Depressive symptoms and other risk factors predicting suicide in middle-aged men: A prospective cohort study among Korean Vietnam War veterans

Sang-Wook Yi, Jae-Seok Hong

Background. Few studies have prospectively examined whether depressive symptoms and other risk factors are associated with a higher risk of increase suicide death in individuals other than high-risk populations, such as psychiatric patients and individuals with self-harm histories. The purpose of the study is to prospectively examine whether depressive symptoms assessed by the Beck Depression Inventory (BDI) are associated with greater risk of suicide death and whether depressive symptoms and other risk factors are independent predictors of suicide in general-risk populations. Another aim is to evaluate the sensitivity of the BDI for predicting suicide death. **Methods.** 10,238 Korean Vietnam War veterans (mean age: 56.4 years) who participated in two surveys in 2001 were followed up for suicide mortality over 7.5 years. **Results.** 41 men died by suicide. Severely depressed participants had a higher adjusted hazard ratio (aHR=3.4; 95% CI=1.5-7.7) of suicide than non-to-moderately depressed ones. Higher suicide risk was associated with more severe depressive symptoms (p for trend=0.009). After adjustment for depressive symptoms and other factors, very poor health, low education, and past drinking were associated with higher suicide risk, while good health, body mass index, and marital status were not associated with suicide. The sensitivity at the cut-off score of 31 for detecting suicide was higher during the earlier 3.5 years of the follow-up (75%; 95% CI=50-90) than during the latter 4 years (60%; 95% CI=41-76). **Conclusions.** Depressive symptoms are a strong independent predictor and very poor health, low education, and drinking status may be independent predictors of future suicide. The BDI may have acceptable diagnostic properties as a risk assessment tool for identifying people with depression and suicidal potential among middle-aged men.

30 **Abstract**

31 **Background.**

32 Few studies have prospectively examined whether depressive symptoms and other risk factors

33 are associated with a higher risk of suicide death in individuals other than high-risk populations,

34 such as psychiatric patients and individuals with self-harm histories. The purpose of the study is

35 to prospectively examine whether depressive symptoms assessed by the Beck Depression

36 Inventory (BDI) are associated with greater risk of suicide death and whether depressive

37 symptoms and other risk factors are independent predictors of suicide in general-risk populations.

38 Another aim is to evaluate the sensitivity of the BDI for predicting suicide death.

39 **Methods.**

40 10,238 Korean Vietnam War veterans (mean age: 56.4 years) who participated in two surveys in

41 2001 were followed up for suicide mortality over 7.5 years.

42 **Results.**

43 41 men died by suicide. Severely depressed participants had a higher adjusted hazard ratio

44 (aHR=3.4; 95% CI=1.5-7.7) of suicide than non-to-moderately depressed ones. Higher suicide

45 risk was associated with more severe depressive symptoms (p for trend=0.009). After adjustment

46 for depressive symptoms and other factors, very poor health, low education, and past drinking

47 were associated with higher suicide risk, while good health, body mass index, and marital status

48 were not associated with suicide. The sensitivity at the cut-off score of 31 for detecting suicide

49 was higher during the earlier 3.5 years of the follow-up (75%; 95% CI=50-90) than during the

50 latter 4 years (60%; 95% CI=41-76).

51 **Conclusions.**

52 Depressive symptoms are a strong independent predictor and very poor health, low education,

53 and drinking status may be independent predictors of future suicide. The BDI may have

54 acceptable diagnostic properties as a risk assessment tool for identifying people with depression

55 and suicidal potential among middle-aged men.

59

Introduction

Over 800,000 people die by suicide worldwide every year (World Health Organization 2014). Suicide prevention is a high priority in many countries. Understanding the risk factors leading to suicide is crucial for effectively preventing suicide and managing individuals at risk of suicide. Depression has been strongly associated with suicide in retrospective psychological autopsy studies (Hawton & van Heeringen 2009; Yoshimasu et al. 2008), although an over-/underestimation of the association, and biases such as interviewer bias, surrogate interview bias, and recall bias may not be ruled out (Hjelmeland et al. 2012). Prospective studies have been conducted mainly among patients with psychiatric disorders, who may not represent the people with psychiatric disorders in the community (Agerbo 2007). Meanwhile, physical health indicators such as health status (Jee et al. 2011) and body mass index (BMI) (Jee et al. 2011; Mukamal et al. 2010), marital status (Masocco et al. 2010), drinking status (Akechi et al. 2006), and socioeconomic status (Milner et al. 2014) have also been linked with suicide. Despite many studies supporting these associations, it has seldom been evaluated and is unclear whether each of those factors were independently associated with suicide after adjusting for the others and, notably, for depression, one of the most important known precursors of suicide (Milner et al. 2014; Mukamal et al. 2010).

