Background: The block phase in the swimming start requires a quick reaction to the starting signal and a large take-off velocity that is primarily horizontal in direction. Due to the principle of specificity of training, there is a potential benefit of performing a greater proportion of horizontal force production exercises in a swimmers' dry-land resistance training sessions. Therefore, the purpose of this pilot study was to provide an insight into the effects of a horizontal- (HF) versus vertical-force (VF) training intervention on swim start performance. Methods: Eleven competitive swimmers (six males (age 20.9 ± 1.8 years, body mass 77.3 ± 9.7 kg, height 1.78 ± 0.05 m) and five females (age 21.4 ± 2.0 years, body mass 67.5 ± 7.4 kg, height 1.69 ± 0.05 m)) completed two weekly sessions of either a horizontal- or vertical-force focused resistance training program for eight weeks. Squat jump force-time characteristics and swim start kinetic and kinematic parameters were collected pre- and post-intervention. Results: Across the study duration, the swimmers completed an average of nine swimming sessions per week with an average weekly swim volume of 45.5 ± 17.7 km (HF group) and 53 ± 20.0 km (VF group), but little practice of the swim start per week ($n = 9$). Within-group analyses indicated a significant increase in predicted 1RM hip thrust strength in the HF group, as well as significant increases in grab resultant peak force but reductions in resultant peak force of the block phase for the VF group. No significant between-group differences in predicted 1RM hip thrust and back squat strength, squat jump force-time and swim start performance measures were observed after eight weeks of training. Significant correlations in the change scores of five block kinetic variables to time to 5 m were observed, whereby increased block kinetic outputs were associated with a reduced time to 5 m. This may be

indicative of individual responses to the different training programs. Discussion: The results of this current study has been unable to determine whether a horizontal- or vertical-force training program enhances swim start performance after an eight-week training intervention. Some reasons for the lack of within and between group effects may reflect the large volume of concurrent training and the relative lack of any deliberate practice of the swim start. Larger samples and longer training duration may be required to determine whether significant differences occur between these training approaches. Such research should also look to investigate how a reduction in the concurrent training loads and/or an increase in the deliberate practice of the swim start may influence the potential changes in swim start performance.

Abstract

4   Background: The block phase in the swimming start requires a quick reaction to the starting
5   signal and a large take-off velocity that is primarily horizontal in direction. Due to the principle
6   of specificity of training, there is a potential benefit of performing a greater proportion of
7   horizontal force production exercises in a swimmers' dry-land resistance training sessions.
8   Therefore, the purpose of this pilot study was to provide an insight into the effects of a
9   horizontal- (HF) versus vertical-force (VF) training intervention on swim start performance.

10 Methods: Eleven competitive swimmers (six males (age 20.9 ± 1.8 years, body mass 77.3 ± 9.7
11 kg, height 1.78 ± 0.05 m) and five females (age 21.4 ± 2.0 years, body mass 67.5 ± 7.4 kg,
12 height 1.69 ± 0.05 m)) completed two weekly sessions of either a horizontal- or vertical-force
13 focused resistance training program for eight weeks. Squat jump force-time characteristics and
14 swim start kinetic and kinematic parameters were collected pre- and post-intervention.

15 Results: Across the study duration, the swimmers completed an average of nine swimming
16 sessions per week with an average weekly swim volume of 45.5 ± 17.7 km (HF group) and $53 \pm$
17 20.0 km (VF group), but little practice of the swim start per week ($n = 9$). Within-group analyses
18 indicated a significant increase in predicted 1RM hip thrust strength in the HF group, as well as
19 significant increases in grab resultant peak force but reductions in resultant peak force of the
20 block phase for the VF group. No significant between-group differences in predicted 1RM hip
21 thrust and back squat strength, squat jump force-time and swim start performance measures were
22 observed after eight weeks of training. Significant correlations in the change scores of five block
23 kinetic variables to time to 5 m were observed, whereby increased block kinetic outputs were
24 associated with a reduced time to 5 m. This may be indicative of individual responses to the
25 different training programs.

