proximal phalanx. Scale bars represent 10
1163 mm.

1164 Figure 7. Complex distribution of characteristics linked to terrestrial capabilities in non-
1165 pterodactyloids in a simplified pterosaur phylogeny (based on Lü et al. 2012). Other pterosaur
1166 phylogenies suggest different arrangements of non-pterodactyloid taxa (see text for details), but
1167 the distribution of these characteristics would be as complex, if not more so, in competing
1168 arrangements.

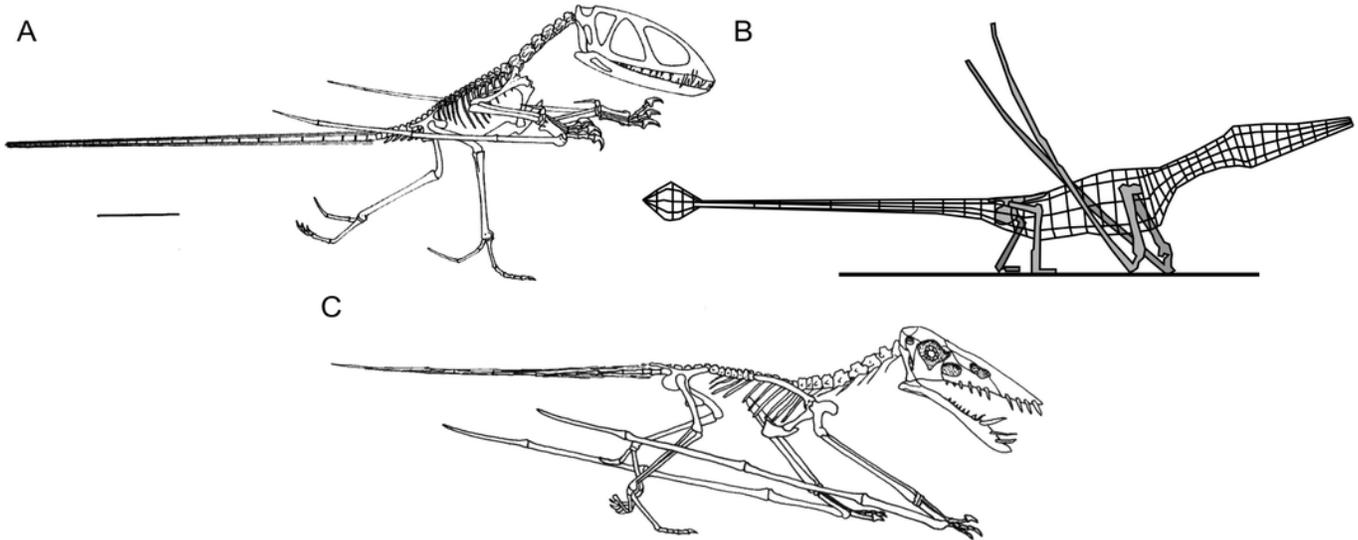

1169

1170 Figure 8. Potential variation in terrestrial locomotion gait in non-pterodactyloid pterosaurs. A,
1171 life restoration of the Early Jurassic rhamphorhynchine *Dorygnathus banthensis* with obligated
1172 crouching, somewhat sprawled forelimbs; B, life restoration of the Early Jurassic *Dimorphodon*
1173 *macronyx* with fully adducted humeri and completely erect gait, shown here facilitating
1174 subcursorial, rapid terrestrial locomotion in pursuit of sphenodontian prey. Both animals are
1175 restored with retracted claws on digits possessing antungual sesamoids.