Meanwhile, suicide risk assessment using depression tools could be relatively easily embedded in the various health care settings to help primary physicians and public health professionals identify people with depression and suicidal potential. However, to the best of our knowledge, the diagnostic characteristics of depression instruments that can be used for suicide risk assessment have never been evaluated in general-risk populations for predicting suicide death.

83   The primary aim of this study was to prospectively examine whether more severe

84   depressive symptoms assessed by the Korean translation of the Beck Depression Inventory (BDI)

85   would be associated with a greater risk of suicide in middle-aged Korean men, specifically

86   Korean veterans of the Vietnam War. The secondary aim was to evaluate the diagnostic

87   properties of the BDI for predicting suicide death, such as sensitivity, specificity, and area under

88   the receiver operating characteristics (ROC) curve (AUC). The tertiary aim was to examine

89   whether risk factors such as self-rated health status, drinking, BMI, marital status, and socio-

90   economic status were independently associated with suicide after adjusting for each other and for

91   depressive symptoms. Korean Vietnam War veterans have had the same suicide mortality (crude

92   mortality, 35.4 deaths per 100,000 person-years during 1992-2005; standardized mortality

93   ratio=0.95, 95% CI=0.89-1.02) expected from the general Korean population in previous

94   research (Yi & Ohrr 2011).

95

96   **Methods**

97   ***Study participants***

98   We identified 187,897 Vietnam War veterans during 1999-2000 with the cooperation of

99   the Ministry of Defense and then the Ministry of Government Administration and Home Affairs

100   (Yi et al. 2014). Among them, 20,000 veterans were selected by a simple random sample. After

101   excluding 1737 individuals who were deceased, had emigrated to another country, or had an

102   unknown residency status as of July 2000, 18,263 were recruited for a health exam or survey.

103   Among them, randomly selected 5000 veterans (health exam group) were invited to a health

104   exam and a survey by mail on May 4, 2001, and the other 13,263 (survey-only group) received a

105   survey sent out on July 20, 2001. In the end, 10,238 veterans who participated in the health exam

106 or survey (health exam group, n=2005; survey-only group, n=8233) were followed up on suicide

107 mortality until December 31, 2008 (Figure S1). The veterans were provided with a written

108 summary about the research and an invitation to the health exam by post. Return of the postal

109 survey and voluntary participation of health exam were considered implied consent. This study

110 was approved by the Institutional Review Board of Kwandong University (Approval No: KD-13-

111 0105).

112

113 ***Follow-up and ascertainment of suicide death***

114   The deaths from suicide were ascertained from the 2001-2008 death records of the

115 National Statistical Office. When veterans had emigrated to another country or their residential

116 status was unknown between enrollment and December 2008, the changed date of the residential

117 status was considered the date of a loss to follow-up. A complete follow-up was made for 10,181

118 veterans (99.4%). Suicide was identified by the International Classification of Diseases, 10th

119 Revision codes X60-X84.

120

121 ***Measures of depressive symptoms***

122   The self-administered BDI, with 21 items each measured on a 4-point Likert scale (0-3)

123 and a total score range of 0-63, was used to assess depressive symptoms.(Beck et al. 1961) The

124 previous Korean-language version of the BDI, translated by two psychiatrists and a clinical

125 psychologist,(Rhee et al. 1995) was modified for the present study by two medical doctors, and

126 several graduate students of public health. The internal consistency assessed by Cronbach's

127 alpha was 0.937 in a complete data analysis.

