Households are known to be high-risk locations for the transmission of communicable diseases. Numerous modelling studies have demonstrated the important role of households in sustaining both communicable diseases outbreaks and endemic transmission, and as the focus for control efforts. However, these studies typically assume that households are associated with a single dwelling and have static membership. This assumption does not appropriately reflect households in some populations, such as those in remote Australian Aboriginal and Torres Strait Islander communities, which can be distributed across more than one physical dwelling, leading to the occupancy of individual dwellings changing rapidly over time. In this study, we developed an individual-based model of an infectious disease outbreak in communities with demographic and household structure reflective of a remote Australian Aboriginal community. We used the model to compare the dynamics of unmitigated outbreaks, and outbreaks constrained by a household-focused prophylaxis intervention, in communities exhibiting fluid versus stable dwelling occupancy. We found that fluid dwelling occupancy can lead to larger and faster outbreaks in modelled scenarios, and may interfere with the effectiveness of household-focused interventions. Our findings suggest that while short-term restrictions on movement between dwellings may be beneficial during outbreaks, in the longer-term, strategies focused on reducing household crowding may be a more effective way to reduce

the risk of severe outbreaks occurring in populations with fluid dwelling occupancy.

ABSTRACT

Households are known to be high-risk locations for the transmission of communicable diseases. Numerous modelling studies have demonstrated the important role of households in sustaining both communicable diseases outbreaks and endemic transmission, and as the focus for control efforts. However, these studies typically assume that households are associated with a single dwelling and have static membership. This assumption does not appropriately reflect households in some populations, such as those in remote Australian Aboriginal and Torres Strait Islander communities, which can be distributed across more than one physical dwelling, leading to the occupancy of individual dwellings changing rapidly over time. In this study, we developed an individual-based model of an infectious disease outbreak in communities with demographic and household structure reflective of a remote Australian Aboriginal community. We used the model to compare the dynamics of unmitigated outbreaks, and outbreaks constrained by a household-focused prophylaxis intervention, in communities exhibiting fluid versus stable dwelling occupancy. We found that fluid dwelling occupancy can lead to larger and faster outbreaks in modelled scenarios, and may interfere with the effectiveness of household-focused interventions. Our findings suggest that while short-term restrictions on movement between dwellings may be beneficial during outbreaks, in the longer-term, strategies focused on reducing household crowding may be a more effective way to reduce the risk of severe outbreaks occurring in populations with fluid dwelling occupancy.

44 INTRODUCTION

45 For many infectious diseases, it is assumed that the risk of transmission within households exceeds
46 that in the wider community due to the increased opportunity they provide for repeated and prolonged
47 close contact between the people who live in them (Goeyvaerts et al., 2018; Endo et al., 2019). Due to
48 this increased risk, households are often the focus of infectious disease control strategies. For example,
49 household contacts of invasive Group A *Streptococcus* cases are estimated to have a 2000-fold increased
50 risk of developing the disease themselves (Oliver et al., 2019). For Meningococcal disease, the equivalent
51 increase in risk is estimated to be between 500–800-times (De Wals et al., 1981). As such, prophylaxis
52 of household contacts of cases for both of these infectious diseases is recommended to prevent further
53 spread (Oliver et al., 2019; De Wals et al., 1981).

54 Much of our understanding of household structure, and hence its representation in mathematical
55 models of disease transmission comes from descriptions of census data. However, these descriptions
56 frequently rely on the notion of a stable ‘nuclear household’ (*i.e.*, comprising two parents and their
57 children). This notion may fail to capture the complexities and nuances of populations with very different
58 household structure and dynamics. In many settings, households differ in their composition—the people
59 they contain and their relationships to each other. Households may contain extended family members,
60 multiple family units, and unrelated people. For example, in Thailand, the proportion of households *not*
61 considered to be ‘nuclear’ is estimated at close to 50% (Dommaraju and Tan, 2014). In Vietnam, this
62 proportion is estimated to be one third, the majority of which are so-called ‘stem households’ which
63 include adults, their parents, and possibly their children (Dommaraju and Tan, 2014). The proportion of
64 households where there is co-residence of children under 15 years of age with older people over 60 differs
65 greatly throughout the world—in Senegal it is 37% , but just 0.2% in the Netherlands (United Nations,
66 Department of Economic and Social Affairs, Population Division, 2017).

67 Patterns of membership of households may also vary over time. People may spend time in multiple
68 housing units, blurring the relationship between the household as a unit of social organisation and the
69 physical dwelling (Smith, 1992). For example, a study in Northern Malawi found that households were
70 distributed across between one and twelve dwellings (mean of 1.7 dwellings per household), with between
71 one and nineteen persons occupying each dwelling per night (mean 3.0) (Fine et al., 1997). Australian
72 Aboriginal and Torres Strait Islander households can also be distributed across more than one physical
73 dwelling. One study of the occupancy of a single dwelling in a remote Australian Aboriginal community
74 over time revealed that in addition to core residents, the dwelling was also regularly occupied (although
75 less frequently) by an extended household comprising other relatives and close associates (Musharbash,
76 2008). Over the course of just over a year, more than 100 unique people were observed to stay at the
77 dwelling for at least one night. The flux in occupancy of individual dwellings potentially results in an
78 increased risk of introduction into dwellings, and a continually changing population at risk of household-
79 level infection transmission, particularly if there is also high rates of overcrowding (27.3% of Indigenous
80 Australians living in remote communities live in households requiring at least one additional bedroom,
81 based on the Canadian National Occupancy Standard for Housing Appropriateness, compared to 5.5% for
82 non-Indigenous Australians, AIHW (2017)). The implications of this type of fluid dwelling occupancy on
83 infectious disease transmission and control are unknown.

