Despite considerable tolerance to salt and alkali stress, *Leymus chinensis* populations on the southwestern Songnen Plain in northern China are threatened by increasing soil salinity and alkalinity. To explore the species' responses to saline-alkali stress, we grew it in substrates with varying concentrations of nitrogen (N) and phosphorus (P) while applying varying levels of saline-alkali stress (increasing in 14-, 17- or 23 -day intervals). We measured the plants' contents of N and P, and the N:P ratio, and calculated their homeostasis indices ( $H_N$ ,  $H_P$  and  $H_{N:P}$ ) under each nutrient and saline-alkali stress treatment. The N content was found to be more sensitive to saline-alkali stress than the P content. The N and P contents were highest and the N:P ratio was stable at pH 8.4. At both pH 8.1 and 8.4,  $H_{N:P} > H_N > H_P$ , but the indices and their relations differed at other pH values. Exposure to saline-alkali stress for the 14-day incremental interval had weaker effects on the plants. Rapid changes in salinity-alkalinity weakened both the positive effects of the weakly alkaline conditions (pH 7.5-8.4) and the negative effects of more strongly alkaline conditions (pH 8.7 or 9.3) on *L. chinensis*. When *L. chinensis* plants lack N, applying N fertilizer will be extremely efficient. The optimal concentrations of N and P appeared to be 16 and 1.2 mmol/L, respectively. When the *L. chinensis* plants were N- and P-limited, the specific growth rate correlated positively with N:P, when limited by N it correlated positively with the environmental N concentration, and when limited by P it was weakly positively correlated with the environmental P concentration.

## 1 INTRODUCTION

2 Ecological stoichiometry (ES) is the study of the balances of elements and energy in ecosystems,  
3 which have profound effects on living organisms, their interactions, and associated ecological  
4 processes (Cambardella and Elliott, 1993; Elser *et al.*, 2000; Güsewell, 2004; Bradshaw *et al.*,  
5 2012). ES theory focuses primarily on elements required by all living organisms, so it can be  
6 readily generalized across taxa and systems (Sanders and Taylor, 2018). A key concept is  
7 homeostasis: a system's capacity to maintain constant conditions internally when external  
8 conditions vary, a fundamental property of organisms (Kooijman, 1995; Cooper, 2008;  
9 Halvorson *et al.*, 2019). Characterizing both the degrees and consequences of homeostasis is  
10 important for understanding responses to environmental changes (Meunier *et al.*, 2014;  
11 Halvorson *et al.*, 2019). In ES-based analyses, the homeostasis concept is used to infer organisms'  
12 responses to changes in ratios of elemental resources, and predict their feedback effects on  
13 resources' availability through changes in the acquisition, storage, and release of nutrients,  
14 particularly limiting nutrients such as nitrogen (N) and phosphorus (P) (Halvorson *et al.*, 2019).  
15 A general assumption is that stoichiometric homeostasis is stronger in heterotrophs than  
16 autotrophs (Sterner and Elser, 2002), so environmental stoichiometry is believed to be reflected  
17 more closely by plant and algal stoichiometry than by animals' stoichiometry. However, Yu *et al.*  
18 (2011) found that homeostatic regulation of N and P varies widely in vascular plants, so the  
19 patterns and processes involved are complex and far from fully understood.

20 Another core concept of ES is the growth rate hypothesis (GRH), which postulates that  
21 organisms' specific growth rates correlate positively with their phosphorus (P) contents because  
22 P is essential for the ribosomal RNA production needed to sustain growth (Moody *et al.*, 2017)  
23 and for many other processes including photosynthesis, respiration, enzyme production, and

24 generation of ATP (Li *et al.*, 2019). Thus, organisms with high specific growth rates have high  
25 nutrient demands and (*inter alia*) low tissue C:nutrient ratios, low N:P ratios, and potentially  
26 competitive advantages in high-P environments, but disadvantages in low-P environments.  
27 Hence, plants' abilities to compete for nutrients depend on both their tissue nutrient contents and  
28 life history traits (Mulder and Elser, 2009; González *et al.*, 2010; Sanders and Taylor, 2018).