26 Discussion: The results of this current study has been unable to determine whether a horizontal-
27 or vertical-force training program enhances swim start performance after an eight-week training
28 intervention. Some reasons for the lack of within and between group effects may reflect the large
29 volume of concurrent training and the relative lack of any deliberate practice of the swim start.
30 Larger samples and longer training duration may be required to determine whether significant
31 differences occur between these training approaches. Such research should also look to
32 investigate how a reduction in the concurrent training loads and/or an increase in the deliberate
33 practice of the swim start may influence the potential changes in swim start performance.

34

Introduction

36 The important role that muscular strength and power play in enhancing swimming performance
37 has led to the widespread adoption of dry-land resistance training modalities into a concurrent
38 training model for competitive swimmers (Aspenes et al. 2009; Crowley et al. 2017; Haycraft &
39 Robertson 2015). While much of the swimming strength and conditioning research has been on
40 the free swim portion (Crowley et al. 2017), there is now a greater focus on starts and turns since
41 swimmers have to rapidly apply large forces on the starting block or wall to increase horizontal
42 impulse and velocity (Born et al. 2020; Jones et al. 2018; Rebutini et al. 2014).

43 Changes in the starting block and starting technique may have further increased the importance
44 of lower body strength and power for swim start performance. The OSB11 start block, which

45   was introduced by the International Swimming Federation in 2010, has an angled kick plate at
46   the rear of the block that enables the swimmer to adopt a kick start technique (Tor et al. 2015a).
47   The additional kick plate allows for an increased duration of effective force application (i.e.
48   greater horizontal force component) on the blocks, which can increase horizontal impulse and
49   take-off velocity (Honda et al. 2010).

50   With the new OSB11 start block and kick start technique, the swim start may share some
51   similarities to the sprint start in track and field regarding the starting position, importance of a
52   quick reaction to the starting stimulus, and the need to produce large horizontal impulse on the
53   starting blocks (Čoh et al. 2017; Harland & Steele 1997). Analysis of the force-time
54   characteristics of swimmers performing the squat jump has identified concentric impulse as a
55   strong predictor of swim start performance as assessed by time to 5 m and 15 m (Thng et al.
56   2020). Further, near perfect correlations ($r > 0.90$) between countermovement jump height or
57   take-off velocity and very large correlations for measures of maximal strength ($r = 0.7$-0.9) to
58   swim start performance have been reported in a recent systematic review (Thng et al. 2019).

59   Despite the strength of this cross-sectional literature (Thng et al. 2019), there is relatively little
60   research quantifying the chronic effects of resistance training on swim start performance. Three
61   studies have utilised jump and plyometric exercise programs (Bishop et al. 2009; Rebutini et al.
62   2014; Rejman et al. 2017), two studies (Breed & Young 2003; Garcia-Ramos et al. 2016) used a
63   more general resistance training program, and one study (Born et al. 2020) compared the effects
64   of maximal strength resistance training to plyometrics. The three plyometric studies included
65   adolescent (Bishop et al. 2009) and national level swimmers (Rebutini et al. 2014; Rejman et al.
66   2017) who performed six to nine weeks of plyometrics, twice a week. Significant improvements
67   in time to 5 m and 5.5 m, take-off velocity and horizontal forces and impulse were observed as a
68   result of these plyometric exercise programs (Bishop et al. 2009; Rebutini et al. 2014; Rejman et
69   al. 2017). In contrast, the remainder of these plyometric and resistance training studies typically
70   reported no significant changes in time to 5 m or 15 m, or any block phase kinetic or kinematic
71   characteristics (Born et al. 2020; Breed & Young 2003; Garcia-Ramos et al. 2016). The only
72   exception to this was the significant improvements in time to 5 m and 15 m observed for the
73   subset of under 17 year old swimmers who performed maximal strength training, with no such
74   effects reported for the under 17 year old plyometric group (Born et al. 2020).