128   The participants were categorized into two groups (no-to-moderate [0-30] and severe [31-

129 63]) and five groups (depressive symptoms [BDI score]: none [0-13], mild [14-21], moderate

130 [22-30], severe [31-39], and extreme [40-63]) based on quartiles and the highest decile of BDI

131 score. For a sensitivity analysis, they were also categorized based on cut-off score in previous

132 research into two groups (no-to-moderate [0-29] and severe [30-63]) and five groups (none [0-9],

133 mild [10-16], moderate [17-29], severe [30-40], and extreme [41-63]) (Al-Turkait & Ohaeri 2010;

134 Beck & Steer 1987; Smarr & Keefer 2011).

135

136 ***Measures of other risk factors***

137 Self-rated health, smoking, drinking ("Do you drink alcohol?" [Yes, No. I quit drinking,

138 or Never]), marital status, educational status, and household monthly income were collected

139 through self-reported survey. Self-rated health was assessed by a 5-point Likert scale. Weight

140 and height were measured among participants in health exams, while they were self-reported

141 among the survey-only group. The BMI was obtained from weight divided by the height squared

142 (kg/m^2).

143

144 ***Statistical Analysis***

145 Among the 10,238 participants, 3156 (30.8%) had one or more missing baseline data

146 including smoking (n=55), drinking (n=84), BMI (n=102), self-rated health (n=186), marital

147 status (n=143), educational status (n=195), income status (n=426), or at least one item on the

148 BDI (n=2761). Multiple imputation was performed to estimate the missing baseline data with

149 SAS PROC MI. Markov chain Monte Carlo sampling methods and an expectation-maximization

150 algorithm with a separate chain for each imputation (chain=multiple) were used. 100 imputations

151 were made using all variables analyzed in this study and other variables including military

152 variables (such as Agent Orange exposure index, unit served and military rank during Vietnam

153 service), and self-rated health compared to the same age group. Imputation methods including

154 number of imputations were selected to minimize imputation variance and to ensure the

155 confidence intervals and p values to be reliable (White et al. 2011).

156   The chi-squared test and analysis of variance were performed to compare individual

157 characteristics by two categories of depressive symptoms. A Cox proportional hazards model

158 including various risk factors was implemented to calculate hazard ratios (HRs). The variables

159 included in the Cox model were age at enrollment (years), smoking (current, past, and never

160 smoker), drinking (current, past, and never drinker), BMI (<18.5, 18.5-22.9, 23-24.9, 25-26.9,

161 ≥27), self-rated health (very good or good, fair, poor, and very poor; since no suicide death was

162 observed in those with very good health, those with very good and good health were combined

163 into one group), marital status (living with spouse, living without spouse), education (elementary

164 school or less, middle school, and high school and more), monthly income (less than 1,000,000

165 Korean won [KRW], 1,000,000-1,990,000 KRW, and 2,000,000 KRW and more, where 1300

166 KRW was about one US dollar as of June, 2001) and participant group (survey-only group and

167 health exam group).

168   The sensitivity (proportion of true positives [suicides] correctly identified) and specificity

169 (proportion of true negatives [non-suicides] correctly identified) at a cut-off score of 31 (or 30)

170 were estimated and their 95% CI was calculated using the Wilson score method (Newcombe

171 1998). The AUC was estimated using Proc Logistic (ROC statement) and averaged over 100

172 imputed data. A diagnostic test with an AUC value of 1.0 or 0.5 represents a perfect test or an

173 uninformative test, respectively. Predictive values were not calculated because they are of little

174 use to other populations with different suicide mortality.

175   The test for trend was done to demonstrate the dose-response relationships of the risk

176   factors (every variable with three or more categories) to suicide by analyzing categories of a risk

177   factor as ordinal variables. Additionally, analyses in all of the participants with follow-up until

178   2004, and analyses in survivors as of January 1, 2005 with follow-up until 2008, were done to

179   evaluate whether the association of depressive symptoms and other risk factors with suicide, and

180   the diagnostic characteristics of the BDI differ by follow-up period, and these calculations served

181   as sensitivity (robustness) analyses. To test the non-response bias and potential harm of the

182   screening for suicide, the suicide mortality and age-adjusted hazard ratio (HR) of suicide of the

183   participants (n=10,238) were compared with those of the non-participants (n=7867).