84 In this study, we introduce an individual-based model incorporating a more flexible representation
85 of household membership distributed across multiple dwellings. We calibrate our model to a remote
86 Australian Aboriginal community to capture observed demographic, household and mobility charac-
87 teristics of the population. We then use the model to simulate unmitigated and mitigated (through a
88 household-focused prophylaxis intervention) outbreaks of an influenza-like illness where the risk of
89 infection transmission between contacts residing in the same dwelling is greater than those in the wider
90 community. Model outputs are compared to those from a more traditional household model assuming
91 stable dwelling occupancy, to quantify the impact of distributed households and fluid dwelling occupancy
92 on the dynamics and control of communicable diseases outbreaks.

93 MATERIALS AND METHODS

94 Individual-based model of population and infection dynamics

95 *Population structure.*

96 Our individual-based model tracks the age and current residence of individuals in a community over time.
 97 The community is comprised of N individuals and H physical dwellings. An individual's age is updated
 98 each day, and individuals are lost due to natural death at an age-dependent rate. When a death occurs, a
 99 new individual aged zero is born into the population so that the population size N is constant.

100 *Population mobility.*

101 The mobility model is based on the Australian Indigenous mobility framework proposed in (Musharbash,
 102 2008). This study tracked the number of people that stayed at least one night in a particular dwelling
 103 in the remote Australian Aboriginal community, Yuendumu during the 221 nights for which this data
 104 was recorded (these 221 nights were not continuous, but occurred during the 467 day study period). The
 105 cumulative number of nights stayed by each person was reported. The authors identified four types of
 106 residents, based on the amount of time spent in the dwelling: so called core residents, who were present
 107 60-100% of the time, regular residents, who were present 20-34% of the time, other residents who stayed
 108 less frequently on an on-and-off basis and were present 4-16% of the time, and many sporadic short-term
 109 visitors who stayed for between 1–6 nights.

110 In line with this framework, individuals in our model are assigned (uniformly at random) to a fixed set
 111 of three dwellings within their community, which we assume remain fixed over the time frames we are
 112 considering in this study (less than one year), and which we refer to as their *dwelling set*. These dwellings
 113 represent their core residence, where they spend most nights, a regularly-visited residence, and an on-off
 114 residence, where they stay less frequently on an on-and-off basis (see Figure 1). We refer to individuals
 115 who have the same core residence as a *core household*, while an individual's *extended household* consists
 116 of all core, regular and on-off residents of their dwelling set.

117 An individual's *current residence* can change due to population mobility. We have two types of
 118 mobility in the model: between-dwelling mobility (intra-community); and between-community mobility
 119 (inter-community).

120 Within the community, each day, an individual's current residence is chosen to be either their core,
 121 regular or on/off residence with respective probabilities p_c , p_r and p_o , where $p_c > p_r > p_o$. There is also
 122 a small probability p_s , where $p_s < p_o$ and $\sum_i p_i = 1$, that their current residence will be a dwelling chosen
 123 uniformly at random.

124 To capture inter-community mobility, each day, A individuals (where A is a Poisson distributed random
 125 variable with mean αN , and α is the mean per capita migration rate) are chosen uniformly at random to be
 126 replaced by immigrants (thus ensuring that community size remains constant). Immigrants are assumed to
 127 have a similar age to individuals in the population. This is implemented by specifying that an immigrant
 128 will have the same age as an individual selected uniformly at random from the population. Immigrants are
 129 assigned a current residence chosen uniformly at random from all dwellings in the community, as are the
 130 dwellings which make up their dwelling set (their core, regular and on/off residences). All immigrants are
 131 assumed to be susceptible to infection.

132 In an extended version of the model (described in the supplementary material) we consider an
 133 additional type of mobility – the regular influx of temporary visitors into the community due to two types
 134 of events: funerals (which take place after the death of a community resident) and reoccurring events,
 135 such as sporting matches or festivals. This type of mobility leads to temporary changes in the community
 136 size.

137 *Infection dynamics.*

138 We use an *SEIR* (Susceptible-Exposed-Infectious-Recovered) transmission model to simulate an outbreak
 139 of an influenza-like illness in the community (see Figure 1c). Individuals in the community are classified
 140 according to their infection status: they are either susceptible to infection (i.e., they can acquire the
 141 infection from an infectious contact), exposed (i.e., they have a latent infection and are not infectious),
 142 infectious (i.e., they have an active infection and can infect susceptible contacts), or recovered (i.e., they
 143 have recovered from the infection and are protected from re-infection). This infection status can change
 144 over time due to a transmission event, the progression to infectiousness, or due to the clearance of an
 145 infection (detailed below).

