Plant mating system determines, to a great extent, the demographic and genetic properties of populations, hence their potential for adaptive evolution. Variation in plant mating system has been documented between phylogenetically related species as well between populations of a species. A common evolutionary transition, from outcrossing to selfing, is likely to occur under environmental spatial variation in the service of pollinators. Here, we studied two phenotypically (in floral traits) and genetically (in neutral molecular markers) differentiated populations of the annual, insect-pollinated, plant *Datura innoxia* in Mexico, that differ in the service of pollinators (Mapimí and Cañada Moreno). First, we determined the populations' parameters of phenotypic and genetic variance in herkogamy, outcrossing and selfing rates with microsatellite loci, and assessed between generation (adults and seedlings) inbreeding, and inbreeding depression. Second, we compared the relationships between parameters in each population. Results point strong differences between populations: plants in Mapimí have, on average, approach herkogamy, higher outcrossing rate ($t_m = 0.68$), lower primary selfing rate ($r = 0.35$), and lower inbreeding at equilibrium ($F_e = 0.24$) and higher inbreeding depression ($\delta = 0.25$), than the populations of Cañada. Outcrossing seems to be favored in Mapimí while selfing in Cañada. The relationship between r and F_e were negatively associated with herkogamy in Mapimí; here, progenies derived from plants with nil or reverse herkogamy had higher selfing rate and inbreeding coefficient than plants with approach herkogamy. The difference $F_e - F$ is positively related to primary selfing rate (r) only in Cañada Moreno which suggests inbreeding depression in selfing individuals and then genetic purging. In conclusion, mating system evolution may occur differentially among maternal lineages within populations of *Datura innoxia*, in which approach herkogamy favors higher outcrossing rates and low levels of inbreeding and inbreeding depression, while nil or reverse herkogamy leads the evolution of the selfing syndrome following the purge of deleterious alleles

despite high inbreeding among individuals.

1 Introduction

2 Plant mating system has important consequences affecting, to a large extent, the demographic
3 and genetic properties of plant populations and, in the long term, their evolutionary potential
4 (Charlesworth & Charlesworth, 1979; Eckert et al. 2009). For the case of self-compatible plant
5 populations, mating systems display wide variation from predominant or complete selfing to
6 complete outcrossing. However, intermediate mating systems, those that combine selfing and
7 outcrossing strategies (i.e. mixed mating systems), are common in nature (Stebbins, 1957;
8 Goodwillie, Kalisz & Eckert, 2005; Barrett, 2010).

9 It is well documented that the transition from outcrossing to selfing is one of the more
10 frequent evolutionary shifts in flowering plants (Stebbins, 1957; Barrett, 2010; Sicard &
11 Lenhard, 2011). Evidence of this evolutionary outcome spans from phylogenetic studies
12 (Goodwillie, 1999; Foxe et al., 2009), between populations within species variation, and at
13 different geographic scales (Duncan & Rausher, 2013; Wright, Kalisz & Slotte, 2013). The
14 mating system transition of outcrossing to selfing is predicted by two main hypotheses. One is
15 the transmission advantage of selfers relative to outcrossers (3:2 genomes), that would promote
16 the expansion of selfing modifiers in a population unless selection prevents this (Fisher, 1941).
17 The second hypothesis considers that under unfavorable ecological conditions for cross-
18 pollination, i.e., low abundance or absence of potential mates and/or pollen vectors, natural
19 selection would favor reproductive assurance through selfing (Baker, 1955; Stebbins, 1957;
20 Schoen & Lloyd, 1992; Schoen, Morgan & Bataillon, 1996). Nevertheless, despite the potential
21 advantage of selfing, it may restrict gene flow within and among populations producing high
22 levels of inbreeding between individuals and increasing homozygosity (H_o), and thus the
23 likelihood of inbreeding depression (δ) (Charlesworth & Charlesworth, 1987; Charlesworth &

24 Wright, 2001; Takebayashi & Morrell, 2001). For these reasons, it is expected that the
25 inbreeding coefficient (F) would covariate positively with the level of selfing. In the long term,
26 however, theoretical models and empirical evidence predict that increasing inbreeding would
27 promote selection against inbred individuals, purging the populations of lethal or deleterious
28 alleles thus reducing genetic load (Husband & Schemske, 1996; Takebayashi & Delph, 2000;
29 Crnokrak & Barrett, 2002; Morran, Parmenter & Phillips, 2009). Populations with a long history
30 of inbreeding would suffer low levels of inbreeding depression in the face of high levels of
31 inbreeding.

