Despite considerable tolerance to salt and alkali stress, *Leymus chinensis* populations on the southwestern Songnen Plain in northern China are threatened by increasing soil salinity and alkalinity. To explore the species' responses to saline-alkali stress, we grew it in soils with varying concentrations of nitrogen (N) and phosphorus (P) while applying varying levels of saline-alkali stress (increasing in 14-, 17- or 23-day intervals). We measured the plants' contents of N and P, and the N:P ratio, and calculated their homeostasis indices ( $H_N$ ,  $H_P$  and  $H_{N:P}$ ) under each nutrient and saline-alkali stress treatment. We also calculated the specific growth rate of aboveground parts of *L. chinensis* under each treatment, and investigated its relationship with the N:P ratio. The N content was found to be more sensitive to saline-alkali stress than the P content. The N and P contents were highest and the N:P ratio was stable at pH 8.4. At both pH 8.1 and 8.4,  $H_{N:P} > H_N > H_P$ , but the indices and their relations differed at other pH values. In conclusion, when *L. chinensis* plants lack N, applying N fertilizer will be extremely efficient, but excessive N concentrations in the environment will inhibit their growth. Conversely, applying excess P-fertilizer will not inhibit growth. The optimal concentrations of N and P appeared to be 16 and 1.2 mmol/L, respectively. When the *L. chinensis* plants were N- and P-limited, the specific growth rate correlated positively with N:P, when limited by N it correlated positively with the environmental N concentration, and when limited by P it was weakly positively correlated with the environmental P concentration. Exposure to saline-alkali stress for the shortest (14 d) incremental interval had weaker effects on the plants.

## 1 INTRODUCTION

2 Ecological stoichiometry (ES) is the study of the balances of elements and energy in ecosystems,  
3 which have profound effects on living organisms, their interactions, and associated ecological  
4 processes (Cambardella and Elliott, 1993; Elser *et al.*, 2000; Güsewell, 2004; Bradshaw *et al.*,  
5 2012; Wang *et al.*, 2018). ES theory focuses primarily on elements required by all living  
6 organisms, so it can be readily generalized across taxa and systems (Sanders and Taylor, 2018).  
7 A key concept is homeostasis: a system's capacity to maintain constant conditions internally  
8 when external conditions vary, a fundamental property of organisms (Kooijman, 1995; Cooper,  
9 2008; Halvorson *et al.*, 2019). Characterizing both the degrees and consequences of homeostasis  
10 is important for understanding responses to environmental changes (Meunier *et al.*, 2014;  
11 Halvorson *et al.*, 2019). In ES-based analyses, the homeostasis concept is used to infer organisms'  
12 responses to changes in ratios of elemental resources, and predict their feedback effects on  
13 resources' availability through changes in the acquisition, storage, and release of nutrients,  
14 particularly limiting nutrients such as nitrogen (N) and phosphorus (P) (Halvorson *et al.*, 2019).  
15 A general assumption is that stoichiometric homeostasis is stronger in heterotrophs than  
16 autotrophs (Sterner and Elser, 2002), so environmental stoichiometry is believed to be reflected  
17 more closely by plant and algal stoichiometry than by animals' stoichiometry. However, (Yu *et*  
18 *al.*, 2011) found that homeostatic regulation of N and P varies widely in vascular plants, so the  
19 patterns and processes involved are complex and far from fully understood.

20 Another core concept of ES is the growth rate hypothesis (GRH), which postulates that  
21 organisms' growth rates correlate positively with their phosphorus (P) contents because P is  
22 essential for the ribosomal RNA production needed to sustain growth (Moody *et al.*, 2017) and  
23 for many other processes including photosynthesis, respiration, enzyme production, and

24 generation of ATP (Li *et al.*, 2019). Thus, organisms with high growth rates have high nutrient  
25 demands and (*inter alia*) low tissue C:nutrient ratios, low N:P ratios, and potentially competitive  
26 advantages in high-P environments, but disadvantages in low-P environments. Hence, plants'  
27 abilities to compete for nutrients depend on both their tissue nutrient contents and life history  
28 traits (Mulder and Elser, 2009; González *et al.*, 2010; Sanders and Taylor, 2018).