184   All statistical analyses were performed using SAS version 9.4 (SAS Inc., Cary, NC,

185   USA). The p-value was calculated with two-sided tests. The proportional hazard assumption was

186   tested using Martingale residuals and Schoenfeld residuals in complete data and imputed data

187   analyses. No variables had evidence of a violation of the proportional hazard assumption except

188   for a dummy variable of self-reported health (very good or good, only one suicide) in the

189   complete data analysis.

190

191   **Results**

192   *Characteristics of participants*

193   The total follow-up person-years was 73,916. 41 men died by suicide (5.5 per 10,000

194   person-years, 95% CI=4.1-7.5) during around 7.5 years of follow-up. The average (SD) age of

195   the Korean veterans was 56.4 (3.7) years at enrollment. Participants with severe depressive

196   symptoms were slightly younger than those with no-to-moderate symptoms, and they tended to

197   be current smokers, past drinkers, slim, living without a spouse, unhealthy, and have little formal

198   education and low earnings, compared to those with no-to-moderate symptoms (Table 1).

199

200   ***Associations of depressive symptoms and other risk factors with suicide***

201   In the unadjusted analysis, participants with severely depressive symptoms had a higher

202   HR of suicide than those with no-to-moderately depressive symptoms, and increasing HR of

203   suicide was associated with increasing depressive symptoms across the five categories of

204   intensity (p for trend <.001) (Table 2, Table S1). Additionally, higher suicide risk correlated with

205   a higher BDI score. After adjustment for various risk factors for suicide, the association of

206   depressive symptoms with suicide (although somewhat weaker than before) remained strong.

207   Unadjusted HRs indicated that very poor health (p<0.001), low education (p=0.002), low

208   household income (p=0.03), past drinking (p=0.07) and living without a spouse (p=0.09) were

209   associated with a higher risk of suicide, while obesity (BMI≥25) with a lower risk of suicide

210   (p=0.07) (Table 3). In the unadjusted trend test across categories of risk factors, poorer self-rated

211   health, lower education, and lower income were associated with a higher risk of suicide, while

212   more obese subjects were less likely to die by suicide. After adjustment for depressive symptoms

213   and other risk factors, very poor health, low education, and past drinking were still related to a

214   higher HR of suicide, while BMI and marital status were not associated with suicide (Table 3,

215   Table S6). In the adjusted trend test across categories of risk factors, only educational status

216   remained statistically significantly associated with suicide (p=0.03).

217   The associations of depressive symptoms with suicide were generally stronger during the

218   earlier period of follow-up than during the later period (Table 4, Table S2). The associations of

219   most of the other risk factors with suicide were also generally stronger (although none of them

220   had a p-value below 0.05 due to the small number of suicide deaths) during the earlier period

221   than the later period, while educational status was more strongly associated with suicide during

222   the later period than the earlier period (Table S3).

223

Diagnostic properties of the Beck Depression Inventory

225   For the unbinned total score and cut-off score of 31 or above, respectively, the AUC

226   values were 0.71 and 0.69 during the follow-up, and they were higher during the first half of

227   follow-up (2001-2004) than during the latter half (2005-2008) (Table 5, Figure S2, Table S4).

228   The overall sensitivity and specificity of the 2-group test at a cut-off score of 31 or above on

229   predicting suicide during 7.5 years of follow-up were 66% (95% CI=50-78) and 73% (95%

230   CI=72-74), respectively. The sensitivity decreased over the follow-up period, while the

231   specificity remained relatively unchanged. The AUC analyses showed that cut-off score of 31 or

232   above had the highest AUC values across cut-off scores of BDI for predicting suicide (Table S5).

233

Discussion

Depressive symptoms and suicide

236   Severe depressive symptoms were more strongly associated with suicide compared to no-

237   to-moderate depressive symptoms in this study, after adjusting for other potential risk factors for

238   suicide, although the association was weaker than that of depressive disorders examined in

239   psychological autopsy studies (Yoshimasu et al. 2008). The association of depressive symptoms

240   with suicide was stronger during the first 3.5 years of follow-up than during the latter 4-year

241   period in accordance with previous research (Bramness et al. 2010; Sun et al. 2012). This

242   indicates that a cohort study of long follow-up with one baseline assessment and without

243   considering the change in depressive symptoms during the follow-up, may underestimate the

244   effects of depressive symptoms on suicide (Bramness et al. 2010). Additionally, in the current

245   study, higher suicide risk was associated with a higher depressive symptom score in accordance

246   with previous cohort studies in general-risk populations (Bramness et al. 2010; Sun et al. 2012).

