To date, official data on the number of people infected with the SARS-CoV-2 - responsible for the CoViD-19 - have been released by the Italian Government just on the basis of a non representative sample of population which tested positive for the swab. However a reliable estimation of the number of infected, including asymptomatic people, turns out to be crucial in the preparation of operational schemes and to estimate the future number of people, who will require, to different extents, medical attentions. In order to overcome the current data shortcoming, this paper proposes a bootstrap- driven, estimation procedure for the number of people infected with the SARS-CoV-2. This method is designed to be robust, automatic and suitable to generate estimations at regional level. Obtained results show that, while official data at March the 12th report 12.839 cases in Italy, people infected with the SARS-CoV-2 could be as high as 105.789.

CoViD-19: An Automatic, Semiparametric Estimation Method for the Population Infected in Italy

Livio Fenga

livio.fenga@istat.it*

Abstract: To date, official data on the number of people infected with the SARS-CoV-2 - responsible for the CoViD-19 - have been released by the Italian Government just on the basis of a non-representative, heavily skewed, sample of population. Such a bias is due to the fact that *ad hoc* lab tests are administrated only to those showing flu-related symptoms. However, a reliable estimation of the number of infected, including the asymptomatic people, is a vital information for the implementation of policies and actions aimed at counteracting the spread of the virus. Therefore, this paper proposes a bootstrap-driven estimation procedure for the number of people infected with the CoViD-19. This method is designed to be robust, automatic and suitable to generate estimations at a national and regional level. The result obtained show that, while official data at March the 12th report 12.839 cases in Italy, the number of people infected with the CoViD-19 could be as high as 105.789.

KEYWORDS: Autoregressive metric; CoViD-19; maximum entropy bootstrap; model uncertainty; number of Italian people infected.

1. Introduction

COVID-19 epidemic has severely hit Italy and its diffusion throughout Europe is expected soon. In such a scenario, the availability of reliable information related to its spread plays a significant role in many regards. In fact, many targeted measures, such as the coordination among emergency services or the implementation of operative actions (e.g. hard or light lock-downs or even curfew) can only be efficiently taken when reliable estimates of the epidemic spread are available at the population level.

At the moment, official data on the infection in Italy are based on non-random, non-representative samples of the population: people are tested for CoViD-19 on the condition that some symptoms related to the virus are present. These data can ensure a proper estimation of the number of both deaths and hospitalizations due to the virus and are crucial for the optimization of the available resources. Nonetheless, from a statistical point of view, the number of people tested positive for COVID-19 represents a simple count which is not suitable to provide a reliable assessment of the “true”, unknown, number of infected people (thereafter “positive cases”). In addition to the strong bias components induced by this testing strategy, there is at least another mayor obstacle to the construction of a valid estimator: the small sample size available. Unavoidable at the early stages of an epidemic, the shortness of the time series of interest might lead to a strong bias in the asymptotic results and therefore to the construction of incorrect confidence intervals.

Based on the number of the deaths and of the observed positive cases and improving on the methodology originally proposed by Pueyo (2020), this paper aims at estimating the “true” number of people infected by the CoViD-19 in each of the 20 Italian regions. In more details, the presented procedure is designed to reduce the impact of the biasing components on the parameter estimations, by employing a resampling scheme, called Maximum Entropy Bootstrap and proposed by Vinod et al. (2009). In addition to that, a distance measure – based on the theory of stochastic processes and proposed by Piccolo (1990) – has been used to find pairs of similar regions. As it will be explained later, this has been done to maintain the same methodology in those cases where a variable employed in the model – i.e. the number of deaths – was missing.

2. The proposed method

In small data sets it is essential to save degrees of freedom (DOF) which are inevitably lost in a amount correlated with the complexity of the statistical model entertained. With this in mind, the proposed method is of the type semiparametric and consists of two parts: a purely non-parametric and a parametric one. While the former does not pose problems in terms of DOF, the latter clearly does. However, the sacrifice in terms of DOF is very limited as an autoregressive model of order 1 (employed in a suitable distance function, as below illustrated) has proved sufficient for the purpose. DOF-saving strategy is also the driving force behind the choice to not consider exogenous variables such as the regions geolocation or their population – e.g. in a regression-like scheme – but to implicitly assume these (and other) variables embedded in the dynamic of the time series considered.