29 ES has been widely applied in various areas of plant science, including in studies on the  
30 growth of individual plants, population dynamics, limiting elements, succession, and stability of  
31 vegetative communities (Güsewell, 2004). Soil is a key component of terrestrial ecosystems  
32 because it supports numerous ecological processes (Normand *et al.*, 2017; Wang *et al.*, 2018),  
33 plays crucial roles in plant growth, and directly affects plant communities' composition, stability,  
34 and succession (Wardle *et al.*, 2004). N and P are key elements with profound effects on plants  
35 growth because they play major roles in microbial dynamics, litter decomposition, food webs,  
36 and the accumulation and cycling of nutrients in soil (Elser *et al.*, 2003; Griffiths *et al.*, 2012).  
37 Moreover, dynamic changes in concentrations and distributions of soil nutrients are highly  
38 interactive and have tightly integrated effects on ecological processes (Wang *et al.*, 2018).  
39 Changes in plants' N:P ratios (*inter alia*) may thus reflect adaptations to environmental  
40 conditions (Tang *et al.*, 2018), including (of particular interest here) salinity and alkalinity.

41 According to incomplete UNESCO and FAO statistics, the area of saline-alkali land is  
42 growing globally (Kerr, 2017) and amounts to  $9.5438 \times 10^8$  hm<sup>2</sup>, including  $0.9913 \times 10^8$  hm<sup>2</sup> in  
43 China (Li *et al.*, 2017a). This is a severe problem because salinization impairs seed germination,  
44 root extension, and plant development, resulting in land degradation, reductions in cultivated  
45 land quality, and limitation of agricultural development (Wu *et al.*, 2016). Most saline-alkali soil  
46 in northeast China is on the Songnen Plain, and its area is increasing through grassland

47 salinization (Li, 2000). The dominant species in saline-alkali grassland on the Songnen Plain is  
48 *Leymus chinensis* (*L. chinensis*), which can provide high yields of high quality gramineous  
49 forage if the salinity and alkalinity are not too severe. It can play an important role in restoring  
50 saline-alkali land (Liu *et al.*, 2014), but there is a need to reduce the salinity and alkalinity of  
51 affected grassland and improve the species' yield and stress tolerance. It is therefore important to  
52 study the ecological stoichiometric homeostasis of N and P, associated ecological processes, and  
53 the effects of saline-alkali stress on the growth rate and survival strategy of *L. chinensis*.

54 Previous research on saline-alkali tolerance in *L. chinensis* has mainly focused on  
55 physiological processes (such as the osmoregulatory roles of ions, organic acids, soluble sugars  
56 and other substances) and morphological traits (such as tiller buds, root distribution, and  
57 rhizomes' internode length and branching angles) (Zheng *et al.*, 2017). C, N, and P dynamics in  
58 soil-*L. chinensis* systems have also been addressed (Li *et al.*, 2016; Li *et al.*, 2017b; Li *et al.*,  
59 2018). However, soil salinization is a long-term dynamic process, and there is relatively little  
60 information on relations between the effects of saline-alkaline stress (and of variation in its  
61 duration) and ecological stoichiometric characteristics. Here, we demonstrate that the ecological  
62 stoichiometric characteristics of *L. chinensis* are influenced by the duration of saline-alkali stress  
63 and the available concentrations of both N and P.

## 64 MATERIALS AND METHODS

### 65 The experimental site

66 We performed experiments in a polytunnel on the campus of the College of Earth Sciences, Jilin  
67 University, Changchun, Jilin Province, northeast China. This is in the north temperate  
68 continental climatic zone, which has four distinct seasons. The mean annual temperature and  
69 precipitation are 4.8°C and 567 mm, respectively, and mean winter and summer temperatures are

70 -14 and 24 °C, respectively (Zhang *et al.*, 2017).