29 ES has been widely applied in various areas of plant science, including in studies on the  
30 growth of individual plants, population dynamics, limiting elements, succession, and stability of  
31 vegetative communities (Güsewell, 2004). Soil is a key component of terrestrial ecosystems  
32 because it supports numerous ecological processes (Normand *et al.*, 2017; Wang *et al.*, 2018),  
33 plays crucial roles in plant growth, and directly affects plant communities' composition, stability,  
34 and succession (Wardle *et al.*, 2004). N and P are key elements with profound effects on plants  
35 growth because they play major roles in microbial dynamics, litter decomposition, food webs,  
36 and the accumulation and cycling of nutrients in soil (Elser *et al.*, 2003). Changes in plants' N:P  
37 ratios (*inter alia*) may reflect adaptations to environmental conditions (Tang *et al.*, 2018),  
38 including (of particular interest here) salinity and alkalinity.

39 According to incomplete UNESCO and FAO statistics, the area of saline-alkali land is  
40 growing globally (Kerr, 2017) and amounts to  $9.5438 \times 10^8$  hm<sup>2</sup>, including  $0.9913 \times 10^8$  hm<sup>2</sup> in  
41 China (Li *et al.*, 2017a). This is a severe problem because salinization impairs seed germination,  
42 root extension, and plant development, resulting in land degradation, reductions in cultivated  
43 land quality, and limitation of agricultural development (Wu *et al.*, 2016). Most saline-alkali soil  
44 in northeast China is on the Songnen Plain, and its area is increasing through grassland  
45 salinization (Li, 2000). The dominant species in saline-alkali grassland on the Songnen Plain is  
46 *Leymus chinensis* (*L. chinensis*), which can provide high yields of high quality gramineous

47 forage if the salinity and alkalinity are not too severe. It can play an important role in restoring  
48 saline-alkali land (Liu *et al.*, 2014), but there is a need to reduce the salinity and alkalinity of  
49 affected grassland and improve the species' yield and stress tolerance. It is therefore important to  
50 study the ecological stoichiometric homeostasis of N and P, associated ecological processes, and  
51 the effects of saline-alkali stress on the growth rate and survival strategy of *L. chinensis*.

52 Previous research on saline-alkali tolerance in *L. chinensis* has mainly focused on  
53 physiological processes (such as the osmoregulatory roles of ions, organic acids, soluble sugars  
54 and other substances) and morphological traits (such as tiller buds, root distribution, and  
55 rhizomes' internode length and branching angles) (Zheng *et al.*, 2017). C, N, and P dynamics in  
56 soil-*L. chinensis* systems have also been addressed (Li *et al.*, 2018). The secret of *L. chinensis*  
57 adapting to saline-alkali stress has been discussed deeply from many perspectives. However, soil  
58 salinization is a long-term dynamic process, and there is relatively little information on relations  
59 between the effects of saline-alkaline stress (and of variation in its duration) and ecological  
60 stoichiometric characteristics. And few studies point out a certain range in which *L. chinensis*  
61 can adapt to lasting saline-alkali stress. We make the hypothesis that the adaptability of *L.*  
62 *chinensis* under different saline-alkali stress conditions is different (positive effects? or negative  
63 effects?) and there is a certain range. Here, we demonstrate that the ecological stoichiometric  
64 characteristics of *L. chinensis* are influenced by the duration of saline-alkali stress and the  
65 available concentrations of both N and P.

## 66 **MATERIALS AND METHODS**

### 67 **The experimental site**

68 We performed experiments in an outdoor terrace on the campus of the College of Earth Sciences,  
69 Jilin University, Changchun, Jilin Province, northeast China. This is in the north temperate

70 continental climatic zone, which has four distinct seasons. The mean annual temperature and  
71 precipitation are 4.8°C and 567 mm, respectively, and mean winter and summer temperatures are  
72 -14 and 24 °C, respectively (Zhang *et al.*, 2017).