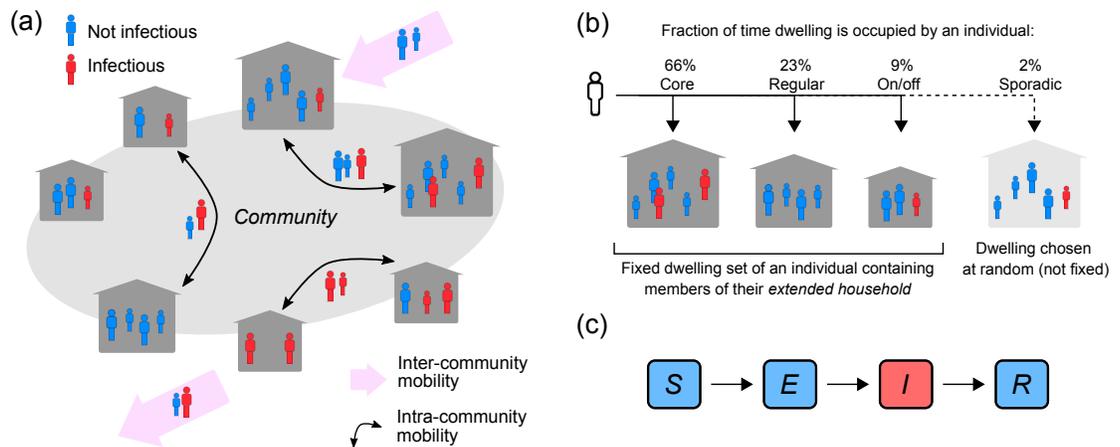

Figure 1. Population, mobility and infection model. (a) Intra- and inter-community mobility results in the movement of infectious (I) and non-infectious individuals (S, E, R) within and between communities. (b) Individuals identify with three dwellings in their community: their core residence, where they spend most nights, a regularly-visited residence, and an on-off residence, where they stay less frequently on an on-and-off basis. Individuals may also sporadically stay in a dwelling chosen uniformly at random from all dwellings in the community. (c) $SEIR$ outbreak model. Individuals are born susceptible to infection, can become exposed to infection through contact with an infectious person, before progressing to infectiousness, and then become immune to re-infection following recovery from infection.

146 Each day, individuals with the same current residence make contact with each other (we refer to
 147 these contacts as household contacts), and we simulate daily contacts that occur between individuals in
 148 the wider community (i.e., between individuals with different current residences, which we refer to as
 149 community contacts). These community contacts occur at age-dependent rates $c_{u,v}$, where $c_{u,v}$ is the daily
 150 rate of contact of an individual in age-category u with individuals in age category v . Community contacts
 151 are chosen uniformly at random from the pool of individuals in the relevant age category.

152 If a susceptible person makes contact with an infected individual with a different current residence, the
 153 susceptible person becomes infected (entering the exposed class) with probability q . Household contacts
 154 (between individuals with the same current residence) are assumed to be more intense than community
 155 contacts. We translate this increased intensity into a probability of transmission per contact that is higher
 156 by a factor of $\hat{q} \geq 1$ for these household contacts, compared to community contacts. The duration of latent
 157 and active infection are assumed to be exponentially distributed with respective mean duration of $1/\sigma$
 158 and $1/\gamma$. Once an individual clears an infection (and enters the recovered class), they can no longer be
 159 infected.

160 Simulated outbreaks were seeded with one infectious individual (chosen uniformly at random), and
 161 with the rest of the population in the susceptible class, and were run until the end of the outbreak (when
 162 there were zero infected individuals left in the population).

163 **Dynamics of a core household-focused prophylaxis intervention.**

164 Finally, we also consider outbreaks where a prophylaxis intervention is administered to the core household
 165 members of an infectious person.

166 We assume that this prophylaxis intervention is administered once an infected person enters the
 167 infectious state. We do not explicitly model the onset of symptoms in the model. However, if symptom
 168 onset corresponds to the onset of infectiousness, then the timing of this intervention corresponds to there
 169 being no delay in the core household receiving prophylaxis from symptom onset of the index case.

170 We consider outbreak scenarios where the intervention is 100% and 50% effective at protecting the
 171 core household from contracting the infection, if they hadn't been previously infected and/or recovered.

172 **Model parameterisation and description of outbreak simulation scenarios**

173 We parameterised the model to be consistent with demography and mobility in remote Australian
 174 Aboriginal and Torres Strait Islander communities.

We considered outbreaks in communities of size $N = 2500$ and $N = 500$ individuals, with respective number of dwellings $H = 358$ and $H = 80$, that are reflective of a large and small-medium community in the NT (Australian Bureau of Statistics, 2018a). With these values, the mean number of core residents per house was 7 and 6.3, respectively. We also explored scenarios in populations with lower numbers of core residents per house (i.e., with either $(N, H) = (2500, 833)$ or $(N, H) = (500, 160)$, so that the mean number of core residents per house was 3 and 3.1, respectively), to explore the impact of fluid dwelling occupancy in less-crowded communities.

Mortality rates and the initial age distribution were taken from the most recent census data of Aboriginal and Torres Strait Islander Australians in the Northern Territory (NT), Australia (Australian Bureau of Statistics, 2018b) (see Figure 2(a)). We set the intra-community mobility probabilities to be $(p_c, p_r, p_o, p_s) = (0.66, 0.23, 0.09, 0.02)$ based on data (summarised above) of house occupancy over time in a single household from the remote Australian Aboriginal mobility study in Yuendumu (Musharbash, 2008). Inter-community mobility patterns are not described in this setting although, anecdotally, Aboriginal Australians are described as having a higher than average rate of mobility compared to non-Aboriginal Australians (Morphy, 2007). We set the per capita expected migration rate α to be between $[0.002, 0.004]$ per day, which corresponds to, on average, between $[5, 10]$ migration events per week when the population size $N = 2500$.

To date, there have been no studies measuring contact patterns outside of households in remote Indigenous Australian communities. Age-dependent contact data that differentiates between household and non-household contacts is available for rural populations in Kenya (Kiti et al., 2014), and we used this to specify the age-dependent community contact rates $c_{u,v}$ in our model.