## 71 **Experimental design**

### 72 **Experimental preparation**

73 Experiments were performed from August 7 to November 6, 2017. To minimize interference  
74 from impurities in the soil, the substrate used was fine nutrient-poor sand, sieved with 10 and 75  
75 mesh sieves and thoroughly washed with distilled water to minimize its nutrient content. To  
76 avoid effects of different soil loadings on growth of experimental plants, the sand was air-dried  
77 and equal portions were placed in plastic flowerpots (diameter 30 cm, height 23 cm). The  
78 portions were roughly equivalent to two-thirds of the pots' volume. Small holes in the bottom of  
79 each flowerpot were sealed with waterproof tape. *L. chinensis* seeds were immersed in water for  
80 48 hours and air-dried in the dark to avoid dormancy and increase the germination rate, then  
81 about 100 seeds were sown evenly in each flowerpot. About seventy percent of the seeds  
82 survived, and all pots were similar with respect to the number, size, and vitality of surviving  
83 seedlings.

### 84 **N and P addition**

85 After the seeds germinated, a 200 ml portion of Hoagland's nutrient solution (obtained from  
86 South China Agricultural University) with adjusted N and P concentrations was added to each  
87 pot once every two days. The elemental composition of Hoagland's solution is described in  
88 detail elsewhere (Li *et al.*, 2018); briefly, the version used here contained  $\text{Ca}(\text{NO}_3)_2$  (945 mg/L),  
89  $\text{KNO}_3$  (607 mg/L),  $\text{NH}_4\text{H}_2\text{PO}_4$  (115 mg/L),  $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$  (493 mg/L) and various microelements.  
90 In five sets of nine pots, the N concentration was adjusted using ammonium nitrate to establish  
91 five N concentration treatments (2, 4, 8, 16, and 24 mmol/L) in which the concentration of P was  
92 fixed at 1 mmol/L. In another five sets of nine pots, the P concentration was adjusted using

93 potassium dihydrogen phosphate to establish five P concentration treatments (0.3, 0.6, 1.2, 2.4,  
94 and 4.8 mmol/L) in which the concentration of N was fixed at 14 mmol/L. The experiment thus  
95 involved 10 nutrient treatments and a total of 90 pots (10 treatments×3 replicates×3 salinity  
96 stress intervals). The N and P concentration gradients were set on the basis of previously  
97 reported results (Yu et al., 2011).

### 98 **Saline-alkali stress**

99 On 7 Aug 2017, after the *L. chinensis* plants had grown to adulthood, plants in triplicate pots  
100 were subjected to the saline-alkali stress treatments shown in Table 1, by adding NaHCO<sub>3</sub> to the  
101 previously described treatment solution to simulate various degrees of land salinization  
102 encountered in the western regions of Jilin Province. To avoid excessively stressing the plants,  
103 the pH was increased at intervals of 14, 17, or 23 days. For the 14-day interval treatment, the pH  
104 was raised from 7.5 to 8.1, and then to 8.4, 8.7, and finally 9.3. For the 17-day interval treatment,  
105 the pH was raised from 7.5 to 8.1 and then to 8.4 and finally 8.7. For the 23-day interval  
106 treatment, the pH was raised from 7.5 to 8.1 and finally to 8.4. Aboveground parts of *L.*  
107 *chinensis* plants subjected to these treatments were harvested according to the schedule shown in  
108 the table.

### 109 **Sample collection and testing methods**

110 Aboveground parts of *L. chinensis* plants were cut according to the harvesting schedule shown in  
111 Table 1. The samples were rinsed with distilled water, dried with absorbent paper, deactivated  
112 for 15 min in a dry air oven (105 °C) and dried for 12 h at 65 °C to eliminate water completely.  
113 After cooling the samples to room temperature, they were weighed, crushed, screened with a 100  
114 mesh sieve, and finally quartered. The resulting sub-samples were then packed in sealed bags for  
115 analysis.

116 Total N and total P in the *L. chinensis* samples were respectively determined by Chinese  
117 standard methods LY/T 1269-1999 (using a SAN++ Continuous Flow Analyzer; Skalar,  
118 Netherlands) and LY/T 1270-1999 (using an ICPS-7500 inductively coupled plasma atomic  
119 emission spectrometer; Shimadzu, Kyoto, Japan).