### 73 **Experimental design**

#### 74 **Experimental preparation**

75 Experiments were performed from August 7 to November 6, 2017. To minimize interference  
76 from impurities in the soil, the substrate used was fine nutrient-poor sand, sieved with 10 and 75  
77 mesh sieves and thoroughly washed with distilled water to minimize its nutrient content. To  
78 avoid effects of different soil loadings on growth of experimental plants, the sand was air-dried  
79 and equal portions were placed in plastic flowerpots (diameter 30 cm, height 23 cm). The  
80 portions were roughly equivalent to two-thirds of the pots' volume. *L. chinensis* seeds were  
81 immersed in water for 48 hours and air-dried in the dark to avoid dormancy and increase the  
82 germination rate, then about 100 seeds were sown evenly in each flowerpot. About seventy  
83 percent of the seeds survived, and all pots were similar with respect to the number, size, and  
84 vitality of surviving seedlings.

#### 85 **N and P addition**

86 After the seeds germinated, a 200 ml portion of Hoagland's nutrient solution with adjusted N and  
87 P concentrations was added to each pot once every two days. The elemental composition of  
88 Hoagland's solution is described in detail elsewhere (Li *et al.*, 2018). In five sets of nine pots, the  
89 N concentration was adjusted using ammonium nitrate to establish five N concentration  
90 treatments (2, 4, 8, 16, and 24 mmol/L) in which the concentration of P was fixed at 1 mmol/L.  
91 In another five sets of nine pots, the P concentration was adjusted using potassium dihydrogen  
92 phosphate to establish five P concentration treatments (0.3, 0.6, 1.2, 2.4, and 4.8 mmol/L) in

93 which the concentration of N was fixed at 14 mmol/L. The experiment thus involved 10 nutrient  
94 treatments and a total of 90 pots (10 treatments×3 replicates×3 salinity stress intervals) in a  
95 randomized complete block design. The N and P concentration gradients were set on the basis of  
96 previously reported results (Yu et al., 2011).

#### 97 **Saline-alkali stress**

98 On 7 Aug 2017, after the *L. chinensis* plants had grown to an average height of about 15 cm,  
99 plants in triplicate pots were subjected to the saline-alkali stress treatments shown in Table 1, by  
100 adding NaHCO<sub>3</sub> to the previously described treatment solution to simulate various degrees of  
101 land salinization encountered in the western regions of Jilin Province. To avoid excessively  
102 stressing the plants, the pH was increased at intervals of 14, 17, or 23 days. The pH was raised  
103 from 7.5 to 8.1, and then to 8.4, 8.7, and finally 9.3. Aboveground parts of *L. chinensis* plants  
104 subjected to these treatments were harvested (cutting from the ground level) according to the  
105 schedule shown in the table 1.

#### 106 **Sample collection and testing methods**

107 Aboveground parts of *L. chinensis* plants were cut according to the harvesting schedule shown in  
108 Table 1. The samples were rinsed with distilled water, dried with absorbent paper, deactivated  
109 for 15 min in a dry air oven (105 °C) and dried for 12 h at 65 °C to eliminate water completely.  
110 After cooling the samples to room temperature, they were weighed, crushed, screened with a 100  
111 mesh sieve, and finally quartered. The resulting sub-samples were then packed in sealed bags for  
112 analysis.

113 Total N and total P in the *L. chinensis* samples were respectively determined by Chinese  
114 standard methods LY/T 1269-1999 (using a SAN++ Continuous Flow Analyzer; Skalar,  
115 Netherlands) and LY/T 1270-1999 (using an ICPS-7500 inductively coupled plasma atomic

116 emission spectrometer; Shimadzu, Kyoto, Japan).