Select hypotheses for non-pterodactyloid poses made in the last 35 years

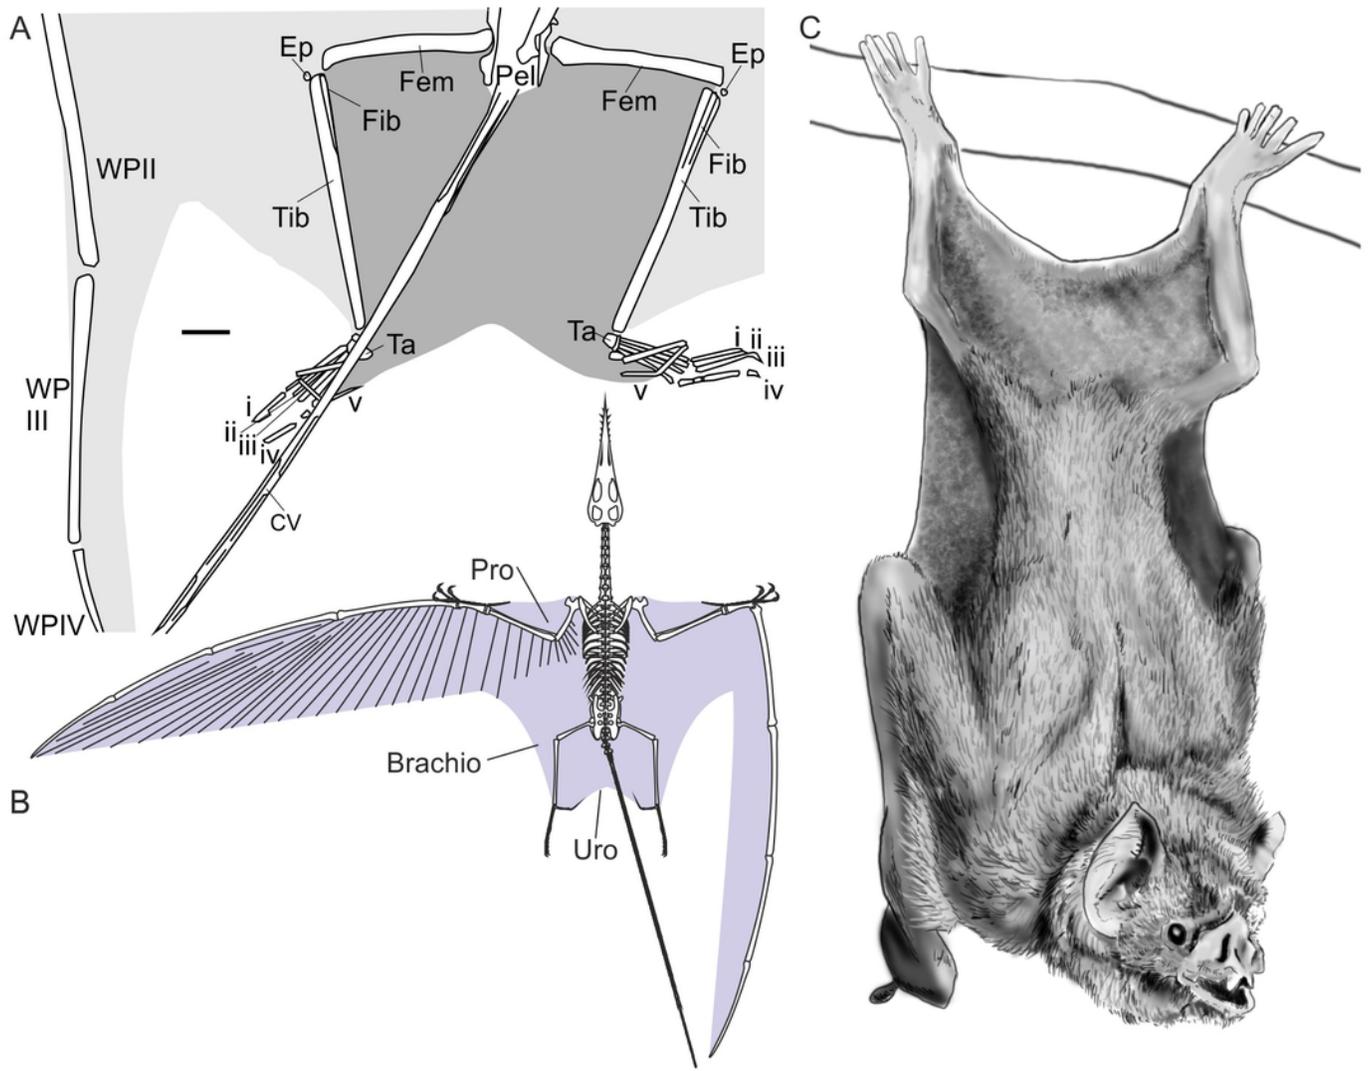

Figure 1. Select hypotheses for non-pterodactyloid poses made in the last 35 years . A, Padian's (1983a) bipedal *Dimorphodon macronyx*; B, redrawn lateral view of the 'Roborhamphus' model discussed by Unwin (2005); C, quadrupedal *Dorygnathus banthensis* with sprawling forelimbs, reversed from Padian (2008b).