Infection parameters were chosen to be consistent with influenza-like illness: the mean duration of latency $1/\sigma$ was set to be between $[1, 3]$ days, as was the duration of infectiousness $1/\gamma$. We do not have data to inform the within-house transmission factor \hat{q} . Therefore, we considered two different scenarios: a high household-infection risk scenario where \hat{q} is set between $[3, 5]$, and a medium household-infection risk scenario where \hat{q} is set between $[1, 3]$. We set the community transmission probability q to be between $[0.002, 0.004]$ which, in the high household-infection risk scenario, led to outbreaks where greater than 50% of the population became infected, when the outbreaks took off. Results are also provided in the supplementary material where we assumed a higher transmissibility of the infection with q set to be between $[0.004, 0.006]$.

To account for uncertainty in the model parameters, for each population and infection scenario considered, we generated 1000 samples from the parameter space using Latin Hypercube Sampling (Blower and Dowlatabadi, 1994). The parameters α , $1/\sigma$, $1/\gamma$, \hat{q} , and q were sampled from uniform distributions with upper and lower bounds as described above. All other parameters were held constant.

All outbreak scenarios were re-run in a population assuming stable dwelling occupancy (i.e., with the intra-community mobility probabilities set to $(p_c, p_r, p_o, p_s) = (1, 0, 0, 0)$, and again in populations where the core household-focused prophylaxis interventions, described above, were implemented, to understand the implications of fluid dwelling occupancy on outbreak dynamics and control.

The model is implemented in MATLAB and the code needed to regenerate all figures and tables is available at <https://github.com/rhchisholm/transmission-complex-households>.

RESULTS

Population mobility model leads to dwelling occupancy distributions consistent with observations in a remote Australian Aboriginal community

To determine whether our model leads to dwelling occupancy distributions that are consistent with that observed in Yuendumu, we first set up our model population to have similar characteristics to this community. According to the most recent census data, Yuendumu has a population size $N = 759$, an average household size of 4.3 (which we used to estimate the number of dwellings $H = 176$), and people have a median age of 28 (Australian Bureau of Statistics, 2016). We then simulated population and mobility dynamics using our model, collecting occupancy data from all dwellings over 221 nights (randomly selected during a 467 day period), and compared this to the occupancy distribution from the Yuendumu study (data was extracted from Figure 10 in (Musharbash, 2008) using the open-source tool, Engauge Digitizer Version 12.1). A sample of these model outputs is shown in Figure 2. The median of the distribution of the number of current residents over time closely matches the average household size observed in Yuendumu (panel c), and the maximum occupancy in the model fluctuates between 9–22,

229 which is consistent with other studies reporting household size in remote communities (McDonald et al.,
 230 2008; Vino et al., 2017). There are clear steps in the distribution of the cumulative number of nights
 231 stayed by different resident types (panels d–h), as was observed in the original study (panel i). We found
 232 that the widths of these occupancy steps were a reflection of the number of residents of each type (core,
 233 regular, on/off and sporadic visitors) associated with a dwelling, which differed between dwellings (panel
 234 e). The observed cumulative occupancy in the Yuendumu dwelling (Musharbash, 2008) largely matched
 235 the distribution of model occupancy from a dwelling with the same number of core, regular and on/off
 236 residents as this dwelling (panel i). There was limited overlap of the observed data with the distribution
 237 of cumulative occupancy for *all* houses in the population (comparing panels d and i). However, this
 238 was expected, given the difference in the number of residents in the Yuendumu dwelling, compared to
 239 the population average in the model (which was much lower). The greatest discrepancy between the
 240 observed and model occupancy for the single dwelling with the same number of residents related to the
 241 most regularly occupying core residents, with the model consistently underestimating the nights stayed
 242 by these residents. This was also the case when we considered the extended model with event migration
 243 (Figure S1). Nevertheless, both models qualitatively capture the fluid dwelling occupancy observed in a
 244 remote Australian Aboriginal community.

245 Fluid dwelling occupancy leads to faster, and more-intense outbreaks

246 We then used our model to simulate outbreaks of an influenza-like illness in communities with a popu-
 247 lation size and core dwelling size distributions reflective of large and small-medium remote Aboriginal
 248 communities in the NT, Australia (the population sizes were 2500 and 500, and the mean number of
 249 core residents per dwelling was 7 and 6.3, respectively) (Australian Bureau of Statistics, 2018a). Key
 250 model outputs are shown in the main manuscript for large communities, and the analogous outputs for
 251 the small-medium communities are provided in the electronic supplementary material. All outbreaks
 252 were seeded with a single infectious person, and model outputs (summarised in Tables 1 and S1) were
 253 compared to those from equivalent simulations in communities assuming stable dwelling occupancy.

254 We found that infection introductions were just as likely to lead to outbreaks in communities with
 255 fluid dwelling occupancy as they were in communities with stable dwelling occupancy. However, for
 256 outbreaks which did take off, those which occurred in communities with fluid dwelling occupancy were
 257 consistently more intense than those in communities with stable dwelling occupancy (Figure 3(a)). That
 258 is, in communities with fluid dwelling occupancy, outbreaks were typically larger in overall size (the total
 259 number of people infected during outbreaks), had a higher, and earlier peak (the time in the outbreak
 260 when the number of infectious people was highest), and had a shorter duration than those in communities
 261 with stable dwelling occupancy.