### 117 **Data analysis**

118 The acquired data were statistically analyzed using SPSS 24 (SPSS Inc., USA). Homeostasis

119 indices were calculated using the stoichiometric homeostasis model  $y = cx^{\frac{1}{H}}$ . Here,  $x$  is the  
120 measured content of an element in the soil,  $y$  is the measured content of the same element in *L.*

121 *chinensis*,  $c$  is a constant coefficient, and  $H$  is the homeostasis index. The results were visualized

122 using Sigmaplot 12.5 (Systat Software, Inc.). We calculated specific growth rates based on

123 recorded changes in dry mass and instantaneous growth rates using the equation  $u = \ln(M_t / M_0) / t$ ,

124 where  $u$  is the specific growth rate ( $\text{day}^{-1}$ ),  $M_t$  and  $M_0$ , are the final and initial dry mass,

125 respectively, and  $t$  is experiment duration in days. Details of several statistical analyses are

126 included in Appendix 1 and Appendix 2.

## 127 **RESULTS**

### 128 **Effects of incremental increases in saline-alkali stress on N, P contents and N:P ratios**

129 The 14-day stress increment yielded the highest N and P contents in the plants when the N

130 concentration in the substrate was low (2-8 mmol/L), but not when the N concentration in the

131 substrate was higher (16 or 24 mmol/L). The variation in the N and P contents, and the N:P ratio,

132 was similar under all three stress intervals: the N content and N:P ratio were highest with 17-day

133 intervals, while the P content was highest with 14-day intervals (Fig. 1).

### 134 **Homeostasis characteristics of *L. chinensis***

135 The homeostasis index of N ( $H_N$ ) in *L. chinensis* ranged from 2.35 to 7.25, and first rose then fell

136 as salinity-alkalinity increased, independently of interval length (Fig. 2). Under the 14-, 17- and

137 23-day intervals,  $H_N$  ranges were 3.10-7.25, 2.35-5.36 and 3.19-3.87, respectively. It was

138 consistently highest at pH 8.4, and higher at pH 8.1 and 8.7 than at pH 7.5 and 9.3 (Table 2).

139 Under the 14-day stress intervals, the changes in  $H_N$  were moderate, and  $H_N$  was high at all pH  
140 values. The index was lower at both pH 8.1 and 8.7 under the 17- and 23-day intervals.

141 Under our treatments,  $H_P$  of *L. chinensis* ranged from 2.60 to 5.33. Under all three saline-  
142 alkali stress intervals, it first rose and then declined (Fig. 2). Under the 14-, 17-, and 23-day  
143 saline-alkali stress intervals, the ranges of  $H_P$  were 2.84-5.33, 2.65-4.90 and 2.60-4.10,  
144 respectively, and the highest values of  $H_P$  occurred at pH 8.1, 8.7, and 8.1, respectively (Table 2).  
145 At pH 8.1,  $H_P$  was significantly higher under 14-day intervals than under longer intervals. At pH  
146 8.4, it was highest under 17-day intervals, and at pH 8.7 it declined in the order 17-day > 14-day >  
147 23-day intervals.

148 Plants have strong self-regulating mechanisms, and generally keep their N:P ratios within a  
149 narrow range by adjusting their N and/or P contents in response to environmental changes. For  
150 example, the  $H_{N:P}$  of *L. chinensis* varied from 3.06 to 9.23 in plants exposed to different P  
151 concentrations, while its ranges under the 14-, 17- and 23-day stress interval regimes were 3.15-  
152 9.23, 3.11-6.83 and 3.06-6.44, respectively, and its peak values occurred at pH 8.4, 8.4, and 8.1,  
153 respectively (Table 2). *L. chinensis* plants are thus able to effectively regulate their N:P ratio in  
154 the pH range 8.1 to 8.7, but less so at pH 7.5 and 9.3.

### 155 **The specific growth rate of *L. chinensis***

156 The specific growth rate of the plants rapidly increased then decreased as the N concentration in  
157 the substrate increased, peaking at 16 mmol/L (Fig. 3). This indicates that when *L. chinensis*  
158 plants lack N, initial N addition will be extremely efficient, but saturating or excessive amounts  
159 will not promote (and may even hinder) further growth. Conversely, the plants' specific growth  
160 rate first increased, then decreased, and then increased again with increases in environmental P  
161 concentration. Specifically, it was lowest at a P concentration of 2.4 mmol/L, and higher at both

162 1.2 and 4.8 mmol/L. Thus, high addition of P is beneficial for plant growth but may lead to  
163 wastage of resources. Therefore, the optimum P concentration under our experimental conditions  
164 was 1.2 mmol/L.