## 120 **Data analysis**

121 The acquired data were statistically analyzed using Excel 2010 and SPSS 24 (SPSS Inc., USA).

122 Homeostasis indices were calculated using the model  $y = cx^{\frac{1}{H}}$ . Here,  $x$  is the measured content of  
123 an element in the soil,  $y$  is the measured content of the same element in *L. chinensis*,  $c$  is a  
124 constant coefficient, and  $H$  is the homeostasis index. The results were visualized using Sigmaplot  
125 12.5 (Systat Software, Inc.). We calculated growth rates ( $\text{day}^{-1}$ ) based on recorded changes in dry  
126 mass and instantaneous growth rates using the equation  $u = \ln(M_t / M_0) / t$ , where  $u$  is the growth  
127 rate ( $\text{day}^{-1}$ ),  $M_t$  and  $M_0$ , are the final and initial dry mass, respectively, and  $t$  is experiment  
128 duration in days. Details of several statistical analyses are included in Appendix 1 and Appendix  
129 2.

## 130 **RESULTS**

### 131 **Effects of incremental increases in saline-alkali stress on N, P contents and N:P ratios**

132 The 14-day stress increment yielded the highest N and P contents in the plants when the N  
133 concentration in the substrate was low (2-8 mmol/L), but not when the N concentration in the  
134 substrate was higher (16 or 24 mmol/L). The variation in the N and P contents, and the N:P ratio,  
135 was similar under all three stress intervals: the N content and N:P ratio were highest with 17-day  
136 intervals, while the P content was highest with 14-day intervals (Fig. 1).

### 137 **Homeostasis characteristics of *L. chinensis***

138 The homeostasis index of N ( $H_N$ ) in *L. chinensis* ranged from 2.35 to 7.25, and first rose then fell

139 as salinity-alkalinity increased, independently of interval length (Fig. 2). Under the 14-, 17- and  
140 23-day intervals,  $H_N$  ranges were 3.10-7.25, 2.35-5.36 and 3.19-3.87, respectively. It was  
141 consistently highest at pH 8.4, and higher at pH 8.1 and 8.7 than at pH 7.5 and 9.3 (Table 2).  
142 Under the 14-day stress intervals, the changes in  $H_N$  were moderate, and  $H_N$  was high at all pH  
143 values. The index was lower at both pH 8.1 and 8.7 under the 17- and 23-day intervals.

144 Under our treatments,  $H_P$  of *L. chinensis* ranged from 2.60 to 5.33. Under all three saline-  
145 alkali stress intervals, it first rose and then declined (Fig. 2). Under the 14-, 17-, and 23-day  
146 saline-alkali stress intervals, the ranges of  $H_P$  were 2.84-5.33, 2.65-4.90 and 2.60-4.10,  
147 respectively, and the highest values of  $H_P$  occurred at pH 8.1, 8.7, and 8.1, respectively (Table 2).  
148 At pH 8.1,  $H_P$  was significantly higher under 14-day intervals than under longer intervals. At pH  
149 8.4, it was highest under 17-day intervals, and at pH 8.7 it declined in the order 17-day > 14-day >  
150 23-day intervals.

151 Plants have strong self-regulating mechanisms, and generally keep their N:P ratios within a  
152 narrow range by adjusting their N and/or P contents in response to environmental changes. For  
153 example, the  $H_{N:P}$  of *L. chinensis* varied from 3.06 to 9.23 in plants exposed to different P  
154 concentrations, while its ranges under the 14-, 17- and 23-day stress interval regimes were 3.15-  
155 9.23, 3.11-6.83 and 3.06-6.44, respectively, and its peak values occurred at pH 8.4, 8.4, and 8.1,  
156 respectively (Table 2). *L. chinensis* plants are thus able to effectively regulate their N:P ratio in  
157 the pH range 8.1 to 8.7, but less so at pH 7.5 and 9.3.