3. Data and contagion indicator

The paper makes use of official data, published by the Italian Authorities, related to the following two variables employed in the proposed method, i.e. the number of

1. deaths from CoViD–19 (denoted by the Latin letter M)
2. currently positive cases which have been recorded as a result of the administration of the test (denoted by the Latin letter C).

The data set includes 18 daily data points collected at regional level during the period of February 24th to March 12th. The total number of Italian regions considered is 20. However, one special administrative area (Trentino Alto Adige) is divided in two subregions, i.e. Trento and Bolzano. Therefore, the set containing all the Italian regions – called Ω – has cardinality $|\Omega| = 21$ (the cardinality function is denoted by the symbol $|\cdot|$). Two different subsets are built from Ω i.e. Ω^\bullet – containing the regions for which at least one death, out of the group of tested people, has been recorded and Ω° (no recorded deaths). Those two sets are now specified:

1. $\Omega^\bullet \equiv \text{Piemonte, Lombardia, Veneto, Friuli, Liguria, Emilia, Toscana, Marche, Lazio, Abruzzo, Valle Aosta, Bolzano, Campania, Puglia, Sicilia}$
2. $\Omega^\circ \equiv \text{Trento, Umbria, Molise, Basilicata, Calabria, Sardegna,}$

being $\Omega \equiv \Omega^\bullet \cup \Omega^\circ$. In what follows, the two superscripts \bullet and \circ will be always used respectively with reference to the regions $\{r_1, r_2, \dots, r_{15}\} \in \Omega^\bullet$ and $\{s_1, s_2, \dots, s_6\} \in \Omega^\circ$. The time span is denoted as $\{1, 2, \dots, T\}$.

In the case of the regions included in the set Ω^\bullet , following Pueyo (2020), the total number of positive is estimated as follows:

$$y_{j,T}^{\bullet} = w_T * 2^{\frac{T}{\tau}}, \quad (1)$$

$$w_T = \frac{C_T}{M_T}. \quad (2)$$

75 Here, w_T (Eqn. 2) is the ratio between the current positive cases (C) and the
 76 number of deaths (M) whereas, in Eqn. 1, τ is the average doubling time for the
 77 CoViD-19 (i.e. the average span of time needed for the virus to double the cases) and
 78 δ the average time needed for an infected person to die. These two constant terms
 79 have been kept fixed as estimated according to the data so far available and reported
 80 in Pueyo (2020). They are as follows: $\tau = 17.3$ and $\delta = 6.2$.

81

82

The case of the regions belonging to Ω° is more complicated. The related es-
 83 timation procedure has been carried out as below detailed (the subscript t will be
 84 omitted for the sake of simplicity):

85

86

1. given the series $s_j \in \Omega^{\circ}$, a series $c^{\pi} \in \Omega^{\bullet}$ minimizer of a suitable distance func-
 tion – denoted by the Greek letter $\pi(\cdot)$ – is found. In symbols:

$$c^{\pi} = \underset{(c \in \Omega^{\bullet})}{\operatorname{argmin}} \pi(s, c); \quad (3)$$

87

88

89

2. the estimated number of positives at the population level – already found for c^{π} ,
 say $I_{c^{\pi}}$ – becomes the weight for which the total cases recorded for s_j , are mul-
 tiplied. Therefore, the estimate of the variable of interest for this case becomes

$$y_{j,T}^{\circ} = \frac{I_{c^{\pi}} * C_{s_j}}{C_{r_j}} \quad (4)$$

90

91

92

93

94

95

96

97

98

99

100

The distance function adopted $\pi(\cdot)$ (Eqn. 3), called AR-distance, has been in-
 troduced by Piccolo (2007)). Briefly, this metric can be applied if and only if the pair
 of series of interest are assumed to be realizations of two (possibly of different or-
 ders) ARMA (Autoregressive Moving Average) models (see, e.g. Makridakis and Hibon
 (1997)). Under this condition, each series can be expressed as an autoregressive model
 of infinite order, i.e. $AR(\infty)$, whose (infinite) sequence of AR parameters is denoted
 by $\{\alpha\}_j^{\infty} \equiv \alpha_1, \alpha_2, \dots$.