75   A possible explanation for the uncertainty regarding whether jump/plyometric or more general
76   resistance training programs produces greater improvements in swim start performance may
77   reflect the direction-specific nature of resistance training. In a review by Randell et al. (Randell
78   et al. 2010) on the specificity of resistance training to sports performance, it was proposed
79   training adaptations may be direction-specific, and that athletes who are required to apply forces
80   in the horizontal plane should perform several exercises containing a horizontal component.
81   More recently, this directional specificity of training has been referred to as the force-vector
82   theory (Fitzpatrick et al. 2019), with the hip thrust and prowler push/heavy sled pull being two of
83   the most commonly used horizontal-force exercises (Contreras et al. 2017; Fitzpatrick et al.
84   2019; Morin et al. 2017; Winwood et al. 2015). A study by Contreras et al. (Contreras et al.
85   2017) using the hip thrust significantly improved 10 m and 20 m sprint running times (-1.05%
86   and -1.67%, respectively) compared to the front squat, which is a vertical-force exercise (+0.10%
87   and -0.66%, respectively). The prowler push, which requires the athlete to push a loaded sled in
88   the horizontal plane, has been shown to closely mimic the horizontal plane power requirements
89   of sprinting (Tano et al. 2016). A study involving 30 sub-elite rugby players observed that a

90   horizontal-focused resistance training program including the prowler push significantly
91   improved performance in a number of strength, sprinting, and change of direction tests
92   (Winwood et al. 2015). However, no significant between-group effects were observed between
93   the horizontal-focused and traditional resistance training programs (Winwood et al. 2015).

94   The potential direction specificity of resistance training exercises for improving aspects of swim
95   start performance has been examined in two jump and plyometric training studies (Rebutini et al.
96   2014; Rejman et al. 2017) and two acute training studies utilising post-activation potentiation
97   (PAP) (Cuenca-Fernandez et al. 2015; Cuenca-Fernández et al. 2018). Rebutini et al. (Rebutini et
98   al. 2014) and Rejman et al. (Rejman et al. 2017) observed a 10.4% and 13.8% increase in take-
99   off velocity in the swim start post nine- and six-weeks of plyometric training, respectively that
100 included a variety of horizontal jumps. Acute improvements in time to 5 m (Cuenca-Fernandez
101 et al. 2015; Cuenca-Fernández et al. 2018) and 15 m (Cuenca-Fernandez et al. 2015) after
102 performing PAP protocols that were biomechanically similar to the foot position in the kick start
103 on the OSB11 start block have also been observed. However, out of these four plyometric and
104 PAP studies, only one (Cuenca-Fernandez et al. 2015) utilised the OSB11 start block and the
105 kick start technique currently used by high performance swimmers.

106 Therefore, the primary aim of this pilot study was to gain some preliminary insight into the
107 comparative effects of a horizontal- versus vertical-force resistance training program on swim
108 start performance and squat jump (SJ) force-time characteristics. A secondary aim of the study
109 was to better understand how changes in certain SJ force-time characteristics may be correlated
110 with the changes in swim start performance in competitive swimmers.

111

Materials & Methods

Experimental design

114 An eight-week training program sought to examine how a horizontal-force (HF) compared to
115 vertical-force (VF) oriented emphasis resistance training program would potentially alter swim
116 start performance. Participants were randomly assigned to either a HF or VF training group (HF:
117 $n = 6$, VF: $n = 7$), with each group performing two resistance training sessions per week.

118

Participants

120 Thirteen participants (8 males (age 21.0 ± 1.6 years, body mass 78.6 ± 8.3 kg, height 1.80 ± 0.06
121 m), and 5 females (age 21.4 ± 2.0 years, body mass 67.5 ± 7.4 kg, height 1.69 ± 0.05 m))
122 volunteered to participate in this study. Participants were national level swimmers with at least
123 four years' experience in competing in national championships and at least one year of land-
124 based resistance training experience that included the barbell back squat and hip thrust under the
125 supervision of a strength and conditioning coach. Participants with any known contraindication
126 to maximal training performance and/or injuries that would interfere with their ability to
127 complete the study or compromise their health and wellness were excluded. Prior to participating
128 in this study, participants were briefed on the experimental design and gave written informed
129 consent to participate in the study. This investigation was conducted in accordance with the

130 Declaration of Helsinki and approved by Bond University Human Research Ethics Committee
131 (00088).

132 Assessments were conducted at baseline (week one) and the end of the training program (week
133 nine). Participants were instructed to maintain their nutritional and sleep habits, and to avoid
134 alcohol and caffeine consumption for at least 24 hours before testing sessions. All tests were
135 performed on the same day of the week between 7:00 am and 11:00 am. Participants reported to
136 the gymnasium to perform the squat jump test prior to the swim start performance test.