32 Herkogamy, the spatial segregation of sex organs within the flower, is considering a main
33 floral trait affecting selfing rate (Webb & Lloyd, 1986). In hermaphroditic flowers, the likelihood
34 of selfing is reduced when the stigma surpasses the length of the anthers (i.e. approach
35 herkogamy), preventing contact with its own pollen; this opens the opportunity for outcross
36 pollen to first contact the stigma (Lloyd & Webb, 1986; Webb & Lloyd, 1986). On the other
37 hand, when anthers and stigma are placed at the same spatial level (i.e. no - herkogamy) or the
38 stigmas are below the anthers (i.e. reverse herkogamy), autonomous or facilitated selfing is likely
39 to occur (Lloyd, 1992). Nevertheless, reverse or nil herkogamy, by increasing reproductive
40 components of plant fitness (i.e., seeds), would covariate with selfing rate and be favored by
41 selection. Contrary, natural selection would increase/maintain approach herkogamy promoting
42 higher outcrossing rates (Motten & Stone, 2000; Elle & Hare, 2002; Herlihy & Eckert, 2007).

43 Herkogamy is determined by genetic and ecological factors (Ashman & Majetic, 2006;
44 Oøpedal et al., 2017). Within population, standing genetic variation in herkogamy would depend
45 on the history of selection of individual lineages. If selective pressures exerted by the community
46 of pollinators fluctuate between years, variation in herkogamy between lineages would be

47 maintained, producing differences in selfing rate and variation in inbreeding among individual
48 plants. When these associations are maintained through time, it would be reasonable to expect
49 that selfing rate (s), inbreeding coefficient (F) and herkogamy coevolve at the lineage level.
50 Significant association between high outcrossing rate and approach herkogamy have been
51 reported among populations (Takebayashi, Wolf & Delph, 2006; de Vos et al., 2018; but see
52 Chen et al., 2009; Brys & Jacquemyn, 2012; Oøpedal, Armbruster & Pélabon, 2015; Torång et
53 al., 2017). However, few studies have evaluated the within-population association between
54 herkogamy and outcrossing rate (Karron et al., 1997; Brunet & Eckert 1998; Medrano,
55 Takebayashi & Delph, 2000; Herrera & Barret, 2005) and none with inbreeding coefficient (F) at
56 a lineage level.

57 Annual, self-fertilizing, plant species would evolve in heterogeneous environments (e.g.
58 disturbed and/or arid habitats) where pollinator communities are unpredictable (Friedman &
59 Rubin, 2015). Under high environmental heterogeneity (i.e., in pollination service), daily and
60 seasonal fluctuations represent different opportunities for cross- or self-fertilization producing
61 variable selection on traits that affect the plants' mating system, such as herkogamy or the
62 inbreeding history of each maternal lineage (Schoen & Lloyd, 1992; Schoen, Morgan &
63 Bataillon, 1996; Morgan & Wilson, 2005; Eckert, Samis & Dart, 2006; Barrett, 2010; Shirk &
64 Hamrick, 2014; Pannell, 2015). However, it is not quite clear how strong and how frequent the
65 association between mating strategies, herkogamy and inbreeding history of lineages occur
66 within populations in short-lived species. Here, we assessed the extent of these associations in
67 each of two populations of the annual plant *Datura inoxia* Mill.

68 *Datura inoxia* (Solanaceae) is an annual self-compatible plant that inhabits arid and semi-
69 arid lands in Mexico and Southern USA (i.e. The Chihuahuan desert). Characteristic of these

70 ecosystems is the high daily fluctuation of ambient temperature. *Datura inoxia* produces large,
71 nectar producing, tubular flowers that open at dusk and remain receptive one night only. Genetic
72 differentiation at neutral loci (i.e., genetic structure) and phenotypic differentiation in floral traits
73 related to plants' mating system have previously been documented among and within
74 populations, suggesting adaptive evolution (Jiménez-Lobato & Núñez-Farfán, 2012). Flowers are
75 commonly visited by honeybees and hawkmoths whose activity mainly depends on air
76 temperature (Barclay, 1959). The wide daily range of temperature in populations generates an
77 unpredictable pollinator activity that coupled with variation in herkogamy suggest correlated
78 selection on herkogamy, selfing rates and inbreeding history within populations.

79

80 **Materials and Methods**

81 *Species and sampled populations*

82 *Datura inoxia* Mill. (Solanaceae) is a summer annual herbaceous plant native to Mexico and
83 southwestern USA (Barclay, 1959). It occurs in xeric environments, mainly along the
84 Chihuahuan desert (Barclay, 1959; Lockwood, 1973). The onset of flowering of *D. inoxia* is in
85 July and lasts up to September as others *Datura* species in this region (Bronstein et al., 2009).
86 *Datura inoxia* produces large, funnel-shaped, hermaphroditic and self-compatible white flowers
87 (Barclay, 1959). The flowers, that live one night only, open at dusk when both anthesis and
88 receptivity of stigma occur. During the flowering period, individuals can display from few up to
89 tens of flowers each night. Flower traits related to mating system, herkogamy and flower size,
90 display broad variation within and among populations (Jiménez-Lobato & Núñez-Farfán, 2012).
91 The community of pollinators include hawkmoths (*Manduca sexta*, *M. quinquemaculata*, and
92 *Hyles lineata*) (Grant, 1983) who forage on nectar, and honeybees that collect pollen (Lockwood,

93 1973; McCall et al. 2018; V. Jiménez-Lobato, pers. Obs.). Hawkmoths visit flowers at dusk
94 when night temperatures reach more than 24°C (pers. Obs.), while honeybees visit the flowers in
95 the afternoon even if these are still closed, and early in the morning before flowers wilt and fall
96 (McCall et al., 2018).