165 In summary, the threshold concentrations of N and P in the substrate solution at which the  
166 biomass of *L. chinensis* began to decrease (or stopped increasing) were 16 and 1.2 mmol/L,  
167 respectively. Moreover, plants exposed to 1.2-4.8 mmol/L P were mainly restricted by N, while  
168 those exposed to 16 and 24 mmol/L N were mainly restricted by P, and those exposed to lower  
169 concentrations of P and N were restricted by P and N, respectively (Fig. 4). According to the  
170 results of the correlation analysis, the specific growth rate of *L. chinensis* and the plant N:P ratio  
171 is positively correlated in both N-limited and P-limited environments, and the correlation is  
172 slightly stronger under P-restricted conditions, but neither of them passed the significance test. In  
173 the N and P co-limited environment, the specific growth rate of *L. chinensis* has a positive  
174 correlation with the plant N:P ratio, and the correlation coefficient is 0.46, which is significant at  
175 the level of 0.01.

## 176 DISCUSSION

### 177 N and P contents and the N:P ratio in *L. chinensis*

178 N and P are key nutrients that play major roles in myriad processes in plants and have important  
179 effects on one-another's uptake and metabolism (Han *et al.*, 2009). N:P ratios in plants fluctuate  
180 within relatively narrow ranges, and variations in their N and P contents are restricted by  
181 homeostatic mechanisms. Although P and N contents can influence each other, N affects P  
182 contents more strongly than vice versa, putatively due to the overall higher abundance of N in  
183 plants (Yu, 2005). We found that *L. chinensis* plants absorbed limited amounts of P from soils  
184 with a low N content, and changes in the soil's N contents between 2 and 8 mmol/L had minor

185 effects on the P content of their aboveground parts. However, their P contents were substantially  
186 increased by higher N concentrations in the soil. Similarly, we found that N contents of  
187 aboveground parts of *L. chinensis* are influenced by the environmental P concentration: they  
188 changed greatly when the soil's P content was low but remained very similar at high P  
189 concentrations. In summary, P content is the main constraint on plant growth when the soil's P  
190 content is low, but N content becomes the main constraint of plant growth when the P content is  
191 high.

192 Our experiment examined saline-alkaline environments with different pH values. The N and  
193 P contents in aboveground parts of *L. chinensis* were both high at pH 8.4, indicating that the  
194 plants maintained strong control over their N:P ratios at this pH and confirming the previously  
195 reported finding that this pH promotes growth of *L. chinensis* (Li *et al.*, 2018). *L. chinensis* can  
196 resist mild pH stress but it is inhibited by strong saline-alkali stress (Yan *et al.*, 2006). At high  
197 pH (8.7 and 9.3), we found that its P content was relatively high when there were high soil  
198 concentrations of either N (16 or 24 mmol/L) or P (2.4 or 4.8 mmol/L). However, plants need  
199 more P to cope with pH stress. Plants' nutrient adsorption is related to pH, together with  
200 indications that luxury uptake of N and P under moderate pH stress enables some plants (e.g.  
201 *Rhizoma acori graminei* and *Lythrum salicaria*) to resist strong pH stress (Cheng *et al.*, 2017).  
202 The N and P contents in aboveground parts of *L. chinensis* we observed at various pH values  
203 indicate that N contents in plants are more sensitive to saline conditions than their P contents.