### 158 **The specific growth rate of *L. chinensis***

159 The specific growth rate of the plants rapidly increased then decreased as the N concentration in  
160 the substrate increased, peaking at 16 mmol/L (Fig. 3). This indicates that when *L. chinensis*  
161 plants lack N, initial N addition will be extremely efficient, but saturating or excessive amounts

162 will not promote (and may even hinder) further growth. Conversely, the plants' specific growth  
163 rate first increased, then decreased, and then increased again with increases in environmental P  
164 concentration. Specifically, it was lowest at a P concentration of 2.4 mmol/L, and higher at both  
165 1.2 and 4.8 mmol/L. Thus, high addition of P is beneficial for plant growth but may lead to  
166 wastage of resources. Therefore, the optimum P concentration under our experimental conditions  
167 was 1.2 mmol/L.

168 In summary, the threshold concentrations of N and P in the substrate solution at which the  
169 biomass of *L. chinensis* began to decrease (or stopped increasing) were 16 and 1.2 mmol/L,  
170 respectively. Moreover, plants exposed to 1.2-4.8 mmol/L P were mainly restricted by N, while  
171 those exposed to 16 and 24 mmol/L N were mainly restricted by P, and those exposed to lower  
172 concentrations of P and N were restricted by P and N, respectively (Fig. 4).

## 173 **DISCUSSION**

### 174 **N and P contents and the N:P ratio in *L. chinensis***

175 N and P are key nutrients that play major roles in myriad processes in plants and have important  
176 effects on one-another's uptake and metabolism (Han *et al.*, 2009). N:P ratios in plants fluctuate  
177 within relatively narrow ranges, and variations in their N and P contents are restricted by  
178 homeostatic mechanisms. Although P and N contents can influence each other, N affects P  
179 contents more strongly than vice versa, putatively due to the overall higher abundance of N in  
180 plants (Yu, 2005). (Tao *et al.*, 2017) found that increasing deposition of N in soils could facilitate  
181 P absorption and accumulation in *Suaeda heteroptera*, indicating that N supply limited the plants'  
182 growth. Li *et al.* (2012) detected a significant positive correlation between N and P contents in *S.*  
183 *heteroptera* plants in a coastal saline environment and observed relatively consistent variations in  
184 their N and P demands. We found that *L. chinensis* plants absorbed limited amounts of P from

185 soils with a low N content, and changes in the soil's N contents between 2 and 8 mmol/L had  
186 minor effects on the P content of their aboveground parts. However, their P contents were  
187 substantially increased by higher N concentrations in the soil. Similarly, we found that N  
188 contents of aboveground parts of *L. chinensis* are influenced by the environmental P  
189 concentration: they changed greatly when the soil's P content was low but remained very similar  
190 at high P concentrations. In summary, P content is the main constraint on plant growth when the  
191 soil's P content is low, but N content becomes the main constraint of plant growth when the P  
192 content is high.

193 Our experiment examined saline-alkaline environments with different pH values. The N and  
194 P contents in aboveground parts of *L. chinensis* were both high at pH 8.4, indicating that the  
195 plants maintained strong control over their N:P ratios at this pH and confirming the previously  
196 reported finding that this pH promotes growth of *L. chinensis* (Li *et al.*, 2018). Yan *et al.* (2006)  
197 found that *L. chinensis* can resist mild pH stress but it is inhibited by strong saline-alkali stress,  
198 which (*inter alia*) reduces its tillering rate, average number of roots, relative water content,  
199 relative growth rate, and contents of both chlorophyll and N (Yan *et al.*, 2006). At high pH (8.7  
200 and 9.3) we found that its P content was relatively high when there were high soil concentrations  
201 of either N (16 or 24 mmol/L) or P (2.4 or 4.8 mmol/L). However, plants need more P to cope  
202 with pH stress. Cheng *et al.* (2017) found that plants' nutrient adsorption is related to both their  
203 taxa and pH, together with indications that luxury uptake of N and P under moderate pH stress  
204 enables some plants (e.g. *Rhizoma acori graminei* and *Lythrum salicaria*) to resist strong pH  
205 stress (Cheng *et al.*, 2017). The N and P contents in aboveground parts of *L. chinensis* we  
206 observed at various pH values indicate that N contents in plants are more sensitive to saline  
207 conditions than their P contents.