97 Two populations of *D. inoxia* were selected to assess the relationships between selfing
98 rate, herkogamy and inbreeding coefficient (F) at the lineage level. Collection of plant material
99 (e.gr., seeds) for experimental analyses, described below, was made under the permission SGPA-
100 DGGFS-712-1596-17 (Subsecretaría de Gestión para la Protección Ambiental, Secretaría de
101 Medio ambiente y Recursos Naturales, Mexico). Previous results indicate that these two
102 populations possess ample individual variation in herkogamy and in flower size-related traits
103 (Jiménez-Lobato & Núñez-Farfán, 2012). Cañada de Moreno (CM) is located in the State of
104 Querétaro (21° 17' 43"; 100° 31' 00") in the Mexican Bajío at 1933 m a.s.l. During the
105 flowering period of *D. inoxia* (July to September), this locality has an average temperature of
106 18.8° C, with a daily range from 7.4 °C to 30.8 °C, and a three-month total precipitation of 314
107 mm. The second population, Mapimí (Map), is located at 1157 m a.s.l. in the Mexican Plateau in
108 the States of Coahuila and Durango (26° 41' 11"; 103° 44' 49"). This is a more xeric
109 environment, with a quarterly average temperature of 22.8°C (range: 12.6°C to 32.9°C) and a
110 total three-month precipitation of 253 mm. Because flight activity of hawkmoths and honeybees
111 is dependent on ambient temperature, the wide fluctuation in daily temperature at both sites
112 suggests a heterogeneous and unpredictable pollinator service along the flowering season.

113 *Herkogamy variation within populations*

114 Within each population, in an area of 1 ha, 30 reproductive plants were randomly selected and
115 tagged for sampling. In each individual plant, 4 - 6 open flowers were selected to measure

116 herkogamy. Herkogamy was measured as length of pistil – length of stamens. Approach
117 herkogamy implies that the pistil surpasses stamens length while in reverse herkogamy the
118 opposite occurs. Absence of herkogamy occurs when pistil and stamens overlap. To estimate
119 phenotypic variation in herkogamy in each population, we obtained the variance component
120 among and within individuals. Individual plants were considered a random effect. The residual
121 variance is accounted by the intra-plant variation. The significance of individuals was evaluated
122 by a likelihood-ratio χ^2 test (LRT) between a model that includes individuals as random effect
123 (function lme) and one that does not (LRT1; function gls) (Zuur et al., 2009). Analyses were
124 conducted with nlme package (Pinheiro et al., 2017) in R software (R Development Core Team,
125 2008).

126 *Mating system parameters*

127 In order to estimate mating system parameters from each marked plant in the field, five mature
128 fruits derived from natural pollination were collected, labelled and bagged. In the laboratory,
129 seeds of each fruit were separated and germinated in the glasshouse; seeds of each fruit within
130 each family (maternal plant) were sowed separately. Germination per fruit, per family, was
131 recorded for 30 days. To obtain an average estimate of germination rate per fruit, we recorded
132 the final number of seeds germinated in each pot. Germination percentage was $\geq 90\%$ for all
133 plants. Once seedlings emerged, at least five seedlings per fruit, and 25 seedlings per maternal
134 plant (i.e., family) were collected for further genetic analysis. We collected leaf tissue from
135 young plants, bagged, labelled, and stored in an ultra-freezer at -97°C . Finally, we analyzed 20
136 seedlings per each of 30 maternal families per population ($N = 600$).

137 Seedlings' DNA was extracted following the Miniprep protocol (Doyle & Doyle, 1987).

138 Five microsatellite nuclear loci developed for *D. stramonium* (Andraca, 2009) were amplified for

139 each seedling. Further, we standardized one additional microsatellite locus for *D. innoxia* (F8:
140 R_w: 5' -GGACAACATCTTTGCGACCC- 3') (Supplementary Information), in order to obtain a
141 total of six polymorphic microsatellite loci per individual. Primers were labelled with PET, VIC,
142 6-FAM, and NED dyes (Applied Biosystems) (PCR protocols are shown in Supplementary
143 Information).