262 These differences in outbreak intensity were less noticeable when we considered outbreak scenarios
 263 (i) with a lower increased risk of infection transmission between contacts residing in the same dwelling
 264 compared to those in the wider community (Figure 3(b) and Figure S11(a),(b)); (ii) in communities with a
 265 lower extent of household overcrowding (Figure 3(c)); and/or (iii) with a more transmissible pathogen
 266 (Figure S2(a),(c) and Figure S11(a),(b)). These results were robust to the sizes of the communities
 267 considered (Figure S3), and to the inclusion of event-based mobility in the fluid dwelling-occupancy
 268 model (Figures S4 and S5).

Table 1. Statistics from model scenarios of unmitigated outbreaks in communities of size 2500, including percentage of simulations that led to an outbreak (take off %), and the median (50%CI) of the outbreak duration and final size.

| Scenario | Dwelling occupancy | Take off (%) | Duration (days) | Final size |
|-----------------|--------------------|--------------|-----------------|------------------|
| Baseline | fluid | 52.8 | 112 (91,136) | 1760 (1304,2040) |
| Baseline | stable | 52.3 | 129 (105,160) | 1494 (1073,1789) |
| Lower \hat{q} | fluid | 37.7 | 139 (104,179) | 1051 (507,1414) |
| Lower \hat{q} | stable | 34.3 | 141 (112,183) | 995 (473,1319) |
| Less crowded | fluid | 33.8 | 147 (117,184) | 910 (446,1276) |
| Less crowded | stable | 33 | 140 (88,181) | 725 (118,1070) |