247   Overall, this prospective cohort study confirmed that depressive symptoms were a strong

248   predictor of future suicide.

249

250   ***Diagnostic characteristics of Beck Depression Inventory***

251   To the best of our knowledge, this is the first study that has reported diagnostic

252   characteristics for suicide death in a general-risk population. Although studies on suicidal

253   ideation or attempt have been performed, attempters may share some properties with suicides;

254   however, they may be two different populations, especially among males (Isometsa & Lonnqvist

255   1998; Parra Uribe et al. 2013). The sensitivity and specificity at the cut-off score of 31 or above

256   of the BDI in Korean middle-aged men for predicting future suicide, especially during the earlier

257   period of follow-up, was comparable at least to those of other tools such as the Beck

258   Hopelessness Scale (sensitivity 80%, specificity 42%) (McMillan et al. 2007), Beck Suicide

259   Intent Scale (sensitivity 77%, specificity 49%) (Harriss & Hawton 2005), and a tool constructed

260   from stepwise discriminant analysis of various instruments (sensitivity 56%, specificity

261   74%)(Pokorny 1983) that were mainly applied to inpatients with psychiatric disorders or those

262   who had done self-harm. They are also comparable to those of BDI at cut-off score of 23 or

263   above in psychiatric outpatients (sensitivity 76%, specificity 62%) (Beck et al. 1990) and those

264   of BDI-II at cut-off score of 31 or above in prisoners (for attempted suicide or self-harm incident;

265   sensitivity 80%, specificity 69%) (Perry & Gilbody 2009). Although there is a room for

266   improvement, the BDI may have an acceptable sensitivity and specificity as a suicide risk

267 assessment tool.

268   It has been reported that male patients rarely initiated suicide-related discussions with

269 their physician (Vannoy & Robins 2011), while physicians were also reluctant to discuss suicide

270 for various reasons including the fear of stimulating suicide in patients with depression by asking

271 about it (Crawford et al. 2011; Schulberg et al. 2004). The suicide mortality of the participants in

272 the present study (41 suicides, 5.5 suicides per 10,000 person-years) was not higher than that of

273 the non-participants (34 suicides in 7867 men, 6.0 [95% CI=4.3-8.4] suicides per 10,000 person-

274 years), and the age-adjusted hazard ratio of suicide (0.93, 95% CI=0.59-1.46) also was not higher

275 in the participants compared to non-participants. These results suggest that asking people about

276 depressive symptoms using the BDI does not seem to be associated with a higher risk of suicide.

277

278 ***Other risk factors and suicide***

279   Although physical health, marital status, drinking, and socioeconomic status have been

280 associated with suicide in previous research, their association with suicide has rarely been

281 examined after adjustment for depression (Conwell et al. 2002), especially in a prospective

282 manner. Marital status was not associated with suicide in clinical patients with depression in a

283 systematic review (Hawton et al. 2013), and it was also not associated with suicide after

284 adjusting for other risk factors in a large psychological autopsy study in China (Phillips et al.

285 2002). Although BMI was inversely associated with suicide in large cohort studies, depressive

286 symptoms were not accounted for in those studies (Jee et al. 2011; Mukamal et al. 2010). A

287 review also concluded that much, if not all, of the association of physical health factors with

288 suicide was mediated by affective disorders (Conwell et al. 2002).

289   In prospective studies, evidence linking regular alcohol consumption with suicide death is

290   lacking (Jee et al. 2011; Mukamal et al. 2007), except for serious alcohol-related conditions such

291   as alcohol use disorder and very heavy drinking (Akechi et al. 2006; LeardMann et al. 2013).

292   Meanwhile, higher risks of suicide in past drinkers have also been identified in Japanese middle-

293   aged men (depression was not adjusted for, though, in the Japanese study) (Akechi et al. 2006).

294   As for socioeconomic status, despite a strong dose-response relationship of both educational

295   status and household income with suicide in unadjusted analysis, the association of household

296   income was substantially weakened after adjustment for self-rated health and depressive

297   symptoms, because household income status was strongly associated with self-rated health and

298   depressive symptoms in the current study.