#### 204 **Homeostasis characteristics of N, P, and N:P in *L. chinensis***

205 Homeostasis theory postulates that plants can adjust their growth rate, and rates of both resource  
206 allocation and utilization in mechanisms that maintain their internal homeostasis (Mendez and  
207 Karlsson, 2005). Homeostasis is stronger in animals than in plants, and in higher plants than

208 lower plants (Zeng *et al.*, 2016), suggesting that homeostatic mechanisms have become more  
209 powerful over the course of evolutionary history. We found that the homeostasis indices for N  
210 content, P content and the N:P ratio in *L. chinensis* were within reported ranges for algae, fungi  
211 (Sterner and Elser, 2002), and animals (Yu, 2005; Karimi and Folt, 2006). On the basis of  
212 experiments on Inner Mongolian grassland and sand culture, Yu *et al.* (2009) concluded that  
213 aboveground parts of *L. chinensis* have slightly higher  $H_N$ ,  $H_P$  and  $H_{N:P}$  values (5.88-8.80, 3.37-  
214 6.67 and 4.49-9.46, respectively) than those observed in our study, possibly due to differences in  
215 climatic conditions.

216 We also found that all three homeostasis indexes first increased then decreased with  
217 increases in pH. At pH 8.1 and 8.4, they were all high, showing that *L. chinensis* can maintain  
218 stable levels of nutrients in weakly alkaline environments. However, the indices were lower  
219 under more strongly alkaline conditions (pH>8.7), indicating that such conditions have toxic  
220 effects. This is consistent with previous observations that saline and alkaline stress has both  
221 physiological and biochemical effects on roots and leaves of *L. chinensis* (Liu *et al.*, 2014).

222 Another finding is that  $H_{N:P} > H_N > H_P$ , indicating that the stronger homeostasis of N content  
223 than of P content in plants is mainly due to their significantly higher N content. Accordingly,  
224 homeostasis in zooplankton is reportedly highest for macronutrients, followed by micronutrients,  
225 and lowest for non-essential elements (Karimi and Folt, 2006). Since high N contents in plant  
226 tissues promote high P contents and plants' N:P ratios vary less than their N and P contents, the  
227 N:P ratio may be subject to stronger homeostasis than either N or P individually (Sterner and  
228 Elser, 2002). Plants maintain N:P stability by their adjusting resource allocation and utilization  
229 of resources. The degree of stability may reflect their environmental adaptability, so the N:P ratio  
230 appears to be more important than N and P contents in this respect.

231 The plants' homeostasis is related to the duration of the incremental increases in salinity-  
232 alkalinity stress. With 14-day intervals (rapid changes in alkalinity), the positive effects of a  
233 weakly alkaline environment (pH 7.5-8.4) on leaves of *L. chinensis* are stronger than those  
234 observed with longer intervals: the homeostasis indices of the aboveground parts are relatively  
235 high, and further increases in alkalinity (to pH 8.7 or 9.3) induce relatively little damage to  
236 leaves.  $H_{N:P}$  and  $H_P$  are strongly affected by changes in the duration of the incremental increases.  
237 For example, the variation in  $H_{N:P}$  of aboveground parts is higher with 23-day intervals than with  
238 either 14- or 17-day intervals (rising to a peak and then quickly falling with increases in pH, as  
239 shown in Fig. 2).

#### 240 **Specific growth rate**

241 Specific growth rates are crucial indicators of organisms' adaptation to (and thus ability to  
242 survive and reproduce within) an environment. Clearly, variations in growth capacity can be  
243 linked to variations in elemental demand (Moody *et al.*, 2017). Our results confirm previous  
244 findings (and intuitive expectations) that adding N can significantly enhance growth of N-  
245 deficient plants. However, they also show that adding N can inhibit plants' growth if the  
246 environmental content of N exceeds the plants' requirements. The optimal N and P contents in  
247 the soil under our experimental conditions were 16 and 1.2 mmol/L, respectively. Adding excess  
248 P will not have inhibitory effects, and may even further stimulate growth slightly, but would be a  
249 waste of resources.