137

138 **Training intervention**

139 The training program was organised into two phases. In the first phase (weeks one to four), each
140 group performed three HF and VF lower body exercises, respectively. A direction specific lower
141 body jump was added in the second phase for each group (weeks five to eight) (Table 1). The HF
142 training group was prescribed a "start jump", which is a jump for horizontal distance initiated
143 from a mimicked swim start position (Fig. 1), while the VF training group performed the squat
144 jump. When performing the jumps, the HF group were instructed to jump as far forward as
145 possible, while the VF group were instructed to jump as high as possible with each jump.

146

147 Please insert Figure one about here
148

149 Participants performed the training program utilising sets and repetition ranges typically used for
150 developing maximal strength (Bird et al. 2005). Participants followed two 4-week mesocycle
151 using a 3:1 loading paradigm, with a progressive increase in load for the first three weeks
152 followed by a reduction in load in the fourth week (Turner 2011). This was considered important
153 as the swimmers were still maintaining high volumes of swimming training throughout the
154 intervention. As the majority of propulsive forces in the free swim phase comes from the upper
155 body (Morouço et al. 2015), both groups also performed three sets of several upper body
156 exercises including pull-ups, bench pull or seated row; and three sets of exercises for the
157 abdominals/ lower back region, as successfully used by Contreras et al. (Contreras et al. 2017) in
158 a previous horizontal- versus vertical-force direction study. Sets were separated by a one-minute
159 rest period (Ritchie et al. 2020). Training records were kept for each participant to analyse the
160 load progression of the training program. Predicted one repetition maximum (1RM) of the hip
161 thrust and barbell back squat was calculated pre- and post-intervention using the Brzycki
162 equation: Predicted 1RM = weight lifted /1.0278-0.0278(no. of repetitions) (Brzycki 1993).
163 Repetition ranges used in the predicted 1RM was performed during the first training session
164 (estimated from eight repetitions) and at the last training session (estimated from four
165 repetitions). Participants were asked to refrain from performing any additional resistance training
166 and to maintain their current diet for the course of this study.

167 Please insert Table one about here

168
169 **Squat jump test**

---

170   The SJ test were collected as previously described by Thng et al. 2020. All participants
171   completed a standardised dynamic warm-up consisting of a predetermined series of dynamic
172   joint range of motion of the upper and lower body under the supervision of a strength and
173   conditioning coach. Following the warm-up, participants were given two practice SJs before the
174   test was conducted. All SJs were performed on a force platform (ForceDecks FD4000, London,
175   United Kingdom), with a sample rate of 1000 Hz. Participants started in an upright standing
176   position with their hands on their hips. They were then instructed to keep their hands on their
177   hips to prevent the influence of arm movements for the jump trials. All participants were
178   instructed to adopt a squat position using a self-selected depth that was held for 3 seconds before
179   attempting to jump as high as possible (Mitchell et al. 2017). A successful trial was one that did
180   not display any small amplitude countermovement at the start of the jump phase on the force
181   trace (Sheppard & Doyle 2008). All participants performed three maximal effort SJs with a 30-
182   second passive rest between each effort. The SJ trial with the highest jump height was kept for
183   data analysis. Jump height was determined by the flight-time method (Jump height = $g*t^2/8$,
184   where g is the acceleration due to gravity and t is the flight time) (Linthorne 2001). Ground
185   reaction force data from the SJs were analysed using the commercially available ForceDecks
186   software (ForceDecks, London, United Kingdom). Out of the 46 variables that is provided by
187   ForceDecks, the SJ variables that were identified by Thng et al. (Thng et al. 2020) as significant
188   predictors of swim start performance were extracted for analysis.