299   Our findings suggest that very poor health, low education, and drinking status may be

300   independently associated with suicide, while good or fair health, BMI, household income, and

301   marital status may not be factors independently related factors to suicide. Instead, the

302   associations of these non-independent factors with suicide may rather be mediated through

303   depressive symptoms and other factors in Korean middle-aged men.

304

305   ***Limitations of the study***

306   Despite of the strengths of the study, such as nearly complete prospective follow-up on

307   suicide using national mortality data and the analysis of the diagnostic characteristics of a

308   potential suicide risk assessment tool on suicide death in a general-risk population, this study has

309   some limitations. First, our findings are based on 41 suicides, so the study may have lacked

310   statistical power in some analyses. In particular, risk factors having a weak association with

311   suicide may not be clearly identified in this study. Second, in cohort studies, nonresponse to the

312   baseline survey may introduce bias. However, the suicide mortality of 7867 (43%) non-

313   respondents did not differ from that of participants, and item non-response to questionnaires was

314   minimized with multiple imputation of 100 datasets. Third, the validity of the suicide death listed

315   on death certificates was not examined separately. Since any misclassification on the suicide

316   death could be most likely non-differential according to depressive symptoms, potential

317   misclassifications would not substantially overestimate the hazard ratios.

318   It may be a limitation of its generalizability that this study's participants were Korean

319   Vietnam War veterans. However, among US military personnel, mental health problems but not

320   military-specific variables were independent risk factors for suicide (LeardMann et al. 2013).

321   Additionally, the suicide mortality in Korean Vietnam War veterans did not differ from that from

322   the male population of Korea (Yi & Ohrr 2011). Therefore, we believe that performing the study

323   with Vietnam War veterans did not substantially hinder its generalizability. Meanwhile, although

324   psychological disorders such as depression have been universal risk factors among many cultural

325   groups (Sun et al. 2012; Zhang et al. 2004), the strength of association and the association in

326   itself of some risk factors with suicide may differ by ethnicity, culture, age, and gender

327   (Bjerkeset et al. 2008; Goldston et al. 2008; Milner et al. 2013; Sun et al. 2012; Zhang et al.

328   2004). Therefore, some results in Korean middle-aged men may not be generalizable to other

329   ethnic, cultural, or age groups, or to females.

330

331   **Conclusions**

332   Although the association was weaker than estimated from psychological autopsy studies,

333   this study prospectively confirmed that depressive symptoms are a strong independent predictor

334   of suicide. The sensitivity and specificity at the BDI cut-off score of 31 or above in Korean

335   middle-aged men for predicting future suicide during 2001-2008 were 66% (95% CI=50-78) and

336 73% (95% CI=72-74), respectively. They were 75% (95% CI=50-90) and 73% (95% CI=72-74),

337 respectively, for predicting future suicide during 2001-2004. BDI may have an acceptable

338 sensitivity and specificity as a suicide risk assessment tool to help physicians and public health

339 professionals identify individuals with depression and suicidal potential. This study also suggests

340 that very poor self-rated health, drinking status and low education, but not marital status and

341 BMI, may be independent predictors of suicide.

342

343   Acknowledgement

344   The authors truly thank the staff of the National Statistical Office of Korea for providing the

345   national mortality data.

346

347   Conflict of interest statement: None.

Characteristics of the Korean middle-aged male participants by depressive symptoms

BDI, Beck Depression Inventory; BMI, body mass index; SD, standard deviation. a. Combined p-value of chi-squared analysis over multiple imputed data. b. Combined p-value of analysis of variance over multiple imputed data. c. Sum of the number of participants from both groups may not equal the total due to rounding of averages over multiple imputed data. d. 1300 Korean Won was about one US dollar as of June, 2001 e. Cut-off score based on quartiles and the last decile. f. Cut-off score based on previous research.