144 Multiloci outcrossing (t_m) and selfing ($s = 1 - t_m$) rates, primary selfing rate (r) and
145 inbreeding coefficient (F) were estimated for each maternal family for each population. Mating
146 system parameters (t_m and s) at the family level were calculated using MLTR 3.2 software
147 (Ritland, 2002), with an Expectation-Maximization method (EM) that allows missing data and
148 undetected null alleles (Ritland & Jain, 1981). Standard errors and standard deviation were
149 estimated by bootstrapping, with 1000 replicates and re-sampling individuals at family level. The
150 frequency of null alleles per locus, per population, was assessed using Micro-Checker v.2.2.3
151 (Cock et al., 2004). Since one locus (G8) did not amplified for plants of Cañada de Moreno,
152 analyses were carried out with five loci, and six loci for Mapimí. Selfing rates (s) obtained from
153 molecular markers, after fertilization and germination, might not be completely independent
154 from inbreeding depression and thus may underestimate its true value (Lande, Schemske &
155 Schultz, 1994). Primary selfing rate (r) is a better predictor of mating system because it assesses
156 separately the magnitude of inbreeding depression. Hence, r is referred as the proportion of
157 selfed progeny at the time of fertilization (Lande, Schemske & Schultz, 1994). The primary
158 selfing rate (r) was calculated for each maternal family as: $r = s / [1 - \delta + s\delta]$, where s is the
159 selfing rate obtained from microsatellite loci, and δ is the cumulative inbreeding depression
160 obtained for each population (see below).

161 The inbreeding coefficient (F) may include components of inbreeding other than mating
162 system, such as biparental inbreeding or population substructure. Here, we use this parameter as
163 a proxy of the inbreeding history of each maternal family (i.e., adult cohort) (Latta & Ritland,
164 1994). F 's were inferred with GenePop v.4.2 per lineage from the loci amplified previously
165 (Rousset & Raymond, 1995; Rousset, 2008). In order to infer whether inbreeding depression is
166 associated with the selfing rate and herkogamy, we calculated inbreeding coefficients at
167 equilibrium (F_e) (i.e., progeny cohort) at each lineage, assuming that adult F and t_m are constant
168 among generations (Ritland, 1990). We then related these differences with selfing rate and
169 herkogamy. Since F_e increases in relation to F due to self-fertilization, differences between F
170 and F_e at each maternal lineage would indicate the presence of higher inbreeding depression.
171 Once selection against inbred progeny occurred, F_e and F will be equal (Ritland, 1990; Shirk &
172 Hamrick 2014). F_e 's were calculated as $F_e = (1-t_m) / (1+t_m)$, where t_m is the outcrossing rate
173 calculated from MLTR for each maternal family (Ritland, 1990).

174 Multiloci outcrossing (t_m) and primary selfing rates (r) are highly and inversely correlated
175 (CM: estimated = -1.00, $p = 0.000$, d.f. = 25; MAP: estimated = -0.969, $p = 0.000$, d.f. = 27),
176 hence we present the analyses only for primary selfing rates (r). Since r is a proportion with
177 binomial distribution, correlation with herkogamy was fitted by a generalized linear model with a
178 quasi-binomial distribution error (Crawly, 2013). F , F_e and their differences were associated to
179 herkogamy and r with a generalized linear model with gaussian distribution error (Crawly,
180 2013). All analyses were implemented in R package (R Development Core Team 2008).

181 *Inbreeding depression*

182 To estimate the magnitude of inbreeding depression (δ), we collected 150 fruits from different
183 individual plants in each population, including the maternal families previously analysed. From

184 each fruit, we sowed ten seeds on separated pots under greenhouse conditions. When seeds
185 germinated, only one seedling per fruit was randomly chosen and grown under controlled
186 conditions until reproduction. For each population, 100 individuals were randomly chosen to act
187 as pollen receptors (mothers) and 50 individuals as pollen donors (fathers). Two manual
188 pollination treatments were applied to each maternal receptor. In the first treatment, cross-
189 pollination (*o*), two flowers were emasculated before anthesis and hand-fertilized with pollen of
190 one donor randomly chosen from the same population. In the second, self-pollination treatment
191 (*s*), two flowers of each receptor plant were fertilized with self-pollen. After pollination, flowers
192 of both treatments were bagged individually with a fine nylon mesh. Since many mother plants
193 did not produce the four flowers needed to apply both treatments, the final sample include
194 mother plants that produced at least one fruit per treatment (CM: N = 77, Map: N = 41). Two
195 components of fitness per pollination treatment were evaluated in each population, the mean of
196 seed-set (*i.e.* number of seeds/ number of ovules), and the seed mass. Seed mass was obtained for
197 a random sample of 30 seeds per fruit in an analytical balance (Adventurer OHAUS).

198 Cumulative inbreeding depression coefficient (δ) was calculated for each population as:

199 $\delta = 1 - \frac{\bar{w}_s}{\bar{w}_o}$, where \bar{w}_s and \bar{w}_o are the mean fitness of progenies derived from self- or cross-
200 pollination, respectively. Average fitness of self- and out-cross progenies is the product of seed-
201 set and seed mass (Schemske & Lande, 1985). This value was used to estimate the primary
202 selfing rate (*r*) at each maternal lineage.

203

204 **Results**

205 *Variation in herkogamy between populations of Datura inoxia*

206 The population average of herkogamy in Cañada de Moreno was negative (mean = -4.72; sd =
207 5.5 mm) with a range of 17.48 mm (from -13.83 to +3.65 mm). In this population 20 out of 27
208 individual plants (74%) had reverse or nil herkogamy and 7 (26%) showed approach herkogamy
209 (Fig. 1A). In contrast in Mapimí population (N=29) mean herkogamy was positive and more
210 variable than in Cañada de Moreno (Mean = 2.57 mm, sd = 11.15 mm; range = 44.8mm (from -
211 20 to +24.8 mm) (Fig. 1B).