Without loss of generality, the distance between the series s and c , i.e. $\pi(s, c)$
 (Eqn 4), under $(s_t, c_t) \sim ARMA(\alpha, \beta)$, being α and β respectively the autoregressive
 and moving average parameters, is expressed as

$$\pi(s, c) = \sqrt{\left(\sum_{j=1}^{\infty} \alpha_j(s) - \alpha_j(c)\right)}. \quad (5)$$

101

102

For the asymptotic properties of Eqn. 5 the reader is referred to Corduas and
 Piccolo (2008) and Piccolo (2010).

103

4. The Resampling Method

104

105

106

107

108

The bootstrap scheme adopted proved to be adequate for the problem at hand. Given
 the pivotal role played in the proposed method, it will be briefly presented. In essence,
 the choice of the most appropriate resampling method is far from being an easy task,
 especially when the identical and independent distribution (*iid*) assumption (used in
 Efron's initial bootstrap method) is violated. Under dependence structures embedded

109 in the data, simple sampling with replacement has been proved – see, for example [Carl-](#)
 110 [stein et al. \(1986\)](#) – to yield suboptimal results. As a matter of fact, *iid*-based bootstrap
 111 schemes are not designed to capture, and therefore replicate, dependence structures.
 112 This is especially true under the actual conditions (small sample sizes) where the selec-
 113 tion of the “right” resampling scheme becomes a particularly challenging task. Several
 114 *ad hoc* methods have been therefore proposed, many of which now freely and publicly
 115 available in the form of powerful routines working under software package such as
 116 Python[®] or R[®]. In more details, while in the classic bootstrap an ensemble Γ repre-
 117 sents the population of reference the observed time series is drawn from, in *MEB* a
 118 large number of ensembles (subsets), say $\{\gamma_1, \dots, \gamma_N\}$ becomes the elements belong-
 119 ing to Γ , each of them containing a large number of replicates $\{x_1, \dots, x_J\}$. Perhaps,
 120 the most important characteristic of the *MEB* algorithm is that its design guarantees
 121 the inference process to satisfy the ergodic theorem. Formally, recalling the symbol
 122 $|\cdot|$ to denote the cardinality function (counting function) of a given ensemble of
 123 time series $\{x_t \in \gamma_i; i = 1, \dots, N\}$, the *MEB* procedure generates a set of disjoint
 124 subsets $\Gamma_N \equiv \gamma_1 \cap \gamma_2 \cap \dots \cap \gamma_N$ s.t. $|\Gamma_N| \approx \mu(x_t)$, being $\mu(\cdot)$ the sample mean. Fur-
 125 thermore, basic shape and probabilistic structure (dependency) is guaranteed to be
 126 retained $\forall x_{t,j}^* \in \gamma_i \subset \Gamma$.

127
 128 *MEB* resampling scheme has not negligible advantages over many of the avail-
 129 able bootstrap methods: it does not require complicated tune up procedures (unavoid-
 130 able, for example, in the case of resampling methods of the type Block Bootstrap) and it
 131 is effective under non-stationarity. *MEB* method relies on the entropy theory and the re-
 132 lated concept of (un)informativeness of a system. In particular, the Maximum Entropy
 133 of a given density $\rho(x)$, is chosen so that the expectation of the Shannon Information
 134 $\mathcal{H} = \mathbb{E}(-\log \rho(x))$, is maximized, i.e.

$$\max_{(\rho)} \mathcal{H} = \mathbb{E}(-\log \rho(x)).$$

135 Under mass and mean preserving constraints, this resampling scheme gener-
 136 ates an ensemble of time series from a density function satisfying (4). Technically, *MEB*
 137 algorithm can be broken down, following [Koutris et al. \(2008\)](#), in 8 steps. They are:

- 138 1. a sorting matrix of dimension $T \times 2$, say S_1 , accommodates in its first column the
 139 time series of interest x_t and an Index Set – i.e. $I_{ind} = \{2, 3, \dots, T\}$ – in the other
 140 one;
- 141 2. S_1 is sorted according to the numbers placed in the first column. As a result,
 142 the order statistics $x_{(t)}$ and the vector I_{ord} of sorted I_{ind} are generated and
 143 respectively placed in the first and second column;
- 144 3. compute “intermediate points”, averaging over successive order statistics, i.e.
 145 $c_t = \frac{x_{(t)} + x_{(t+1)}}{2}$, $t = 1, \dots, T - 1$ and define intervals I_t constructed on c_t and r_t ,
 146 using *ad hoc* weights obtained by solving the following set of equations:

i)

$$g(x) = \frac{1}{r_1} \exp\left(\frac{[x - c_1]}{r_1}\right); \quad x \in I_1; r_1 = \frac{3x_{(1)}}{4} + \frac{x_{(2)}}{4}$$

ii)

$$g(x) = \frac{1}{c_k - c_{k-1}}; \quad x \in (c_k; c_{k+1}],$$

$$r_k = \frac{x_{(k-1)}}{4} + \frac{x_{(k)}}{2} + \frac{x_{(k+1)}}{4}; \quad k = 1, \dots, T - 1;$$

iii)

$$g(x) = \frac{1}{r_T} \exp\left(\frac{[c_{T-1} - x]}{r_T}\right); x \in I_T; \quad r_T = \frac{x_{T-1}}{4} + \frac{3x_T}{4};$$

- 147 4. from a uniform distribution in $[0, 1]$, generate T pseudorandom numbers and
 148 define the interval $R_t = (t/T; t + 1/T]$ for $t = 0, 1, \dots, T - 1$, in which each p_j
 149 falls;
- 150 5. create a matching between R_t and I_t according to the following equations:

$$\begin{aligned} x_{j,t,me} &= c_{T-1} - |\theta| \ln(1 - p_j) & \text{if } p_j \in R_0, \\ x_{j,t,me} &= c_1 - |\theta| |\ln(1 - p_j)| & \text{if } p_j \in R_{T-1}, \end{aligned}$$

151 so that a set of T values $\{x_{j,t}\}$, as the j^{th} resample is obtained. Here θ is the
 152 mean of the standard exponential distribution;

- 153 6. a new $T \times 2$ sorting matrix S_2 is defined and the T members of the set $\{x_{j,t}\}$
 154 for the j^{th} resample obtained in Step 5 is reordered in an increasing order of
 155 magnitude and placed in column 1. The sorted I_{ord} values (Step 2) are placed in
 156 column 2 of S_2 ;
- 157 7. matrix S_2 is sorted according to the second column so that the order $\{1, 2, \dots, T\}$
 158 is there restored. The jointly sorted elements of column 1 is denoted by $\{x_{S,j,t}\}$,
 159 where S recalls the sorting step;
- 160 8. Repeat Steps 1 to 7 a large number of times.

161 5. The application of the maximum entropy bootstrap

162 In what follows, the proposed procedure is presented in a step-by-step fashion.

- 163 1. For each time series y_t^\bullet and y_t° the bootstrap procedure is applied so that $B=$
 164 100 “bona fide” replications are available as a result, i.e. $\tilde{y}_{t,b}^\bullet; b = 1, 2, \dots, B$ and
 165 $\tilde{y}_{t,b}^\circ; b = 1, 2, \dots, B$;
- 166 2. for both the series, the row vector related to the last observation T is extracted,
 167 i.e. $\{v^\circ = \tilde{y}_{T,1}^\circ, \tilde{y}_{T,2}^\circ \dots \tilde{y}_{T,B}^\circ\}$ and $\{v^\bullet = \tilde{y}_{T,1}^\bullet, \tilde{y}_{T,2}^\bullet \dots \tilde{y}_{T,B}^\bullet\}$;
- 168 3. the expected values, i.e. $\mathbb{E}(v^\bullet)$ and $\mathbb{E}(v^\circ)$, are then extracted along with the \approx
 169 95% confidence intervals (CI^\bullet and CI°), which are computed according to the
 170 t -percentile method. In essence, through this method, suitable quantiles of an
 171 ordered bootstrap sample of t -statistics are selected and, as a result, the critical
 172 values for the construction of an appropriate confidence interval become avail-
 173 able. A thorough explanation of the t -percentile method goes beyond the scope
 174 of this paper, therefore the interested reader is referred to the excellent paper by
 175 [Berkowitz and Kilian \(2000\)](#).