189

190   **Swim start performance test**

191   Swim starts were collected using methods as described by Thng et al. 2020. Prior to the swim
192   start test, all swimmers completed a pool-based warm-up based on their usual pre-race warm-up
193   routine. Participants then performed three maximal effort swim starts to 15 m with their main
194   swim stroke (front crawl ($n = 8$), butterfly ($n = 3$), or breaststroke ($n = 2$)) and preferred kick
195   plate position, which was recorded to ensure consistency between testing sessions. Trials were
196   started as per competition conditions and swimmers were instructed to swim to a distance past
197   the 15 m mark, in order to ensure that representative values at the 15 m distance were obtained
198   (Barlow et al. 2014). Two-minutes of passive recovery was given between each trial (Tor et al.
199   2015b). The start with the fastest 15 m time were selected for further analysis. Swim starts were
200   collected using a Kistler Performance Analysis System – Swimming (KiSwim, Kistler
201   Winterthur, Switzerland), which utilises a force instrumented starting block, constructed to
202   match the dimensions of the Omega OSB11 block (KiSwim Type 9691A1; Kistler Winterthur,
203   Switzerland). Time to 5 m and 15 m were collected using five calibrated high speed digital
204   cameras operating at 100 frames per second, synchronised to the instrumented KiSwim starting
205   block. One camera was positioned 0.95 m above the water and 2.5 m perpendicular to the
206   direction of travel to capture the start and entry of swimmer into the water, while the other three
207   cameras were positioned 1.3 m underwater at 5 m, 10 m and 15 m perpendicular to the swimmer
208   to capture the time to 15 m. The times to 5 m and 15 m were defined as the time elapsed from the
209   starting signal until the apex of the swimmers' head passed the respective distances (Tor et al.
210   2015b). An Infinity Start System (Colorado Time Systems, Loveland, Colorado, USA) provided
211   an audible starting signal to the athletes and an electronic start trigger to the KiSwim system.
212   Kinetic and kinematic variables of block performance extracted for analysis were identified by
213   Thng and colleagues as key predictors of time to 5 m and 15 m (Thng et al., unpublished data). A
214   description of the SJ and swim start variables analysed are provided in Table 2.

215

216   Please insert Table two about here

217   **Statistical Analysis**

218   Descriptive statistics are reported as mean ± SD for normally distributed continuous variables
219   and frequencies for categorical variables. Normality was checked using histograms, normal Q-Q
220   plots, and the Shapiro-Wilk test. A paired sample *t*-test was used to determine whether
221   statistically significant differences were found between pre- and post-test means within each
222   group. Independent *t*-tests were carried out to test for the difference in change in the outcome
223   between intervention groups. Effect sizes (ES) with 95% confidence intervals (95% CI) were
224   reported in standardized (Cohen's d) units as the change in mean to quantify the magnitude of
225   differences within (i.e. post-intervention – pre-intervention results) and between the two
226   intervention groups (i.e. HF and VF). Criteria to assess the magnitude of observed changes were:
227   0.0-0.2 trivial; 0.20 – 0.60 small; 0.60 – 1.20 moderate; and > 1.20 large (Hopkins 2002). Effect
228   sizes were calculated using a program created by Lenhard and Lenhard (2016).

229   To gain some preliminary insight into how changes in the SJ force-time characteristics may be
230   correlated with the changes in swim start performance, the association between the change scores
231   (calculated as the difference between each individuals' pre- and post-test scores) for these
232   outcomes were assessed by Pearson's product-moment correlation coefficient (*r*). Data were
233   analysed with SPSS version 23.0.0 (SPSS Inc., Chicago, IL). P-values < 0.05 were deemed to
234   indicate statistical significance.

235

236   **Results**

237   **Training compliance**

238   Of the 13 initial participants, 11 participants completed the training study (Table 3). Two
239   participants were removed due to: moving to another swim squad (*n* = 1) and non-adherence to
240   the training protocol (*n* = 1). Participants completed a total of 14 ± 3 out of 16 training sessions,
241   with the primary reasons for missed training sessions being short-term illness or domestic
242   competitions. A summary of the within-group and between-group changes are provided in Table
243   4.