2 **Table 1. Characteristics of the Korean middle-aged male participants by depressive symptoms**

Characteristics		Total	No to moderate symptoms	Severe symptoms	p value[a]
		Number (%)

Hazard ratios of suicides by depressive symptoms in Korean middle-aged men (n=10,238)[a]

a. Hazard ratios were calculated using a Cox proportional hazards model over multiple imputed data. b. Adjusted for age at enrollment, smoking status, drinking status, body mass index, self-rated health, marital status, educational status, household monthly income and participant group. c. Number of suicides may not match those of the other groups of depressive symptoms due to rounding of averages over multiple imputed data. d. Cut-off score based on quartiles and the last decile. e. Five categories of Depressive symptoms were analyzed as ordinal variables.

2 **Table 2. Hazard ratios of suicides by depressive symptoms in Korean middle-aged men (n=10,238)[a]**

Categories of depressive symptoms (score)		No. of suicides[c]	Unadjusted analysis		Adjusted analysis[b]	
			p-value	HR (95% CI)	p-value	HR (95% CI)

Adjusted hazard ratios of suicides by depressive symptoms according to follow-up period[a]

BDI, Beck Depression Inventory; CI, confidence interval; HR, hazard ratio. a. Hazard ratios were calculated using a Cox proportional hazards model over multiple imputed data, after adjustment for age at enrollment, smoking status, drinking status, body mass index, self-rated health, marital status, educational status, household monthly income and participant group. b. Number of suicides may not match those of the other groups of depressive symptoms due to rounding of averages over multiple imputed data. c. Cut-off score based on quartiles and the last decile. d. Five categories of depressive symptoms were analyzed as ordinal variables.

2 **Table 4. Adjusted hazard ratios of suicides by depressive symptoms according to follow-up period[a]**

Categories of depressive symptoms (score)		From 2001 to 2004 n=10,238			From 2005 to 2008 n=9,877		
		No. of suicides[b]	p-value	HR (95% CI)	No. of suicides[b]	p-value	HR (95% CI)
Total BDI score (0-63)	Five-score increase	16	**0.02**	1.3 (1.1-1.8)	25	0.16	1.1 (1.0-1.4)
2-group analysis[c]	No-to-moderate (0-30)	4		1.0 [Reference]	10		1.0 [Reference]
	Severe (31-63)	12	**0.02**	5.2 (1.3-19.8)	15	0.06	2.7 (0.9-7.6)
5-group analysis[c]	No (0-13)	1		1.0 [Reference]	2		1.0 [Reference]
	Mild (14-21)	3	0.70	1.6 (0.1-17.6)	3	0.87	1.2 (0.2-8.4)
	Moderate (22-30)	1	0.99	0.0	4	0.80	1.3 (0.2-9.2)
	Severe (31-39)	4	0.33	3.3 (0.3-37.8)	8	0.21	3.3 (0.5-20.9)
	Extreme (40-63)	8	0.13	7.1 (0.6-88.3)	7	0.23	3.3 (0.5-23.8)
	Trend test[d]	16	**0.03**	1.9 (1.1-3.3)	25	0.09	1.4 (0.9-2.2)

Diagnostic characteristics of Beck Depression Inventory by follow-up period in Korean middle-aged men

AUC, area under the receiver operating characteristics curve; CI, confidence interval. a. Cut-off score based on third quartile. b. 95% CI was calculated using Wilson score method. c. Proportion of true positives (suicides) correctly identified. d. Proportion of true negatives (non-suicides) correctly identified. e. A diagnostic test with an AUC value of 1.0 or 0.5 represents a perfect test or an uninformative test, respectively.

2 **Table 5. Diagnostic characteristics of Beck Depression Inventory by follow-up period in Korean middle-aged men**

Follow-up period	Characteristics	Cut-off of 31 or above[a] Rate (95% CI)[b]	Unbinned Total Score Rate (95% CI)[b]
From 2001-2008	Sensitivity[c]	66 (50-78)	
	Specificity[d]	73 (72-74)	
	AUC[e]	0.69 (0.62-0.77)	0.71 (0.63-0.80)
From 2001-2004	Sensitivity[c]	75 (50-90)	
	Specificity[d]	73 (72-74)	
	AUC[e]	0.74 (0.63-0.85)	0.75 (0.61-0.90)
From 2005-2008	Sensitivity[c]	60 (41-76)	
	Specificity[d]	74 (73-75)	
	AUC[e]	0.67 (0.57-0.77)	0.69 (0.58-0.80)