176 In particular, the lower (upper) CIs will be the lower (upper) bounds of our
 177 estimator while the quantities $\mathbb{E}(v^\bullet)$ $\mathbb{E}(v^\circ)$ are estimated through the mean operator,
 178 i.e.

$$\mu^\circ = \sum_{j=1}^6 v_j^\circ \quad (6)$$

179 and

$$\mu^\bullet = \sum_{j=1}^6 v_j^\bullet \quad (7)$$

180 At this point, it is worth emphasizing that the procedure not only, as just seen,
 181 requires very little in terms of input data (only the time series of the positives and
 182 the deaths are required) but also can be performed in an automatic fashion. In fact,
 183 once the data become available, one has just to properly assign the time series to
 184 the subsets Ω° and Ω^\bullet and the code will process the new data in an automatic way.
 185 The procedure is also very fast, as the computing time needed for the generation of
 186 the bootstrap samples requires – for the sample size in question – less than two min-
 187 utes. Both code and data-set employed in this paper are freely available upon request.
 188 However, the data can also be downloaded free of charge at the following web address:
 189 <https://github.com/pcm-dpc/COVID-19/tree/master/dati-regioni> (the file name is dpc-
 190 covid19-ita-regioni-20200323.csv).

191 6. Empirical evidences

192 In order to give the reader the opportunity to gain a better insight on the different epi-
 193 demic dynamical behaviors, in Figure 2 – 5 the time series of the variable C (as defined
 194 in Eqn. 2) is reported for each region. Note that the sudden variations noticeable in
 195 Figure 5 (Bolzano), Figure 4 (Valle D’Aosta) and Figure 3 (Molise and Campania) are
 196 due to the little number of tests administrated (i.e. the denominator of the variable C_T
 197 (2)) for these cases.

198 That said, the main result of the paper is summarized in Table 2, where three
 199 estimates of the number of positives are reported by region. The regions belonging to
 200 the set Ω° (no deaths) are in Italics whereas all the others, belonging to the set Ω^\bullet , are
 201 in a standard format. In the columns “Mean” and “Lower (Upper) Bounds”, the boot-
 202 strap estimates computed according to Eqn 6 and 7 and the Lower (Upper) Bounds
 203 the lower (upper) bootstrap CIs are respectively reported. The column denominated
 204 “Official Cases” accounts for the number of positives cases released by the Italian Au-
 205 thorities, whereas the column “Morbidity” expresses the percentage ratio between μ^\bullet
 206 (6) or μ° (7) and the actual population of each region, as recorded by the Italian Na-
 207 tional Institute of Statistics. The latter source of data can be freely accessed at the web
 208 address http://dati.istat.it/Index.aspx?DataSetCode=DCIS_POPRES1.

209
 210
 211 By examining the data for the whole Country, it is clear how the data collected
 212 by the Italian Authorities on the positive cases severely underestimate the current situ-
 213 ation by a factor of about 8. As expected, the top three regions in terms of number
 214 of infected persons are Lombardia, Emilia Romagna and Veneto, where the estimated
 215 infected population is respectively (bootstrap mean) around 45,020, 12,299 and 9,343.

216
 217 On the other hand, the risk of contagion is relatively low in some regions –
 218 mostly located in the Southern part of Italy – and in the island of Sardinia.

219
 220 Regarding the regions included in the subset Ω° , the application of the Piccolo
 221 distance (π) has generated the associations reported in Table 1.

223 7. Conclusions

224 It is widespread opinion in the scientific community that current official data on the
 225 diffusion of SARS-CoV-2, responsible of the correlated disease, COVID-19, among pop-
 226 ulation, are likely to suffer from a strong downward bias.

Table 1. Association found between the regions belonging to Ω° and those in Ω^\bullet according to the minimum distance π

Ω°	Ω^\bullet	π
Basilicata	Veneto	0.0389
Calabria	Campania	0.6211
Molise	Lazio	0.4212
Sardegna	Abruzzo	0.0157
Trento	Abruzzo	0.00186
Umbria	Sicilia	0.01398

227 In this scenario, the aim of this paper is twofold: on one hand, it generates
 228 realistic figures on the effective number of people infected with SARS-CoV-2 at a na-
 229 tional and regional level; on the other hand, it provides a methodology representing a
 230 viable alternative to those interested to apply inference procedures on the diffusion of
 231 epidemics.