244

245   Please insert Table three about here

246

247   **Within-group changes post-intervention**

248   Only three significant within-group differences were observed across both groups. For the HF
249   group, a significant increase in predicted 1RM hip thrust strength (*p* = 0.04) was observed. The
250   VF group had a significant increase in KiSwim grab resultant peak force (*p* = 0.007) and a
251   significant decrease in KiSwim resultant peak force (*p* = 0.02).

252

253 **Between-group changes post-intervention**

254 There was a trend for the HF training group to have a greater increase in predicted 1RM strength
255 (50 %) for the hip thrust than the increase in back squat strength for the VF training group (18
256 %) after 8 weeks of training. Moderate effect sizes were observed in two SJ force-time variables
257 and five KiSwim variables (Table 4). Specifically, moderate effect size improvements in SJ jump
258 height and three swim start kinetic measures were observed in the HF group. In the VF group, SJ
259 concentric RPD and two swim start kinetic measures favoured moderate effect size
260 improvements in the VF group.

261

262
263 Please insert Table four about here

264

265 When looking at individual changes across both groups, no significant correlations were
266 observed between the change scores in any of the ForceDecks outcome measures and time to 5 m
267 or 15 m. Similarly, there were no significant correlations in the change score correlations
268 between the KiSwim outcomes and time to 15 m. However, significant correlations between the
269 change scores for five KiSwim outcomes and time to 5 m were observed. These were average
270 acceleration (r = -0.82, p = 0.02), horizontal take-off velocity (r = -0.81, p = 0.03), average
271 power (r = -0.77, p = 0.05), work (r = -0.74, p = 0.01) and rear resultant average force (r = -0.71,
272 p = 0.02).

273
274 **Discussion**

275 The present pilot study was designed to provide some insight into the potential directional
276 specificity of resistance training (now referred to as the force-vector theory) on swim start
277 performance and squat jump (SJ) force-time characteristics in competitive swimmers. This was
278 achieved by examining the within- and between-group training-related changes in swim start
279 performance for two groups of competitive swimmers, who differed on whether they performed
280 a horizontal- or vertical-force oriented emphasis resistance training program.

281 Relatively few significant within-group changes in any outcome measures were observed, with
282 the non-significant changes being trivial to small in their effect sizes. The three significant
283 within-group changes included significant increases in predicted 1RM hip thrust strength for the
284 HF group as well as significant increases in swim start grab resultant peak force but reductions in
285 resultant peak force for the VF group. No significant between-group differences were observed
286 between the HF and VF groups in predicted 1RM strength, SJ force-time and swim start
287 performance measures post-intervention. However, seven moderate between-group effect size
288 differences were observed, with four outcome measures favouring greater improvements for the
289 HF group and three outcome measures favouring the VF group. As such, this current study has
290 been unable to determine whether the inclusion of horizontally oriented exercises has any clear
291 benefit to swim start performance over more conventional vertically oriented exercises.

292 Possible explanations for our lack of significant within- or between-group improvements may
293 include the small number of participants and short duration of the training intervention, inclusion

294 of plyometric and non-plyometric jumps in only the last four of eight weeks of training, the
295 interference effect due to concurrent training and the relative complexity of the swim start.
296 Regarding the length of the intervention, the absence of any significant improvements in swim
297 start performance in the current study was consistent with some studies involving 21 (Born et al.
298 2020) or 23 (Breed & Young 2003) participants performing 6-8 weeks of resistance training, but
299 inconsistent with other plyometric training studies of 6-9 weeks involving nine (Rejman et al.
300 2017), 10 (Rebutini et al. 2014) or 22 (Bishop et al. 2009) participants.