212 The proportion of variance in herkogamy explained by the among individual plants term
213 was higher in Mapimí (77.32%) than in Cañada de Moreno (50.62%), indicating higher intra-
214 individual variation in the latter population (Map: 22.68%; CM: 49.38%). The likelihood ratio χ^2
215 test (LRT) indicate significant variation between individual plants in each population (Map: L =
216 105.04, df = 2, $P < 0.0001$; CM: L = 38.56, df = 2, $P < 0.0001$).

217 *Mating system and inbreeding coefficient (F)*

218 The multi-loci outcrossing rate (t_m) was, on average, higher in Mapimí than in Cañada de
219 Moreno (0.682 vs 0.294, respectively) although high variation in this parameter was detected
220 among lineages in each population (Mapimí, from 0.022 up to 1; Cañada, from 0 up to 1). The
221 distribution of t_m is skewed to low values in Cañada de Moreno (ca. 60% of mother plants) but to
222 high values in Mapimí (50% of the families with $t_m > 0.8$) (Fig. 2). Primary selfing rate (r) was
223 more than two-fold higher in Cañada de Moreno than in Mapimí (0.716 vs. 0.353), varying from
224 $r = 0$ to 1 and from $r = 0$ to 0.978, respectively.

225 Inbreeding coefficients of adult cohorts (F) were negative in the two populations and
226 highly variable (Cañada: $F = -0.193$, from -1 to +0.75; Mapimí: $F = -0.085$, from -0.553 to +1).
227 Inbreeding coefficients at equilibrium (F_e) was higher in Cañada than Mapimí ($F_e = 0.626$, $F_e =$
228 0.238, respectively) and, again, highly variable in both populations (from 0 to 1). The differences

229 between F and F_e was much higher in Cañada Moreno ($F_e - F = 0.819$) than in Mapimí ($F_e - F =$
230 0.323). Cumulative inbreeding depression estimated the average product of seed-set and seed
231 mass was higher in Mapimí than in Cañada ($\delta = 0.25$ vs. $\delta = 0.09$, respectively).

232 *Relationships between mating system parameters and herkogamy*

233 The relationship between primary selfing rate (r), inbreeding coefficient (F), inbreeding
234 coefficient at equilibrium (F_e) and herkogamy within each population were only significant in
235 the Mapimí population (Table 1, Fig. 3). In Mapimí, r and F_e were negatively associated with
236 herkogamy (Table 1; Fig. 3B, F), indicating that individuals with nil or reverse herkogamy had
237 progenies with higher selfing rate and inbreeding coefficient than plants with approach
238 herkogamy. As was expected, progenies' inbreeding coefficient (F_e) increases positively with
239 primary selfing rate (r) at both populations (Table 1; Fig. 4C, D). In addition, selfing is also
240 linked to the breeding history of each maternal lineage (F) only in Mapimí (Fig. 4A, B) but not
241 with herkogamy in the two populations (Table 1; Fig. 3C, D). The difference $F_e - F$ is positively
242 related to primary selfing rate (r) only in Cañada Moreno (Table 1; Fig. 4E), and statistically
243 unrelated to herkogamy in the two populations (Table 1; Fig. 4G, H).

244

245 **Discussion**

246 In annual, short-lived, plant species inhabiting heterogeneous environments, the evolution of
247 plant mating system in association with flower traits, such as herkogamy, depends on the
248 variation of natural selection within populations, and on the opportunity to cross and self-
249 fertilization every year (Shirk & Hamrick 2014). If some associations among traits and mating
250 strategies are favored through time, it is expected to find that different lineages within

251 populations would vary in their history of inbreeding. In this work we evaluated the association
252 among herkogamy, mating system and inbreeding history at a lineage level within two
253 populations of *Datura inoxia*, an annual/short live species distributed in arid and semiarid
254 environments in Mexico and North America.

255 We found that herkogamy, selfing rates, inbreeding coefficients as well as their
256 associations varied considerable within the two populations. In line with expectations, in one
257 population (Mapimí), plants with more pronounced approach herkogamy show, on average,
258 higher outcrossing rates and less inbreeding coefficient of progenies, than those individuals that
259 exhibited nil or reverse- herkogamy. These results are in line with the hypothesis of adaptive
260 herkogamy as a mechanism that prevents selfing in populations and avoiding inbreeding between
261 individuals (Web & Lloyd 1986; Lloyd 1992). Relationship between selfing/outcrossing rate and
262 herkogamy has been found in other species of *Datura* such as *D. stramonium* (Motten &
263 Antonovics, 1992; Motten & Stone, 2000) and *D. wrightii* (Elle & Hare, 2002) but also in other
264 species like *Gilia achilleifolia* (Takebayashi & Morrell, 2001), *Clarkia temblorensis* (Holtsford
265 & Ellstrand, 2006) and *Mimulus ringens* (Karron et al., 1997). However, we did not detect a
266 significant association between inbreeding coefficients of adults' cohort with herkogamy. This
267 suggests that the inbreeding history at each lineage not only depends on herkogamy; instead,
268 purge of inbred individuals and/or biparental inbreeding may also come into play.