232
 233 Following Pueyo (2020), this paper proposes a methodology which uses simple
 234 counts, i.e. the number of deaths and the number of people tested positive to the virus
 235 for Italy, to

- 236 1. provide an estimation at the national and regional level of the number of infected
 237 people and the related confidence intervals;
- 238 2. extend Puejo's methodology to those regions exhibiting no deaths as a conse-
 239 quence of the contraction of the CoViD-19.

240 The entire procedure has been written in the programming language R[®] and
 241 uses official data as published by the Italian National Institute of Health. The whole
 242 code is available upon request.

243
 244 The results obtained show that, while official data at March 12th report, for
 245 Italy, a total of 12.839 cases, the people infected with the SARS-CoV-2 could be as
 246 high as 105.789. This result, along with the estimated average doubling time for the
 247 CoViD-19 (≈ 6.2 days), confirms that this pandemic is to be regarded as much more
 248 dangerous than currently foreseen.

249

Table 2. Estimation of the number of people infected from CoViD-19 by Italian regions. Lower and Upper Bounds are computed through the Bootstrap t-percentile method whereas the mean values is computed as in (6) and (7). The regions belonging to the set Ω° are in Italics

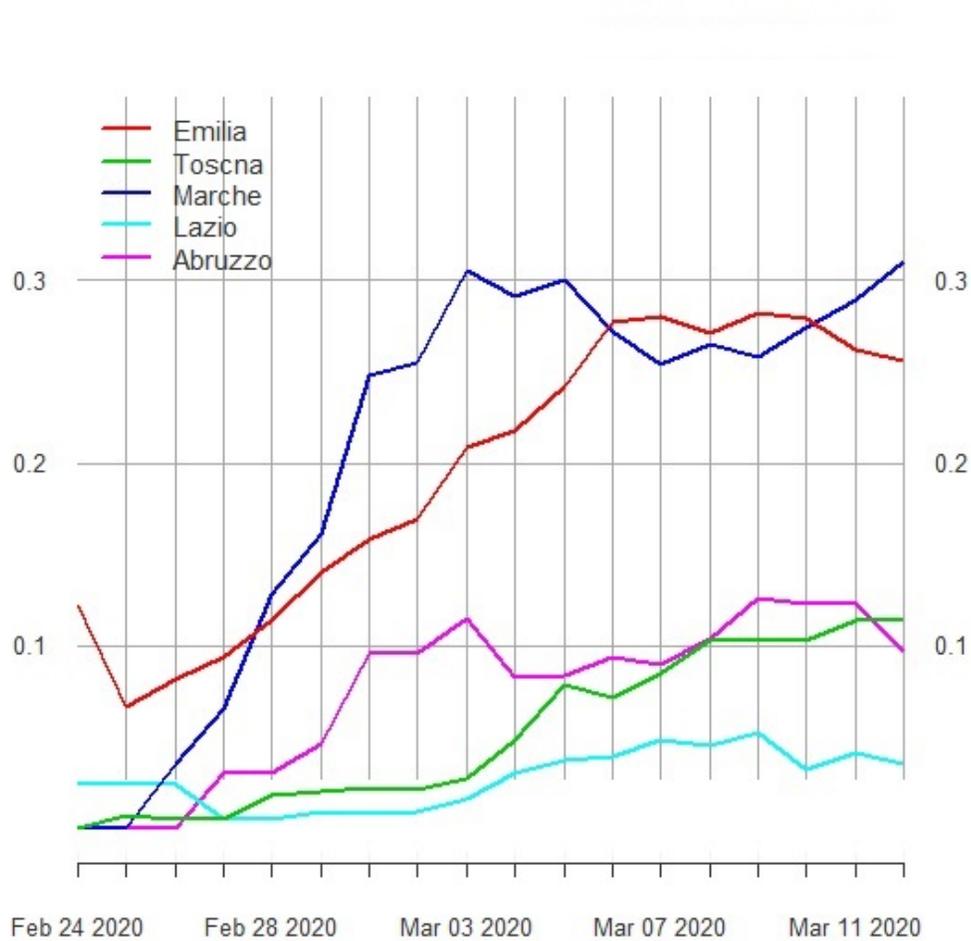

Fig. 2. Percentage ratio deaths / new cases for the following Italian regions Emilia, Toscana, Marche, Lazio and Abruzzo