301 The potentially greater adaptations in swim start performance observed in previous plyometric
302 studies may reflect the between study differences in plyometrics training volume. The present
303 study only included 33 jumps, compared to previous successful plyometric studies (Bishop et al.
304 2009; Rebutini et al. 2014; Rejman et al. 2017), which included ~484–883 jumps across the
305 study. Interestingly, even though Born et al. (2020) included comparable volumes of plyometrics
306 in their training study (~360–588 jumps) to those of the successful studies, the plyometric
307 training group reported no significant improvements in swim start performance. While it cannot
308 be discounted that the present study included an insufficient volume of plyometric exercise, the
309 lack of any widespread changes in lower body force-time characteristics and swim start
310 performance metrics observed in the present study and some of the literature (Born et al. 2020;
311 Breed & Young 2003), may be indicative of the challenges coaches face in making any
312 substantial improvements in strength and power characteristics that transfer to improved sporting
313 performance within such short periods of concurrent training.

314 Concurrent training is complex in that both swim training and resistance training impose
315 different acute stresses on the body that elicit distinct adaptations. In particular, the concurrent
316 development of both muscular strength/power and aerobic endurance from resistance training
317 and swimming training, respectively can lead to conflicting neuromuscular adaptations (Garcia-
318 Pallares et al. 2009). In the current study, participants were primarily middle to long distance
319 swimmers, who performed nine in-water sessions weekly (HF: 45.5 km and VF: 53 km per
320 week). The sessions had an average swimming volume of 5.1 km and 5.8 km for the HF and VF
321 group per session, with two swimming sessions a day performed several days per week. In
322 contrast, the resistance training program was only performed twice per week. The interference
323 effect from concurrent training is more likely observed with ≥ three sessions of high volume
324 endurance training weekly (Bishop et al. 2019). Therefore, the high aerobic training volume for
325 the participants in the present study likely attenuated any resistance training-induced adaptations.
326 Consistent with this view, Haycraft and Robertson (Haycraft & Robertson 2015) recommend
327 swim training volumes be reduced ≤ 5 km per day to enable maximal strength and power gains
328 and minimise neuromuscular fatigue.

329 It should also be acknowledged that the swim start is a discrete skill, requiring a quick reaction to
330 the starting stimulus and the ability to effectively coordinate hand and foot forces to optimise
331 horizontal impulse and take-off velocity. Unfortunately, the swimmers in the present study only
332 performed a small number of swim starts per week ($n = 9 \pm 2$), with this performed either during
333 regular swim training or at the end of the session. It was also interesting to observe that Born et
334 al. (2020) also reported a low volume of swim starts ($n = 16$) performed per week. Breed &
335 Young (2003) emphasised that a higher skill component is involved in executing the swim start
336 in comparison to vertical jump. This may reflect the requirement for how the ankle, knee, and
337 hip joint moments needs to be coordinated effectively with those of the upper body during the
338 block phase to maximise horizontal take-off velocity. Further, minimising the time to 15 m also

339   requires a clean entry into the water and a streamlined glide position with undulatory leg kicks to
340   minimise velocity loss while transitioning into the break-out of full swimming and stroking after
341   15 m (Vantorre et al. 2014). The relative absence of deliberate practice of the swim start coupled
342   with performing the starts in a fatigued state may also help explain the minimal transfer of the
343   resistance training interventions to improved swim start performance in the current study and
344   that of Born et al. (2020). However, significant correlations in the change scores of five block
345   kinetic variables to time to 5 m were observed in the current study, whereby an increase in block
346   kinetic variables was associated with a decrease in time to 5 m. Such correlations suggest that the
347   longitudinal tracking of individual swimmers' SJ force-time characteristics may provide some
348   insight into their potential improvements in swim start performance.

349   Due to the demands of competitive swimming, it seems necessary that a targeted approach of
350   both resistance training and deliberate practice of the swim start is required across the annual
351   periodisation plan to improve swim start performance. This is especially important to minimise
352   the potential adverse effects of concurrent training and maximise skill acquisition, particularly
353   for swimmers who need to improve aspects of their swim start technique, given the complexity
354   of the swim start. Practical recommendations include a targeted block of resistance training
355   focused on improving the strength and power characteristics required for the swim start in a low
356   swimming volume phase such as pre-season for a longer duration than used in the present study.
357   Specifically, extended intervention periods > 6 months have been suggested for an optimal
358   transfer of strength and power qualities to performance in well-trained endurance athletes
359   (Beattie et al. 2014). Incorporating greater amounts of deliberate practice of swim starts,
360   especially at the beginning of each training session when the swimmer is mentally and physically
361   fresh would appear to be beneficial for skill acquisition (Branscheidt et al. 2019).