250 Plants can absorb elements in soils selectively. Moreover, The N:P ratio has a relatively  
251 complex relationship with specific growth rates: they are positively correlated at low specific  
252 growth rates, but negatively correlated once the specific growth rate exceeds a certain threshold  
253 (Agren, 2004). Additionally, specific growth rates of belowground parts of plants were positively

254 correlated with N:P under N constraints, but negatively correlated with N:P under P constraints  
255 (Yu, 2009). In our experiment, growth of *L. chinensis* was restricted by both N and P. The  
256 specific growth rate of aboveground parts was positively related to N:P under N constraint or P  
257 constraint, but the positive correlation was strengthened under the co-constraint of N and P. This  
258 is consistent with the conclusions of Yu *et al.* with respect to the effects of N constraint, but not  
259 those of P constraint. We speculate that this was due to the plant's generally low specific growth  
260 rate in the experiment, and also possibly to effects of salinity-alkalinity on the relationships  
261 between plant growth and other environmental variables. Although effects of plants' nutrient  
262 storage on their specific growth rates have been discussed (Sterner and Elser, 2002; Yu, 2009),  
263 the relationship between their specific growth rates and C:N:P ratios clearly requires further  
264 study.

265       According to the specific growth rate hypothesis, high amounts of ribosomal RNA (rRNA),  
266 and thus P, are needed to synthesize the large quantities of proteins required to sustain high  
267 specific growth rates (Sterner and Elser, 2002). Therefore, organisms with high specific growth  
268 rates have relatively high P contents and low N:P ratios. This hypothesis is supported by both  
269 theoretical considerations and empirical observations of zooplankton, arthropods, and bacteria  
270 (Elser *et al.*, 2003; Watts *et al.*, 2006; Hessen *et al.*, 2007). However, the relationships may be  
271 more complex in higher plants. Accordingly, we observed the positive correlation between the  
272 specific growth rate and N:P ratio of *L. chinensis*, rather than the negative correlation predicted  
273 by the hypothesis. This may have been because we monitored adult *L. chinensis* plants rather  
274 than juveniles, and/or because the specific growth rate of the studied plants was strongly  
275 influenced by the variation of several environmental factors (N content, P content, and pH) and  
276 thus does not reflect their intrinsic potential specific growth rates.

## 277 CONCLUSION

278 The findings presented here demonstrate that *L. chinensis* has the homeostasis ability under a  
279 certain degree of salinity-alkalinity stress. And the N content of *L. chinensis* is more sensitive to  
280 the environmental pH than its P content. At substrate pH values of 8.4 and 8.7, *L. chinensis*  
281 possesses good environmental adaptability. In particular, at a substrate pH of 8.4, *L. chinensis*  
282 were well able to control their contents of N and P as well as the N:P ratio. Weak alkalinity (pH  
283 7.5-8.4) is beneficial for growth and N accumulation in *L. chinensis*, but more strongly alkaline  
284 conditions (pH 8.7 or 9.3) inhibit its growth. At pH values above 8.7, the interval between stress  
285 increments clearly affected the plants' contents of N and P as well as the N:P ratio. The  
286 relationship between the specific growth rate and N:P ratio may become more complex (not  
287 simple linear) because of the salinity-alkalinity stress.

## 288 ACKNOWLEDGEMENTS

289 This work was supported by the Science and Technology Strategy and Planning Research of Jilin  
290 Science and Technology Department (grant no. 20200101119FG). We thank Chenhao Cao,  
291 lunian Gao and Xiaowei Han for their assistance during plant cultivation and harvesting. We are  
292 grateful to the Associate Editor and one anonymous referee for providing valuable comments.

**Table 1** (on next page)

Saline-alkali stress treatments, including durations of exposure to each pH, dates of exposure, and harvest dates.

Notes: There were 10 nutrient treatments and a total of 90 pots were used in the experiment. The salt-alkali stress experiment at incremental interval 23 days with the pH of 9.3 was not carried out due to the sudden drop of local temperature at the end of October.

1

N-P level	Duration (days)	pH	Dates of exposure	Harvest date
		7.5	2017/8/07-2017/8/17	2017/8/18
		8.1	2017/8/18-2017/8/31	2017/9/01