2

Pterosaur and bat uropatagia compared

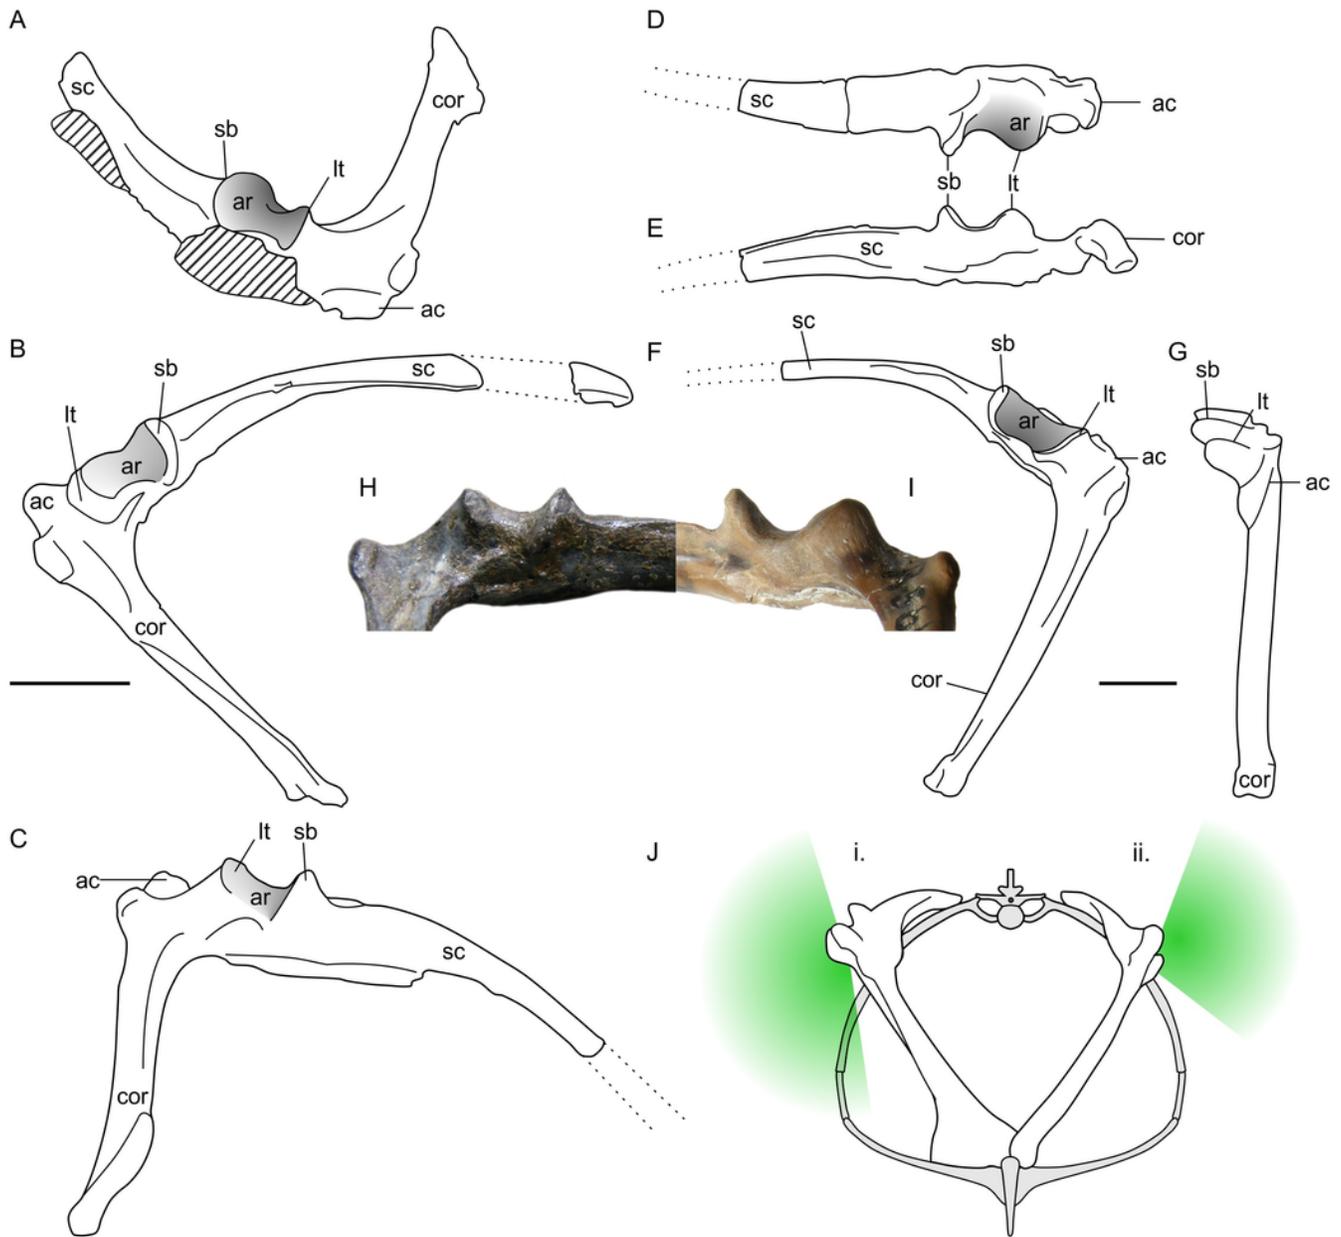

Figure. 2. Pterosaur and bat uropatagia compared. A, line drawing of hindlimb region of *Sordes pilosus* specimen PIN 2885/3, showing extensive, toe-supported uropatagium (dark shading) and associated brachiopatagia (light shading); B, skeletal reconstruction of *Rhamphorhynchus muensteri* showing distribution of membranes in non-pterodactyloid pterosaurs based on fossil remains (see Elgin and Hone 2011); C, line drawing of hanging common vampire bat *Desmodus rotundus*, a terrestrially-competent species with an extensive uropatagium analogous to those of non-pterodactyloid pterosaurs. Note *Desmodus* has a small uropatagium compared to other, terrestrially-adept bat species. Scale bar of A represents 10 mm, other images not to scale. Abbreviations: Brachio, brachiopatagium; CV, caudal vertebrae; Ep, epiphysis, Fem, femur; Fib, fibula; Pel, pelvis; Pro, propatagium; Ta, tarsals; Tib, tibia; Uro, uropatagium; WP, wing phalanx (numerals denote phalanx number); i-v denote pedal digit numbers. A, modified from Unwin and Bakhurina 1994; B, modified from Witton 2013; C, redrawn from photograph in Nowark 1994. _