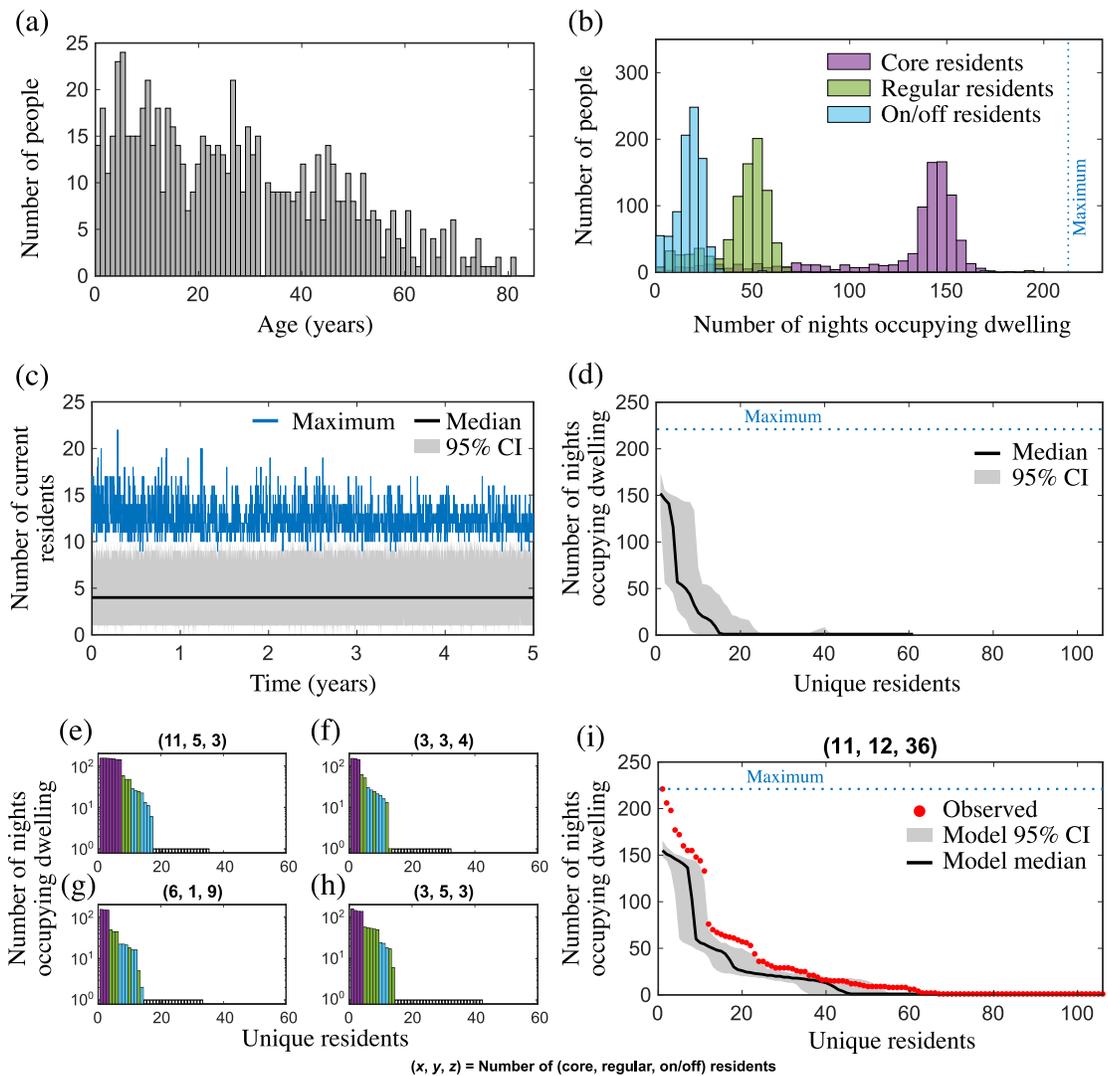

Figure 2. Population and mobility model outputs from (a–h) one simulation; and (i) 100 simulations, for a community with similar characteristics to Yuendumu (NT, Australia). (a) Age distribution of the population in years; (b) Number of nights that core (purple), regular (green) and on/off (blue) residents occupied their core, regular and on/off dwellings, respectively, over 221 nights; (c) The distribution of the number of current residents in each dwelling over 5 years, showing the median (black line), maximum (blue line), and 95%CI (grey shading); (d) The distribution of cumulative dwelling occupancy over 221 nights for all dwellings. The n^{th} unit of the horizontal axis represents the n^{th} -most regular occupant of a dwelling, and the vertical axis represents the median (black line) and 95%CI (grey shading) for the cumulative number of nights stayed by this occupant; (e–h) The cumulative dwelling occupancy over 221 nights for four exemplar dwellings. Each bar represents a unique individual (coloured according to resident type: core, purple; regular, green; on/off, blue; white, sporadic visitor) who stayed at the dwelling for at least one night, and the height of the bar represents the cumulative number of nights the individual was present (note, a log scale is used). Individuals are shown in order of decreasing occupancy, and the title of each subplot shows the number of (core, regular, on/off) residents for that dwelling at the end of the simulation; (i) Observed occupancy (red dots) vs model occupancy (median and 95%CI from 100 simulations) for a dwelling with 11 core, 12 regular, and 36 on/off residents.

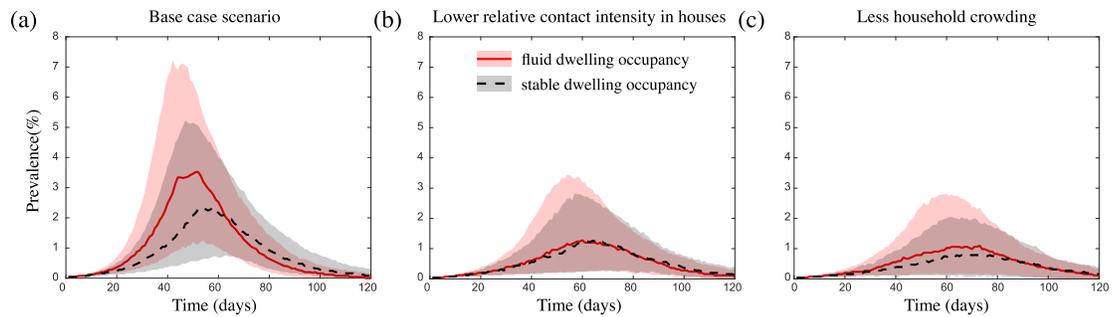

Figure 3. The impact of fluid dwelling occupancy on influenza-like outbreaks in a population of size $N = 2500$ assuming (a) a high-level; (b) a medium-level, of increased risk of transmission from household contacts compared to community contacts; and (c) less crowding in dwellings. The lines and shading show the median and interquartile ranges of the population prevalence of infection over time when there is fluid dwelling occupancy (red solid line, red shading); compared to when there is stable dwelling occupancy (black dashed line and grey shading).

269 **Higher outbreak intensity is driven by an increased number of unique, and higher-risk,**
 270 **household contacts.**

271 To understand why communities with fluid dwelling occupancy experienced more intense outbreaks, we
 272 inspected the number and types of contacts of infectious people over the course of outbreaks (Figure 4
 273 and S6). We found that the greatest relative difference between the contact patterns of infectious people
 274 between the fluid occupancy model (with and without event-based migration) and stable occupancy
 275 model was in relation to the number of unique individuals they contacted within dwellings, which was
 276 much greater in communities assuming fluid dwelling occupancy compared to stable dwelling occupancy,
 277 independent of the community size considered. Neither the number of unique community contacts, nor
 278 the total number of contacts of infectious people within or outside of dwellings were as affected by the
 279 type of dwelling occupancy model assumed, which suggests that the higher outbreak intensity observed
 280 in model communities with fluid versus stable dwelling occupancy was driven by the increased number of
 281 unique, and higher-risk, household contacts.

282 **Fluid dwelling occupancy decreases the impact of a core household-focused prophylaxis**
 283 **intervention**

284 Finally, we explored the effect of fluid dwelling occupancy on the impact of a core household-focused
 285 prophylaxis intervention that could be implemented during outbreaks. This intervention was administered
 286 to an infected person's core household at the time of infectiousness onset (which was, on average, between
 287 1–3 days post exposure), which protected the core household from contracting the infection, if they hadn't
 288 previously been infected and/or recovered.

289 In all scenarios considered, the intervention reduced outbreak size (Tables 2, S2 and S3), although this
 290 occurred to a lesser extent in communities with less crowding in dwellings (likely because the average
 291 population coverage of the intervention per treated core household was reduced) (Figures 5 and S7),
 292 or when we considered either a more transmissible pathogen, or a pathogen with a higher relative risk
 293 of infection transmission within dwellings (Figures S11(c),(d)). In scenarios where we assumed the
 294 intervention was 100% effective at protecting a case's core household from contracting the infection,
 295 the intervention had a greater impact on outbreak size in communities with stable dwelling occupancy,
 296 compared to those with fluid dwelling occupancy (Figures 5 and S7). In scenarios where we assumed
 297 the intervention was 50% effective, there was little to no difference in the impact of the intervention
 298 between communities with fluid versus stable dwelling occupancy, unless household crowding was
 299 reduced. In this latter case, the 50% effective intervention had a greater impact in communities with
 300 stable vs fluid dwelling occupancy (Figures 5(c),(f)). Again, these results were robust to the sizes of the
 301 communities considered (Figure S8), and to the inclusion of event-based mobility in the fluid-household
 302 membership model (Figure S9–S10). In some scenarios where we assumed the intervention was 50%
 303 effective, the duration of the outbreak was increased by the intervention, although the total size was