362   **Conclusion**

363   There were very few significant differences observed, either within or between the HF and VF
364   groups after an eight-week training intervention on swim start performance. Despite exploring
365   the inclusion of a higher proportion of horizontally oriented exercises based on the force-vector
366   theory, the current study did not observe a transfer to improved swim start performance.
367   However, this should not discount the potential value of including horizontally directed exercises
368   to improve swim start performance, given the results were similar to those from more traditional
369   vertically oriented exercises. Future studies should consider an extended training intervention
370   completed during a phase of lower swim training volume to enable strength and power adaptions
371   to occur.

372

373   **Acknowledgements**

374   This work was supported by the Queensland Academy of Sport's Sport Performance Innovation
375   and Knowledge Excellence Unit in conjunction with Bond University Faculty of Health Sciences
376   and Medicine. The authors would like to acknowledge Mr. Andrew Pyke for his assistance with
377   data collection and coach Mr. Adam Mallet for allowing his athletes to be a part of this study.
378   The authors also wish to thank Ms. Evelyne Rathbone for her statistical assistance in this study
379   and resulting manuscript. There is no conflict of interest related to the content of this article.

Description of squat jump variables obtained from the ForceDecks force platform, and the swim start variables obtained from the KiSwim Performance Analysis System.

1 Table 2. Description of squat jump variables obtained from the ForceDecks force platform, and
2 the swim start variables obtained from the KiSwim Performance Analysis System.

	Variable	Description
ForceDecks SJ variables	Concentric impulse (N.s.)	Net impulse of vertical force during the concentric phase
	Concentric mean power (W)	Mean power during concentric phase
	Concentric rate of power development (RPD) (W/s)	Rate of power development between start of concentric phase to peak power
	Jump height (cm)	Jump height calculated from Flight Time (time between take-off and landing) in centimetres
	Reactive strength index modified (RSImod) (m/s)	Jump height (Flight Time) divided by contraction time
KiSwim swim start kinetic variables	Average acceleration (m/s/s)	Horizontal take-off velocity/ seconds from starting gun to take-off
	Average power (W/kg)	The average power relative to the swimmers' body mass produced from the starting signal to when the swimmer leaves the starting block. This was calculated as the product of (absolute force x absolute velocity) / body mass
	Horizontal take-off velocity (m/s)	The horizontal take-off velocity calculated by integrating horizontal acceleration
	Work/kg (J/kg)	Average power x seconds from the starting gun to take-off
	Front horizontal peak force (N)	Peak horizontal force on the front plate of the starting block (grab bar component not subtracted)
	Grab resultant peak force (N/BW)	Peak grab bar resultant force
	Rear horizontal peak force (N)	Peak horizontal force on the foot plate (grab bar component not subtracted)
	Total resultant peak force (N)	Peak resultant force (grab bar component subtracted)
	Rear resultant average force (N/BW)	Average resultant force on the foot plate (grab bar component not subtracted)
Swim start performance times	Time to 5 m and 15 m (s)	Time from the starting signal to a swimmers' head crossing the 5 m and 15 m mark. This is digitised

		at the point where the centre of the swimmers' head crosses 5 m and 15 m.

Physical characteristics of participants (N = 11).

4 BW = bodyweight; 95% CI = confidence interval of the differences within and between measures; ES = effect size; RPD = rate of power
5 development SD = standard deviation; SJ = squat jump. For within group effects, a positive change score and effect size indicated that the post test
6 score was larger than the pre-test score. For between group effects, a positive effect size indicated that the HF group had a larger change than the
7 VF group. Bolded values indicate an effect size difference of moderate or large. $p < 0.05$*; $p < 0.01$**; $p < 0.001$*