3

Non-pterodactyloid glenoid morphology

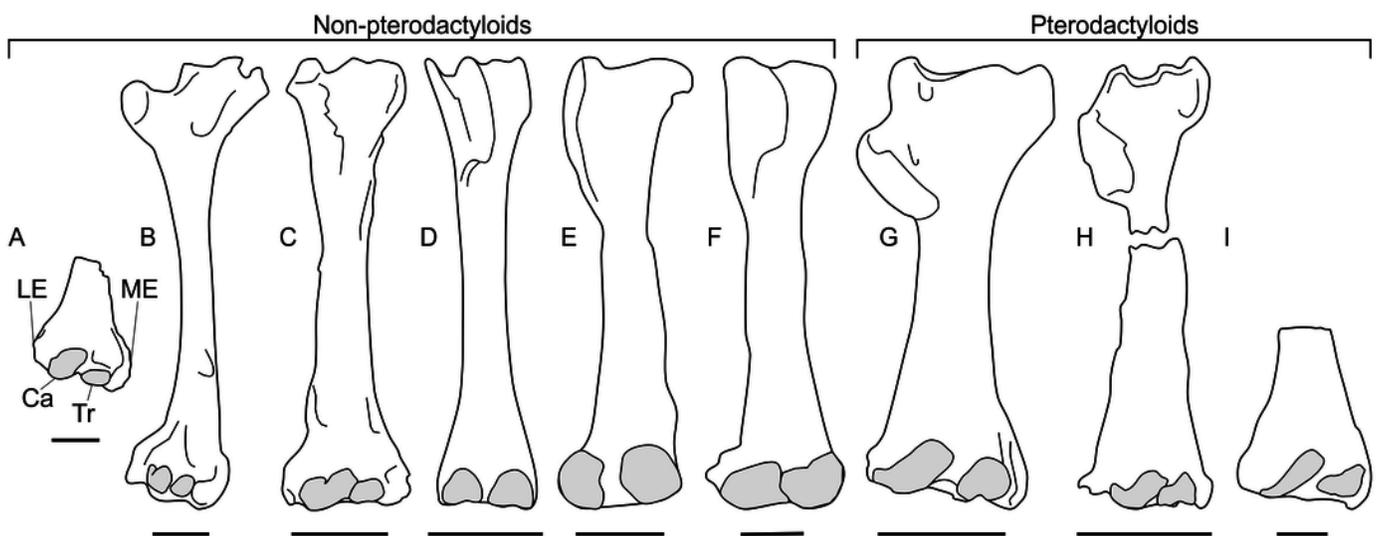

Figure 3. Non-pterodactyloid glenoid morphology. A-C, line drawings of NHMUK R1034 *Dimorphodon macronyx* left scapulocoracoid in anterodorsal (A), lateral (B) and ventrolateral (C) aspect; D-G, NHMUK R5672, indeterminate rhamphorhynchine right scapulocoracoid in dorsal (D), ventral (E), lateral (F) and anterior (G) aspects; H, photograph of the NHMUK R1034 glenoid ('symmetric' morph), in posteroventral aspect; I, photograph of NHMUK R5672 ('asymmetric' morph) in posteroventral aspect; J, schematic reconstruction of a non-pterodactyloid torso with a symmetric (i) and asymmetric (ii) glenoid conditions, where green shading approximates articular range of the humerus in the vertical plane based on extent of articular surface. Scapulocoracoids in J reconstructed based on specimens illustrated herein and models of pectoral anatomy presented for other early pterosaurs (Wellnhofer 1975; 1991; Bennett 2003). Note this is only approximate for *Dimorphodon* because its sternum remains unknown. ac, acromion process; ar, articular face of glenoid; cor, coracoid, lt, lower tubercle; sc, scapula; sb, supraglenoidal buttress. Scale bars represent 10 mm. J, modified from Wellnhofer (1991).