269 Fluctuation of environmental variables but mainly pollinator availability, as it occurs in
270 Mapimí, can contribute to maintain variation in herkogamy within populations. Variation in
271 herkogamy may be linked with plants' reproductive assurance when pollinators are scarce, or
272 with high outcrossing rates when abundant (Kalisz, Vogler & Hanley, 2004; Goodwillie, Kalisz
273 & Eckert, 2005; Chen et al., 2009). Since outcrossing rates in Mapimí are related to herkogamy,

274 it is likely that episodes of differential (or even contrasting) selection on herkogamy among
275 lineages every year, could sometimes favor either outcrossing (approach herkogamy) or selfing
276 (nil or reversal herkogamy). This phenotypic variance in herkogamy could explain the
277 maintenance of the mixed mating system of *D. inoxia* in Mapimí.

278 On the other hand, the mating system of the population of Cañada de Moreno is
279 predominantly of selfing, and no association between selfing rates, herkogamy and inbreeding
280 coefficients in the adult cohort were detected. Nevertheless, like the Mapimí population, there is
281 a positive relationship between selfing rate with inbreeding coefficients in the progenies, and
282 with the F vs. F_e difference. These results suggest inbreeding depression in selfing individuals
283 and then genetic purging (Ritland, 1990). This result is supported by the contrasting average
284 value of inbreeding depression in the two populations of *D. inoxia*. Theoretical models and
285 experimental results have demonstrated that mutations of large effect causing inbreeding
286 depression can be purged from one to another generation (Willis, 1999; Charlesworth & Willis,
287 2009). However, mild in effect and rare mutations are responsible of inbreeding depression and
288 can be maintained in populations for multiple generations ((Lande, Schemske & Schultz, 1994;
289 Charlesworth & Willis 2009). The expression of mutations with mild deleterious effect in inbred
290 individuals of *D. inoxia*, would explain the differences of inbreeding coefficients between
291 progeny and adult generations and the relationship with selfing rate.

292 Phenotypic variance in herkogamy results from genetic (Herlihy & Eckert, 2007),
293 developmental (Vallejo-Marín & Barrett, 2009), and environmental factors, such as soil
294 nutrients, as demonstrated in *Datura stramonium* (Camargo et al. 2017). However, the evolution
295 of mating system, linked to floral traits like herkogamy, requires additive genetic variance. A
296 revision of evidence points out the potential evolution by selection of herkogamy owing to the

297 presence of additive genetic variance (heritability) and genetic additive variation (evolvability)
298 (see revision in Oøpedal et al., 2017). Our results, derived from the partition of phenotypic
299 variance in herkogamy among individual plants and random variation (within individual
300 variation or residual term), indicate a large amount of variance between individuals in each
301 population, but notably more so in Mapimí (77.32%) than in Cañada de Moreno (50.62 %).
302 Thus, there is a strong indication that individual variation in average herkogamy in *D. inoxia* in
303 Mapimí is genetically based and potentially adaptive (see Jiménez-Lobato & Núñez-Farfán
304 2012). High within-individual variation could be adaptive if, on average, high intra-individual
305 variation is linked to higher fitness (Herrera, 2009; Camargo et al. 2017). Otherwise, high intra-
306 individual variation can be maintained in highly heterogeneous environments (i.e., pollination
307 likelihood by animals) through time. In Cañada de Moreno the high within-plant variation in
308 herkogamy could limit selection on it, constraining an adaptive response in this population
309 (Falconer & MacKay, 1996; Lynch & Walsh, 1998).

310 The within-individual variation in plant traits, but particularly in flowers, can originate
311 during development or can be an elicited response to environmental variability (Herrera, 2009).
312 The stability of development or homeostasis has been associated with different levels of
313 heterozygosity, where heterozygous individuals are more stable than their homozygous (Lerner,
314 1954). However, there is not clear consensus on this hypothesis; some evidence points out the
315 potential effect of inbreeding, the fixation of deleterious alleles and genetic drift influencing the
316 level of developmental stability of individuals (Clarke, 1993). To what extent inbreeding and
317 deleterious mutations are responsible of intra-individual variation in CM is not known as yet, but
318 evidence suggests such kind of developmental variation as shown in one highly inbred
319 population of *D. stramonium* (Camargo et al. 2017)

320

321 **Conclusions**

322 Association between herkogamy, mating system and inbreeding history at a lineage level
323 is expected to occur within populations in self-compatible, hermaphroditic plant species.

324 Similarly, as environments do vary, particularly in pollination service by animals, variations in
325 trait values and their correlations are also expected. In *D. inoxia*, as in other species of *Datura*,
326 approach herkogamy is associated to outcrossing rates and to low levels of inbreeding in the
327 progenies. Results of this study show that populations of *D. inoxia* are diverging in mating
328 system with genetic consequences.