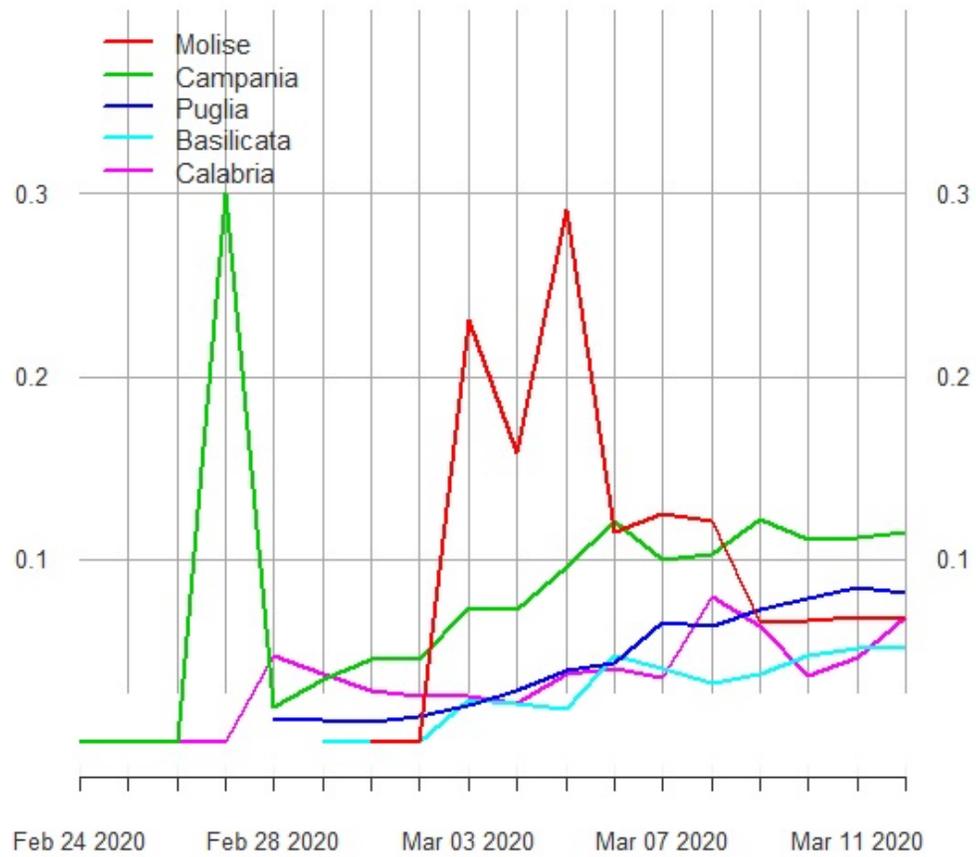

Fig. 3. Percentage ratio deaths / new cases for the following Italian regions: Molise, Campania, Puglia, Basilicata and Calabria