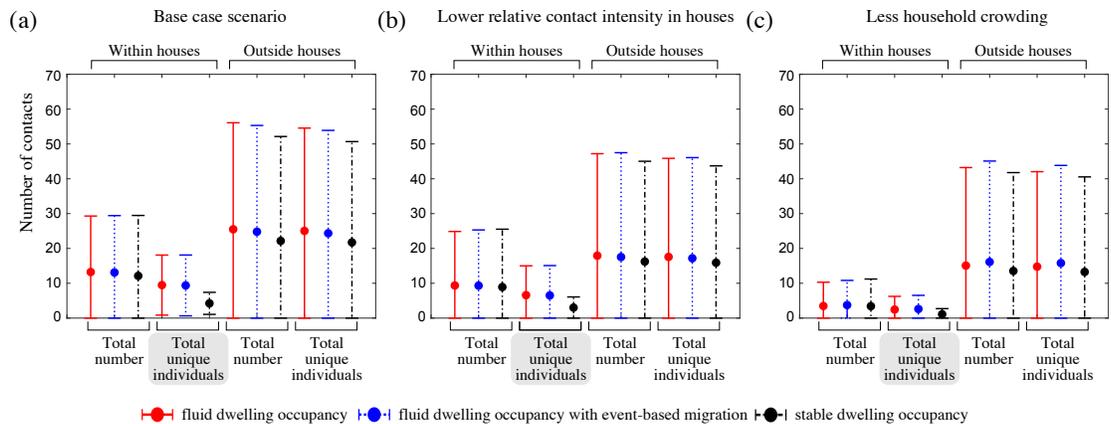

Figure 4. The impact of fluid dwelling occupancy on the distribution of the number of contacts of infectious people during outbreaks in a population of size $N = 2500$ assuming (a) a high-level; (b) a medium-level, of increased risk of transmission from household contacts compared to community contacts; and (c) less crowding in dwellings. Each disk with error bars shows the mean of means \pm one pooled standard deviation of either the total number of contacts, or the total number of unique individuals contacted (as indicated in the plots) during the infectious period of infected individuals, when there is fluid dwelling occupancy (red, solid lines); fluid dwelling occupancy with event-based migration (blue, dotted lines); compared to when there is stable dwelling occupancy (black, dash-dot lines).

304 reduced (Figures 5(a),(d), S7(a),(c),(d),(f), S8(g),(i),(j),(l), S9(a),(d),(g),(i),(j),(l) and S10(g),(j)). This
 305 occurred more frequently in communities of size 2500, and when we considered a more transmissible
 306 pathogen.

Table 2. Statistics from model scenarios of mitigated outbreaks in communities of size 2500, including the percentage reduction in the median value of the outbreak duration and final size, compared to the equivalent unmitigated scenarios, for 100% and 50% effective interventions.

| Scenario | Dwelling occupancy | Median duration reduction (%) with intervention effect | | Median final size reduction (%) with intervention effect | |
|-----------------|--------------------|--|-----|--|-----|
| | | 100% | 50% | 100% | 50% |
| Baseline | fluid | 29 | -4 | 87 | 48 |
| Baseline | stable | 55 | -2 | 97 | 49 |
| Lower \hat{q} | fluid | 45 | 11 | 87 | 61 |
| Lower \hat{q} | stable | 59 | 10 | 94 | 61 |
| Less crowded | fluid | 35 | 10 | 77 | 39 |
| Less crowded | stable | 37 | 13 | 85 | 54 |

307 DISCUSSION

308 It is generally assumed that households are associated with a single physical dwelling which is considered
 309 to be a high-risk location for the transmission of many infectious diseases. However, the assumption of a
 310 one-to-one correspondence between households and dwellings does not appropriately reflect households
 311 in some populations, such as the Australian Aboriginal and Torres Strait Islander communities considered
 312 here, where households can extend across multiple physical dwellings leading to fluid groups of people
 313 occupying individual dwellings. In this study, we showed that communities made up of such extended
 314 households have the potential to experience larger and more intense outbreaks of infectious diseases
 315 spread by close contact, particularly when there are high levels of household crowding.