4

Pterosaur humeri in anterior view

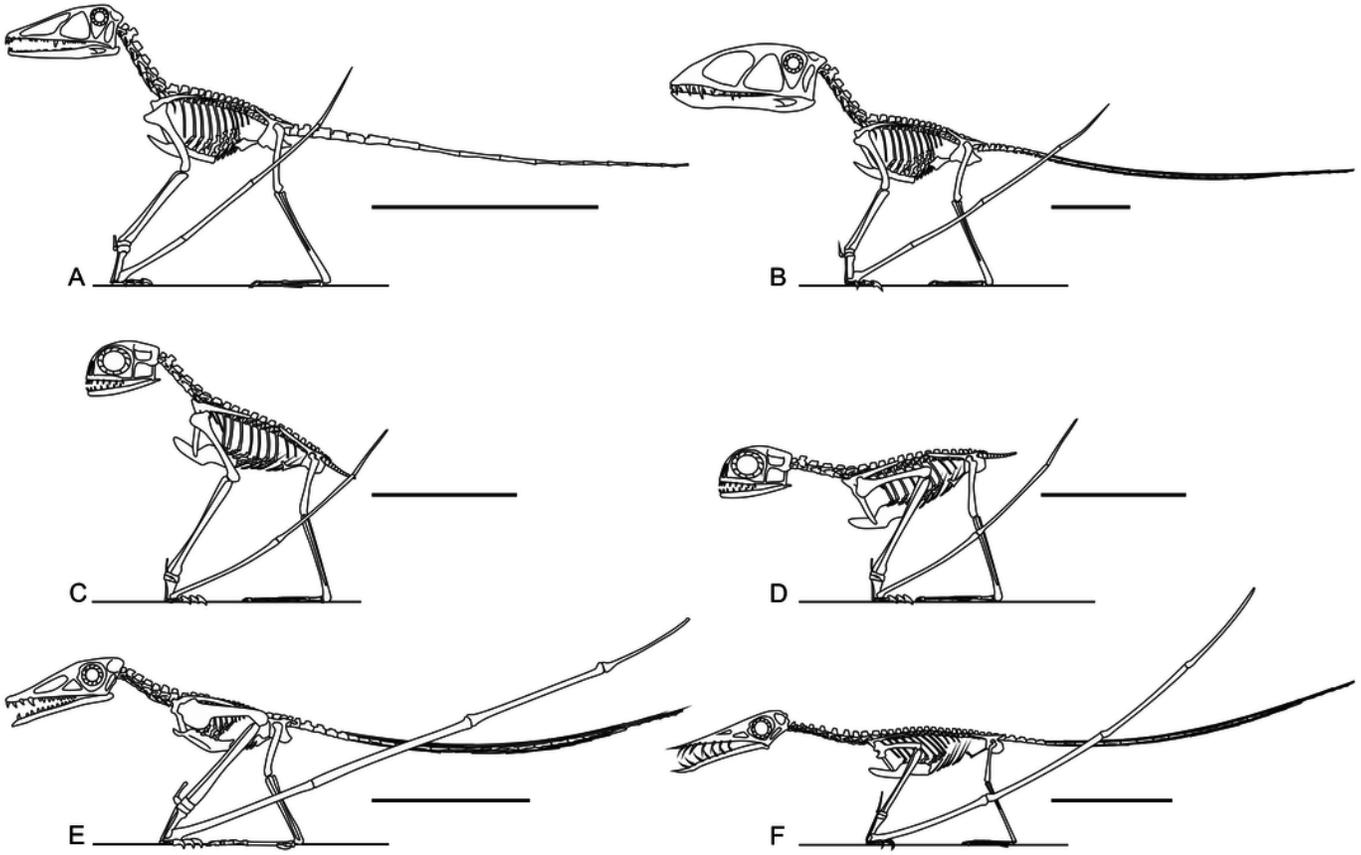

Figure 4. Pterosaur humeri in anterior view, showing development of lateral and medial epicondyles adjacent to the capitula and trochleae (shaded grey) in non-pterodactyloids (A-F) and pterodactyloids (G-I). A, NHMUK 42016, *Dimorphodon macronyx*; B, YPM 350 F, *Di. macronyx*; C, JPM04-0008, *Archaeoistiodactylus linglongtaensis*; D, Wellnhofer's (1975) *Rhamphorhynchus muensteri* humerus; E, SMNS 51827, *Dorygnathus banthensis*; F, SMNS 50164, *Do. banthensis*; G, YPM 1164, *Pteranodon* sp; H, MOR 691, *Montanazhdarcho minor*; I, IVPP V.2777, *Dsungaripterus weii*. Note the relatively poorly developed epicondyles in D-F, and how the distal humeri of A-C resemble those of pterodactyloids more than other non-pterodactyloids. Ca, capitulum; LE, lateral epicondyle; ME, medial epicondyle; Tr, trochlea. Scale bars represent 10 mm, except for G and H, which equal 50 mm. B, after Padian (1983a); D, after Wellnhofer (1975); E, after Padian (2008b); G, modified from Bennett (2001); H, after McGowen et al. (2002); I, after Young (1964). D, E and H are reversed from their sources to enhance comparability. ◆I? ? 0<~◆Tm

5

Skeletal reconstructions of non-pterodactyloid pterosaurs

Figure 5. Are non-pterodactyloids ubiquitously equipped with short, slender limbs? Skeletal reconstructions of taxa such as *Preondactylus bufarini* (A), *Dimorphodon macronyx* (B) and *Anurognathus ammoni* (C and D, in erect and crouched poses respectively, acknowledging the poorly known glenoid condition of anurognathids) show they have proportionally long, robust limbs. Only some non-pterodactyloids, including the Early Jurassic campylognathoidid *Campylognathoides liasicus* (E) and Late Jurassic rhamphorhynchine *Rhamphorhynchus muensteri* (F) have proportionally short and slender hindlimbs. *Preondactylus* has been reconstructed with erect forelimbs based on its grossly similar humeral morphology to *Dimorphodon*, although it remains to be established that this similarity extends to more detailed forelimb anatomy. Scale bars represent 100 mm, except for C and D, which represent 50 mm. Skeletal reconstructions modified from Witton (2013).