**208 Homeostasis characteristics of N, P, and N:P in *L. chinensis***

209 Homeostasis theory postulates that plants can adjust their growth rate, and rates of both resource  
210 allocation and utilization in mechanisms that maintain their internal homeostasis (Mendez and  
211 Karlsson, 2005). Homeostasis is stronger in animals than in plants, and in higher plants than  
212 lower plants (Zeng *et al.*, 2016), suggesting that homeostatic mechanisms have become more  
213 powerful over the course of evolutionary history (Nie *et al.*, 2016). We found that the  
214 homeostasis indices for N content, P content and the N:P ratio in *L. chinensis* were within  
215 reported ranges for algae, fungi (Sterner and Elser, 2002), and animals (Yu, 2005; Karimi and  
216 Folt, 2006). On the basis of experiments on Inner Mongolian grassland and sand culture, Yu *et al.*  
217 (2009) concluded that aboveground parts of *L. chinensis* have slightly higher  $H_N$ ,  $H_P$  and  $H_{N:P}$   
218 values (5.88-8.80, 3.37-6.67 and 4.49-9.46, respectively) than those observed in our study,  
219 possibly due to differences in climatic conditions.

220 We also found that all three homeostasis indexes first increased then decreased with  
221 increases in pH. At pH 8.1 and 8.4, they were all high, showing that *L. chinensis* can maintain  
222 stable levels of nutrients in weakly alkaline environments. However, the indices were lower  
223 under more strongly alkaline conditions (pH>8.7), indicating that such conditions have toxic  
224 effects. This is consistent with previous observations that saline and alkaline stress has both  
225 physiological and biochemical effects on roots and leaves of *L. chinensis* (Liu *et al.*, 2014).

226 Another finding is that  $H_{N:P} > H_N > H_P$ , indicating that the stronger homeostasis of N content  
227 than of P content in plants is mainly due to their significantly higher N content. Accordingly,  
228 homeostasis in zooplankton is reportedly highest for macronutrients, followed by micronutrients,  
229 and lowest for non-essential elements (Karimi and Folt, 2006). Since high N contents in plant  
230 tissues promote high P contents and plants' N:P ratios vary less than their N and P contents, the

231 N:P ratio may be subject to stronger homeostasis than either N or P individually (Sterner and  
232 Elser, 2002). Plants maintain N:P stability by their adjusting resource allocation and utilization  
233 of resources. The degree of stability may reflect their environmental adaptability, so the N:P ratio  
234 appears to be more important than N and P contents in this respect.

235 We also found that the plants' homeostasis is related to the duration of the incremental  
236 increases in salinity-alkalinity stress. With 14-day intervals (rapid changes in alkalinity), the  
237 positive effects of a weakly alkaline environment (pH 7.5-8.4) on leaves of *L. chinensis* are  
238 stronger than those observed with longer intervals: the homeostasis indices of the aboveground  
239 parts are relatively high, and further increases in alkalinity (to pH 8.7 or 9.3) induce relatively  
240 little damage to leaves.  $H_{N:P}$  and  $H_P$  are strongly affected by changes in the duration of the  
241 incremental increases. For example, the variation in  $H_{N:P}$  of aboveground parts is higher with 23-  
242 day intervals than with either 14- or 17-day intervals (rising to a peak and then quickly falling  
243 with increases in pH, as shown in Fig. 2).

#### 244 **Specific growth rate**

245 Growth rates are crucial indicators of organisms' adaptation to (and thus ability to survive and  
246 reproduce within) an environment. Clearly, variations in growth capacity can be linked to  
247 variations in elemental demand (Moody *et al.*, 2017). Our results confirm previous findings (and  
248 intuitive expectations) that adding N can significantly enhance growth of N-deficient plants.  
249 However, they also show that adding N can inhibit plants' growth if the environmental content of  
250 N exceeds the plants' requirements. We found that the optimal N and P contents in the soil under  
251 our experimental conditions were 16 and 1.2 mmol/L, respectively. Our results suggest that  
252 adding excess P will not have inhibitory effects, and may even further stimulate growth slightly,  
253 but would be a waste of resources.