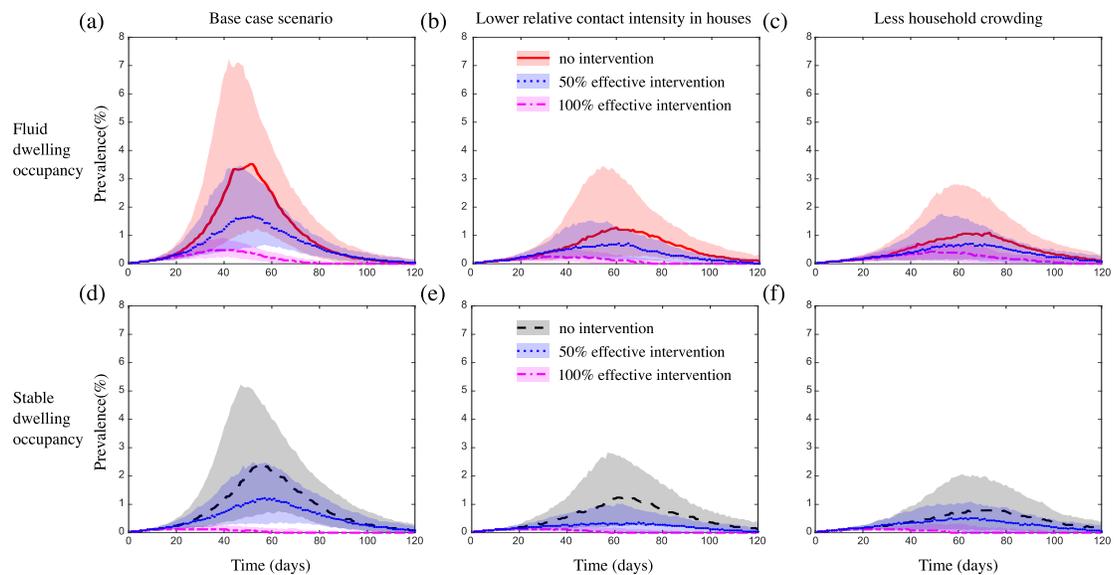

Figure 5. The impact of fluid dwelling occupancy on the effect of a household-focused prophylaxis intervention that is 50% effective and 100% effective in a population of size $N = 2500$ assuming (a,d) a high-level; and (b,e) a medium-level, of increased risk of transmission from household contacts compared to community contacts; and (c,f) less crowding in dwellings. The lines and shading show the median and interquartile ranges of the population prevalence of infection over time when there is (a–c) fluid dwelling occupancy (unmitigated outbreak: red solid line and shading; with 50% effective intervention: blue dotted line and shading; with 100% effective intervention: magenta dash-dot line and shading); compared to when there is (d–f) stable dwelling occupancy (unmitigated outbreak: black dashed line and shading; with 50% effective intervention: blue dotted line and shading; with 100% effective intervention: magenta dash-dot line and shading).

316 **Outbreaks spread rapidly in communities characterised by fluid dwelling occupancy due**
 317 **to close mixing in and between interconnected households.**

318 In our model with fluid dwelling occupancy, the extended household of an individual does not, in general,
 319 overlap with that of others in their extended household. Thus, multiple extended households can be
 320 connected via shared members, leading to large pools of individuals at greater risk of quickly contracting
 321 an infection and spreading it to other extended households, and to faster and larger outbreaks. For
 322 pathogens where there is even greater relative risk of infection transmission between household contacts
 323 compared to between community contacts, the risk of onward transmission beyond an extended household
 324 is amplified further, leading to even larger discrepancies in outbreak intensity between model communities
 325 characterised by fluid versus stable dwelling occupancy.

326 These reflections also help to explain why smaller discrepancies in outbreak intensity were observed
 327 between communities with different dwelling occupancy models when either household crowding was
 328 reduced or a more-transmissible pathogen was considered. In both of these scenarios, the lower-risk
 329 community contacts contributed much more to widespread transmission because, in the first scenario,
 330 the number of household contacts was significantly reduced, and in the latter scenario, the overall risk of
 331 infection transmission from the more-frequent community contacts had increased.

332 **Implications for infectious disease control**

333 Our findings contribute to the evidence base that supports reducing household overcrowding as an effective
 334 strategy to decrease the risk of severe outbreaks in populations with fluid dwelling occupancy (World
 335 Health Organization, 2018). They also highlight the limitations of household-focused interventions in
 336 these settings, which suggests that such interventions should be scaled up to reflect the interconnectedness
 337 of households. Our findings also suggest that an intervention that reduces the number of unique household
 338 contacts during an outbreak by, for example, limiting the amount of movement between dwellings, may

339 reduce outbreak intensity for certain pathogens. Further work could explore the effectiveness of such
340 interventions.

341 **Model limitations**

342 Our study of the impact of a household-focused intervention considered scenarios where the intervention
343 could be implemented at the time of infectiousness onset (on average 1–3 days post exposure). This may
344 not be possible for Australian Aboriginal and Torres Strait Islander people living in remote communities,
345 where access to health care services can be more challenging compared to people living in regional areas
346 or major cities (AIHW, 2018). Given the higher intensity of outbreaks in communities with fluid vs stable
347 dwelling occupancy, we expect that longer delays in implementation would further reduce the ability of
348 household-focused interventions to constrain outbreaks in these settings.

349 The mechanistic model of intra-community mobility proposed in this study was based on data
350 describing the cumulative occupancy over a period of time of a single dwelling in one remote Australian
351 Aboriginal community (Musharbash, 2008). While the occupancy distributions generated from our model
352 do resemble this data, it remains an open question whether our model is an accurate reflection of the
353 mechanisms which led to these cumulative patterns. It is also an open question how generalisable this
354 model is to other dwellings in the same community in which the data was collected, to other remote
355 Australian Aboriginal and Torres Strait Islander communities, and to other population settings where
356 households are distributed across multiple dwellings. Longitudinal data of intra-community mobility from
357 multiple dwellings, in multiple communities, and from different populations could help to inform these
358 open questions.

359 **CONCLUSIONS**

360 Our study highlights why accounting for correct household structure and dynamics in models of infectious
361 diseases that spread through close contacts can be important when analysing outbreaks and the effects
362 of interventions. Our analysis suggests that in populations with fluid dwelling occupancy, short-term
363 restrictions on movement between dwellings may be beneficial during outbreaks, and possibly improve the
364 effectiveness of household-focused prophylaxis interventions. However, in the longer-term, pre-emptive
365 strategies focused on reducing household crowding may be a more effective way to reduce the risk
366 of severe outbreaks occurring in such populations. Pathogens which do not spread via close contacts,
367 for example, those which spread via vectors or which are sexually transmitted, may not necessarily
368 have different outbreak dynamics and responses to interventions in communities with fluid versus stable
369 dwelling occupancy. Further work could explore the implications of complex household structure and
370 mobility for such pathogens, as well as those which are endemic in populations.