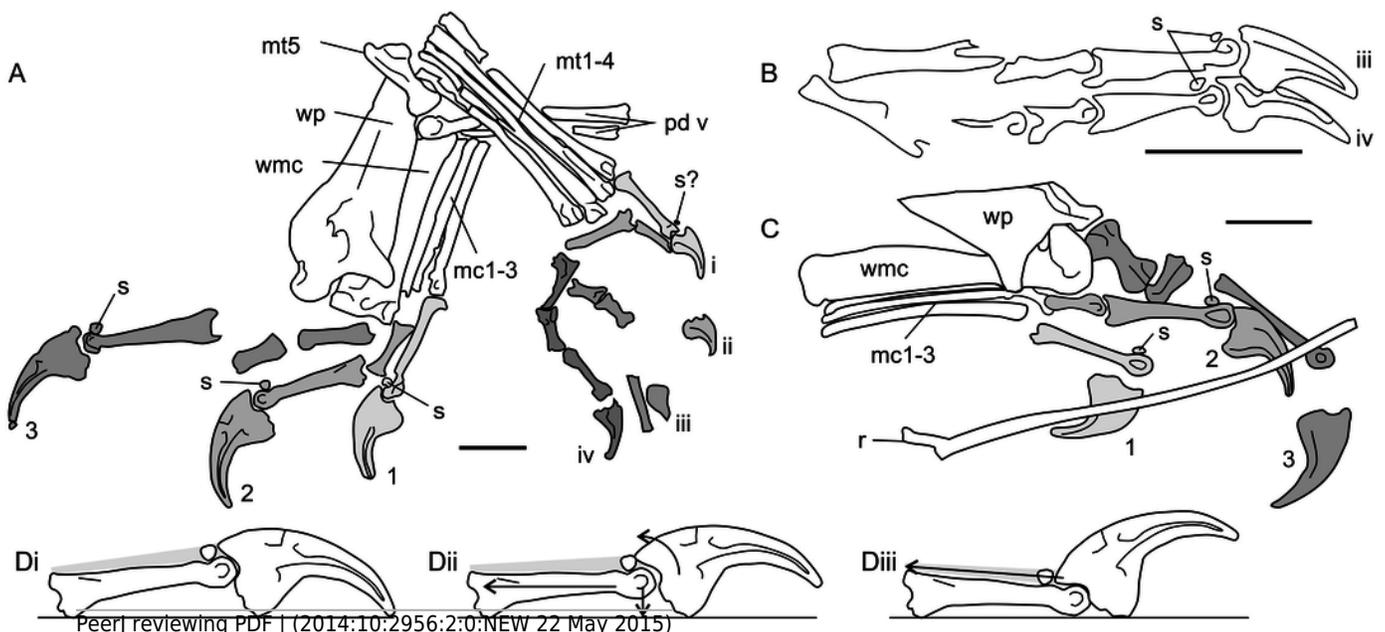

6

Antungual sesamoids in pterosaurs

Figure 6. Antungual sesamoids in pterosaurs. A, manus and pes of NHMUK 41212

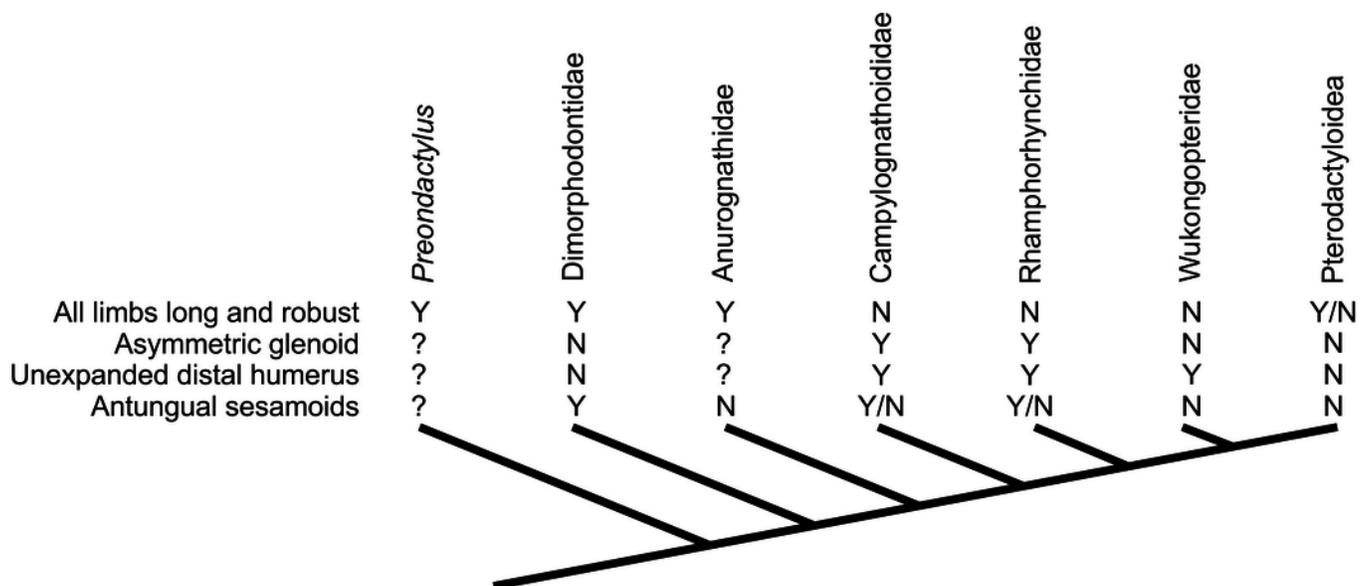

Dimorphodon macronyx; B, partial pes skeleton of GSM 1546 *Di. macronyx*; C, manus of BSP 1938 I 49 *Dorygnathus banthensis*; D, proposed interactions of pterosaur unguals with hard substrates, and utilisation of antungual sesamoids (extensor tendon shown in grey shading). Di, terminal phalanges of *Dimorphodon* manual digit 2 show as resting on a hard substrate without loading; Dii, passive hyperextension of the ungual, where pulling or depressing the phalanges (force vectors shown with arrows) retract the ungual to contact the sesamoid; Diii, active hyperextension of the ungual, where the extensor tendon is pulled to clear the ungual tip of the ground using the additional lever arm length afforded by the sesamoid. A-C, shading and numbers denote identification of clawed digits (Arabic numerals for manual digits, unary for pedal). Some skeletal elements present on the illustrated specimens are omitted for clarity. mc1-3, metacarpals 1-3; mt1-4, metatarsals 1-4; mt5, metatarsal 5; pd v, pedal digit 5; r, dorsal rib; s, sesamoids; wmc, wing metacarpal; wp, wing finger proximal phalanx. Scale bars represent 10 mm.

7

Distribution of characteristics linked to terrestrial capabilities in non-pterodactyloids in a simplified pterosaur phylogeny

Figure 7. Complex distribution of characteristics linked to terrestrial capabilities in non-pterodactyloids in a simplified pterosaur phylogeny (based on Lü et al. 2012). Other pterosaur phylogenies suggest different arrangements of non-pterodactyloid taxa (see text for details), but the distribution of these characteristics would be as complex, if not more so, in competing arrangements.

8

Potential variation in terrestrial locomotion gait in non-pterodactyloid pterosaurs

Figure 8. Potential variation in terrestrial locomotion gait in non-pterodactyloid pterosaurs. A, life restoration of the Early Jurassic rhamphorhynchine *Dorygnathus banthensis* with obligated crouching, somewhat sprawled forelimbs; B, life restoration of the Early Jurassic *Dimorphodon macronyx* with fully adducted humeri and completely erect gait, shown here facilitating subcursorial, rapid terrestrial locomotion in pursuit of sphenodontian prey. Both animals are restored with retracted claws on digits possessing antungual sesamoids. ml> 0