254 Plants can absorb elements in soils selectively. However, the C:N:P ratios in plants vary  
255 more widely than in animals and microorganisms. Moreover, theoretical analyses based on  
256 experiments with algae and birch seedlings indicate that the N:P ratio has a relatively complex  
257 relationship with growth rates: they are positively correlated at low growth rates, but negatively  
258 correlated once the growth rate exceeds a certain threshold (Agren, 2004; Agren, 2008) that  
259 depends on both the taxon in question and the abundance of other nutrients. Other studies  
260 (Cernusak *et al.*, 2010) indicated that the N:P ratios of 13 categories of tropical trees and lianas  
261 are positively related to growth rates when the growth rate is low, but negatively related at high  
262 growth rates. Additionally, Reef *et al.* found an interspecific (but not intraspecific) relationship  
263 between N:P ratios and growth rates of two species of *Rhizophoraceae* (Reef *et al.*, 2010). Yu  
264 found that growth rates of belowground parts of plants were positively correlated with N:P under  
265 N constraints, but negatively correlated with N:P under P constraints (Yu, 2009). In our  
266 experiment, growth of *L. chinensis* was restricted by both N and P. The growth rate of  
267 aboveground parts was positively related to N:P under N constraint, but the positive correlation  
268 was weakened under P constraint. This is consistent with the conclusions of Yu *et al.* with  
269 respect to the effects of N constraint, but not those of P constraint. We speculate that this was  
270 due to the plant's generally low growth rate in the experiment, and also possibly to effects of  
271 salinity-alkalinity on the relationships between plant growth and other environmental variables.  
272 Although effects of plants' nutrient storage on their growth rates have been discussed (Sterner  
273 and Elser, 2002; Agren, 2008; Yu, 2009), the relationship between their growth rates and C:N:P  
274 ratios clearly requires further study.

275 According to the growth rate hypothesis, high amounts of ribosomal RNA (rRNA), and thus  
276 P, are needed to synthesize the large quantities of proteins required to sustain high growth rates

277 (Sterner and Elser, 2002). Therefore, organisms with high growth rates have relatively high P  
278 contents and low N:P ratios. This hypothesis is supported by both theoretical considerations and  
279 empirical observations of zooplankton, arthropods, and bacteria (Elser *et al.*, 2003; Watts *et al.*,  
280 2006; Hessen *et al.*, 2007). However, the relationships may be more complex in higher plants.  
281 Accordingly, we observed a nonlinear relationship between the specific growth rate and N:P  
282 ratio of *L. chinensis*, rather than the negative correlation predicted by the hypothesis. This may  
283 have been because we monitored adult *L. chinensis* plants rather than juveniles, and/or because  
284 the specific growth rate of the studied plants was strongly influenced by the variation of several  
285 environmental factors (N content, P content, and pH) and thus does not reflect their intrinsic  
286 potential growth rates.

## 287 CONCLUSION

288 The findings presented here demonstrate that the N content of *L. chinensis* is more sensitive to  
289 the environmental pH than its P content. At substrate pH values of 8.4 and 8.7, the N:P ratio of *L.*  
290 *chinensis* was stable and effectively regulated, indicating that the species possesses good  
291 environmental adaptability in this pH range. In particular, at a substrate pH of 8.4, the  $H_P$ ,  $H_N$ ,  
292 and  $H_{N:P}$  indices of *L. chinensis* were all high, indicating that the plants were well able to control  
293 their contents of N and P as well as the N:P ratio. Weak alkalinity (pH 7.5-8.4) is beneficial for  
294 growth and N accumulation in *L. chinensis*, but more strongly alkaline conditions (pH 8.7 or 9.3)  
295 inhibit its growth. Rapid changes in salinity-alkalinity (at intervals of 14 or 17 days) weakened  
296 both the positive effects of the weakly alkaline conditions (pH 7.5-8.4) and the negative effects  
297 of more strongly alkaline conditions (pH 8.7 or 9.3) on *L. chinensis*. At pH values above 8.7, the  
298 interval between stress increments clearly affected the plants' contents of N and P as well as the  
299 N:P ratio.

## 300 ACKNOWLEDGEMENTS

301 We thank Chenhao Cao, Junian Gao and Xiaowei Han for their assistance during plant  
302 cultivation and harvesting. We are grateful to the Associate Editor and one anonymous referee  
303 for providing valuable comments.