329

330 **Acknowledgments**

331 We thank to members of the Ecological genetics and evolution lab members for field assistance,
332 particularly to Armando López Velázquez. Thanks to Rosalinda Tapia López for lab help and to
333 Rafael Torres and Adriana Pérez for greenhouse work assistance. Particular gratitude to Kiko
334 Herrera's family in Mapimí Biosphere Reserve and to Tito Galván and family in Cañada de
335 Moreno. This study is part of the Ph. D. Thesis of V. Jiménez-Lobato.

1 * $P < 0.05$, ** $P \leq 0.005$, *** $P < 0.00005$ indicate significant association between variables.

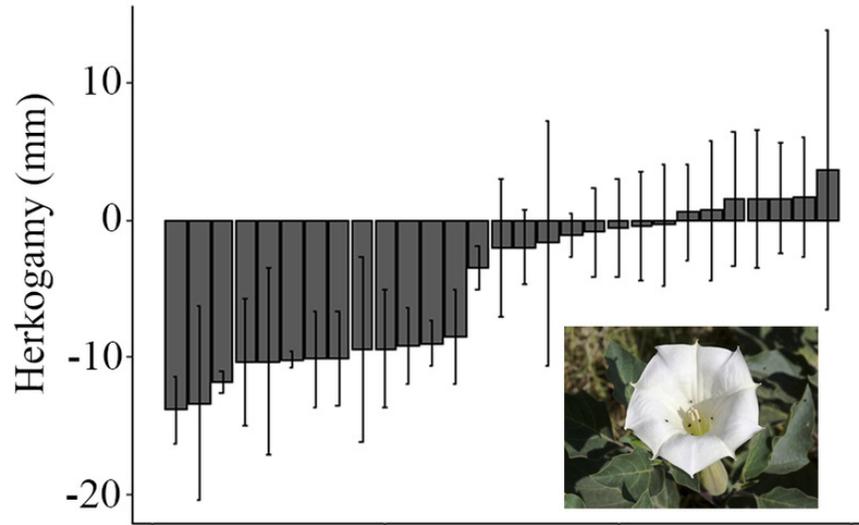

2

Figure 1

Figure 1

Distribution of the herkogamy values at individual level in two populations of *Datura inoxia* in Mexico. A. Cañada de Moreno, B, Mapimí. Bars represent the standard deviation within each individual.

A. Cañada de Moreno

B. Mapimí

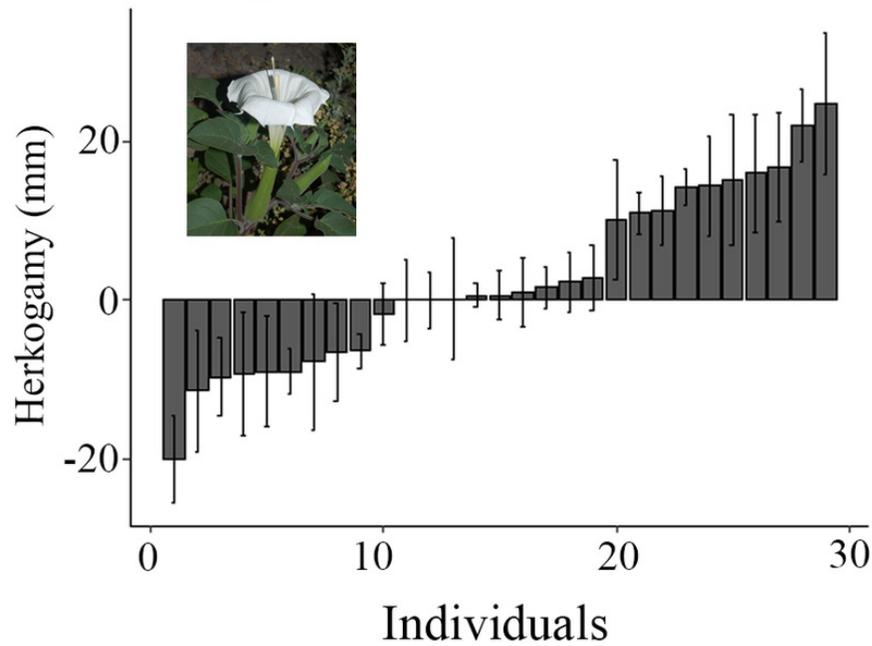

Figure 2

Figure 2

Distribution of outcrossing rates at maternal lineage level within two populations of *Datura innoxia* in Mexico. Boxplots with quartiles and the mean value are shown for each population.