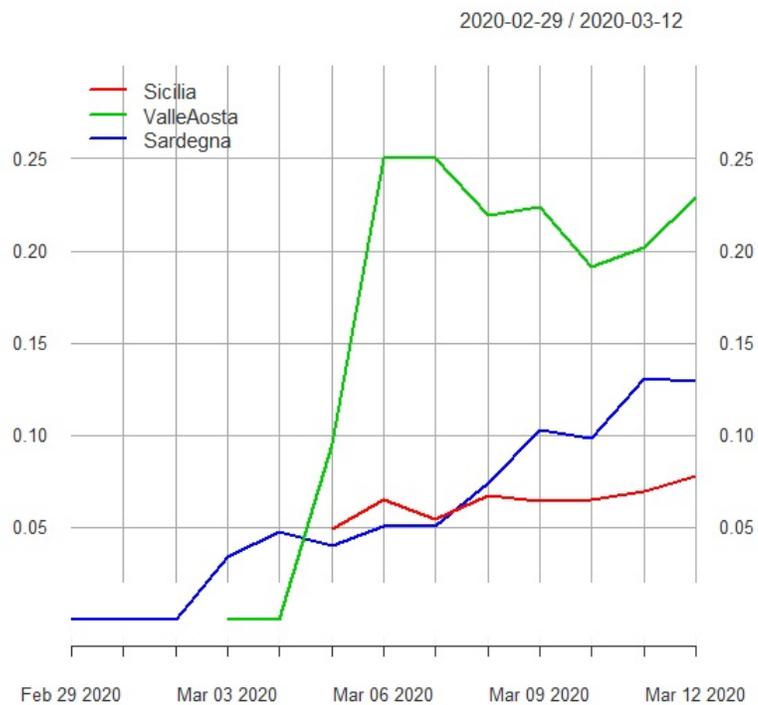

Fig. 4. Percentage ratio deaths / new cases for the following Italian regions: Sicilia, Valle d'Aosta, Sardegna)

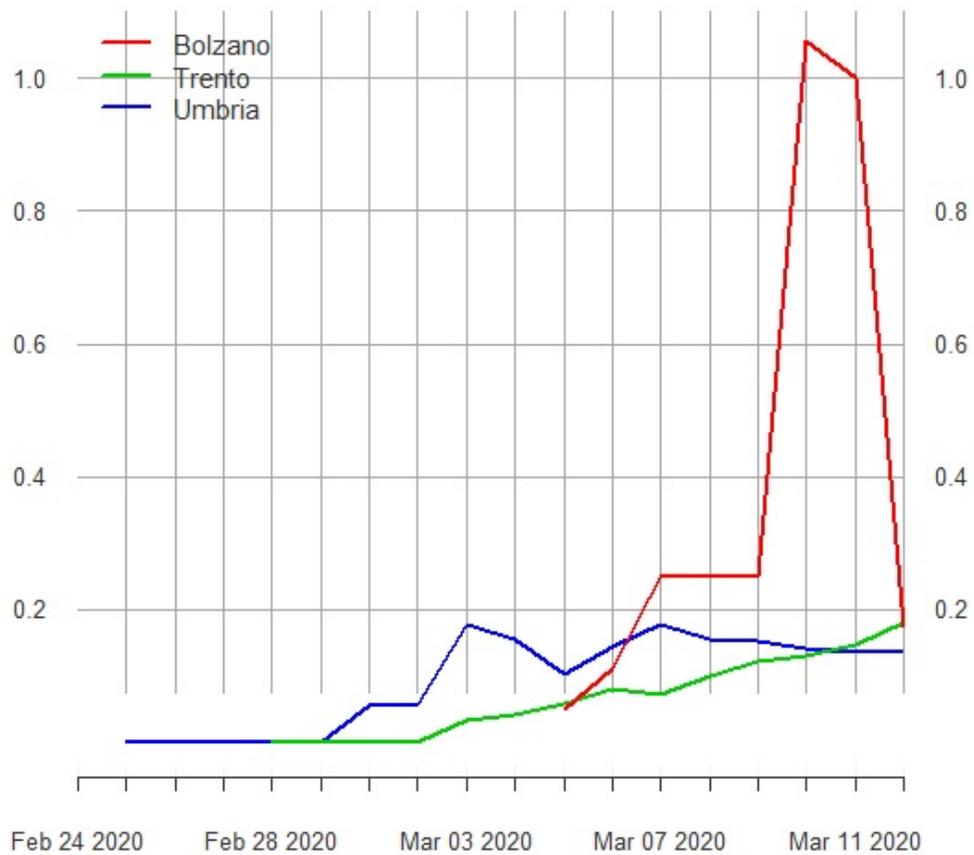

Fig. 5. Percentage ratio deaths / new cases for the following Italian regions: Bolzano, Trento, Umbria)

250 **8. Acknowledgments**

251 The author is deeply grateful to Dr. Luigi Di Landro for the generous help in the proof-
252 reading process.