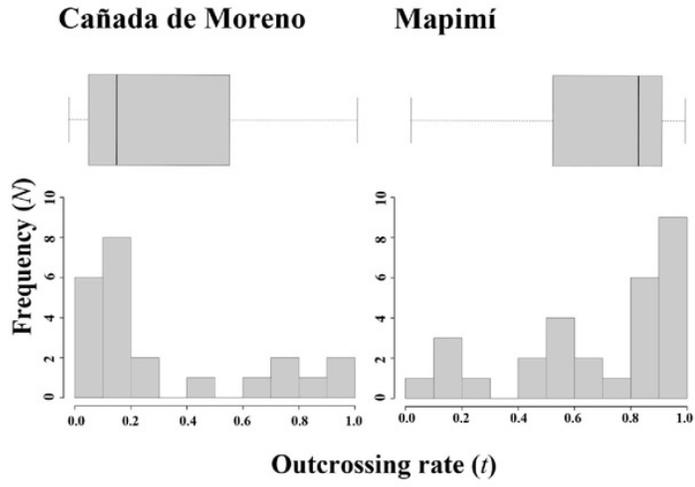

Figure 3

Figure 3

Correlations between primary selfing rates (r), inbreeding coefficients (F), inbreeding coefficients at equilibrium (F_e) and the differences between F_e and F ($F_e - F$) with herkogamy values in two populations of *Datura innoxia* in Mexico. P values are shown only for significant results. Not significant ($n.s.$).

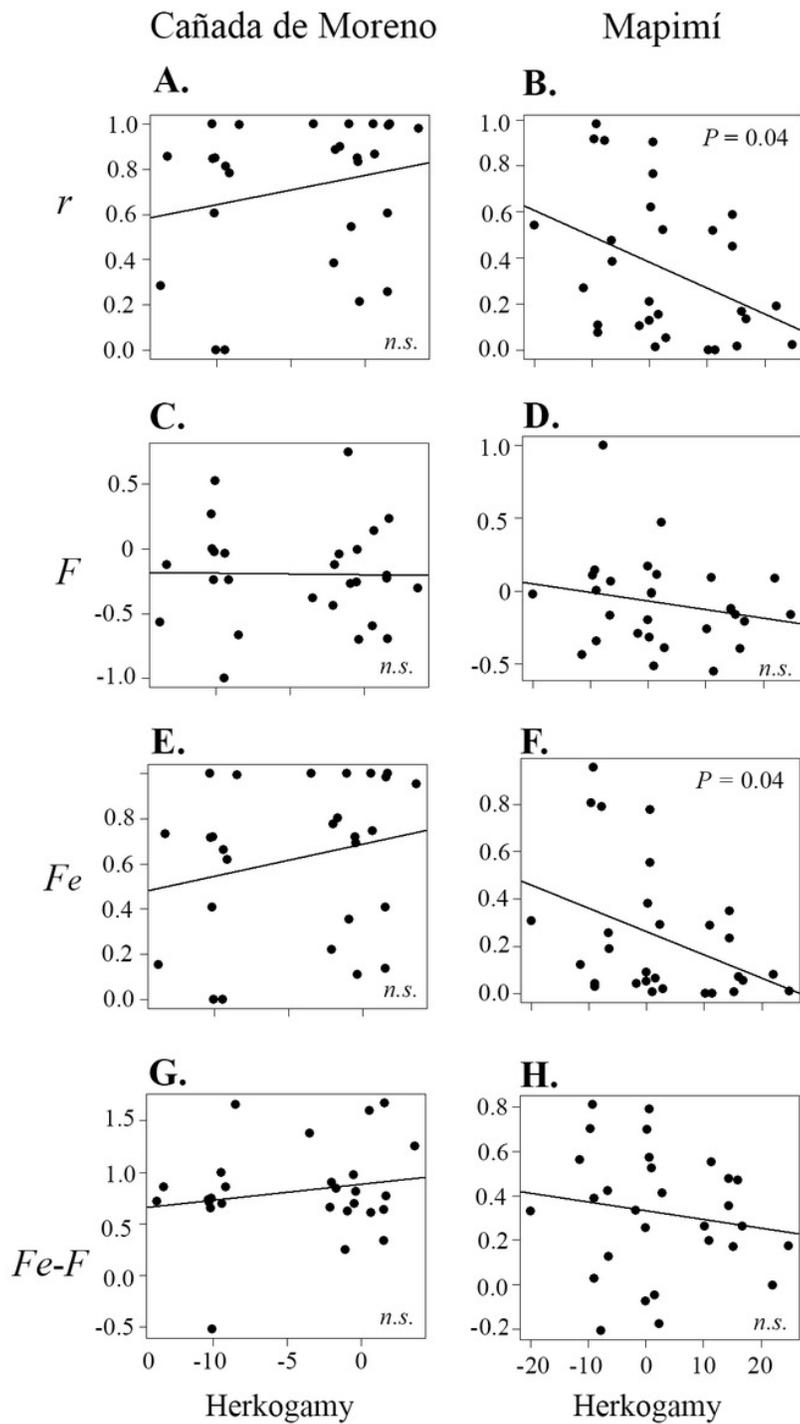

Figure 4

Figure 4

Correlations between inbreeding coefficients (F), inbreeding coefficients at equilibrium (Fe) and differences between Fe and F ($Fe-F$) with primary selfing rates (r) in two populations of *Datura innoxia* in Mexico. P values are shown only for significant results. Not significant (*n.s.*).
