Abstract

The termite gut microbiome is dominated by lignocellulose degrading microorganisms. This study describes the intestinal microbiota of Argentinian higher termite species and provides a contribution towards understanding how the diet shapes termite gut microbiomes. Four Argentinian termite species were selected based on their feeding habits: wood *Microcerotermes strunckii* (hardwood) and *Nasutitermes corniger* (softwood), organic matter from soil/grass sources (*Termes riograndensis*) and herbaceous material (*Cornitermes cumulans*). The bacterial phyla Spirochaetes, Fibrobacteres, Bacteroidetes and Firmicutes dominated in the guts from *M. strunckii*, *N. corniger* and *C. cumulans* gut samples, whereas Fibrobacteres were a relatively minor taxon in *T. riograndensis*. A single bacterial genus, *Treponema* (Spirochaetes), was dominant in all termite species. Prokaryotic α -diversity was higher in the soil/grass feeders than in the wood feeders. In addition, the β -diversity analysis of prokaryotes and fungi were highly dissimilar in strict wood- feeders, whereas that of soil- and grass- feeders grouped more closely. Ascomycota and Basidiomycota were the only fungal phyla detected in all gut samples. In summary, higher microbial diversity was evident in termites with more versatile diet preferences, suggesting diet-driven microbial community assembly in the termite gut.

Introduction

Termites are extremely efficient in degrading lignocellulose, and may be useful as “bioreactor models” for the conversion of lignocellulosic biomass into biofuels and other biomaterials (Brune, 2014).

Termites are broadly separated into ‘lower’ and ‘higher’ groupings, based on the presence or absence of flagellated protistans in the hindgut. The gut microbiota of lower termites consists of Bacteria, Archaea and Eucarya (such as flagellates and yeasts), whereas higher termites lack flagellated protozoans (Ni & Tokuda, 2013). These microbial symbionts have various roles in the digestive processes, by participating in multiple functions including carbohydrate and nitrogen metabolism, oxygen and hydrogen consumption, N₂ fixation, modifications of aromatic polymers and humification (Brune, 2014; Santana et al., 2015).

All termites feed on lignocellulose, the main component of plant cell walls. Lower termites (families Mastotermitidae, Kalotermitidae, Termopsidae, Hodotermitidae, Rhinotermitidae and Serritermitidae) have specific diets restricted to woody tissue, whereas higher termites (family Termitidae) have diverse feeding habits, which include wood, grass, fungi, lichen, litter, dung, humus and soil. Termitidae is the most diverse family of termites (around 75% of all species). This family comprises eight subfamilies: Apicotermitinae, Cubitermitinae, Foraminitermitinae, Macrotermitinae, Nasutitermitinae, Sphaerotermitinae, Syntermitinae and Termitinae. To date, 80 genera and 458 species, distributed in four subfamilies, Apicotermitinae, Nasutitermitinae, Syntermitinae and Termitinae, have been identified in the Neotropical Region (Krishna et al., 2013).

The termite gut microbiome was primary believed to be determined by the host phylogeny, with influence from the diet (Hongoh, 2010; Rahman et al., 2015; Tai et al., 2015).

More recently, *Mikaelyan et al. (2015)* suggested that the diet was the principal determinant of the higher termite gut microbiome composition. Other reports suggest that insect gut bacterial diversity is determined by environmental behavior, diet, developmental stage and host phylogeny (*Hoback & Stanley, 2001; Yun et al., 2014*).

In this study, we used 16S rRNA gene and ITS sequencing to compare the gut microbiota of four higher termite species with different feeding habits and from three different families *Cornitermes cumulans* (Syntermitinae), *Microcerotermes strunckii* (Termitinae, Amitermes group), *Nasutitermes corniger* (Nasutermitinae) and *Termes riograndensis* (Termitinae, Termes group). *C. cumulans* builds mounds and feeds mainly on herbaceous material, predominantly grasses, but its diet may include cow dung and degraded wood (*Souza et al., 2017*). The soil-mound building termite *T. riograndensis* feeds mainly on soil and plant material. Finally, *M. strunckii* and *N. corniger* are strict wood -feeders, and therefore consume dry, wet or partially decayed hardwoods and softwoods (*Scheffrahn et al., 2005*). The analysis was based on 16S rRNA gene and ITS sequencing for prokaryotic and fungal communities, respectively.

Materials & Methods

Sampling site

The termite species *C. cumulans*, *M. strunckii*, *N. corniger* and *T. riograndensis* are widely distributed in Northeastern Argentina.

Individuals were field-collected in Corrientes province, Argentina. *C. cumulans* (S 28°04'50.2": O 58°16'12.1") and *T. riograndensis* (S 27°25'29.7": O 58°38'53.7") were collected from mounds located in grasslands whose natural vegetation consists of *Andropogon lateralis* and *Paspalum notatum*. *M. strunckii* (S 27°42'43.9": O 59°13'35.2") and *N. corniger* (S

27°27'38.3": O 58°49'19.6") were collected in Chaco province from live trees *Astronium*
balansae (hardwood) and *Peltrophorum dibium* (softwood), respectively. The specimens were
 stored at -20°C until further processing.

DNA extraction

Worker caste specimens were surface sterilized with 70% ethanol and their whole guts were
 dissected under a binocular microscope using sterile forceps. Ten dissected whole guts were put
 in a microtube; three independent extractions were performed per termite species. Microbial
 genomic DNA was extracted from the triplicate gut samples using the DNeasy Blood and Tissue
 kit (Qiagen, USA) according to the manufacturer's instructions.

The V3 and V4 hypervariable regions of the bacterial and archaeal 16S rRNA gene were
 amplified using the specific barcoded primers 515F (5'-GTGCCAGCMGCCGCGGTAA 3') and
 806R (5'-GGACTACNNGGGTATCTAAT-3'). The ITS2 region of the ITS rDNA was amplified
 using the specific barcoded primers Forward (5'-GCATCGATGAAGAACGCAGC-3') and
 Reverse (5'-ATATGTAGGATGAAGAACGYAGYRAA-3') to assess fungal diversity. The
 samples were sequenced on an Illumina MiSeq instrument in the Molecular Research DNA (MR
 DNA) sequencing facility (Shallowater, Texas, USA).

Bioinformatics analysis of 16S rRNA and ITS sequences

The paired end short reads were merged into single end reads and demultiplexed using the
 barcode sequences for each sample. The analyses of the 16S rRNA and ITS sequences were
 performed in the Qiime2 v2018.6 (<https://qiime2.org>) (Caporaso et al., 2010). Chimera
 identification and ASV clustering were performed using DADA2 (Callahan et al., 2016) plugin
 in QIIME 2. The sequences were assigned to Amplicons Sequence Variants (ASVs) using

SILVA 128 16S rRNA (*Quast et al., 2013*) and Unite (*Abarenkov et al., 2010*) database for bacteria/archaea and fungi, respectively.

The resulting 16S rRNA representative sequences were aligned using MAFFT aligner (*Katoh et al., 2002*) and an unrooted tree was produced using FastTree 2 (*Price et al., 2010*). The tree was rooted at midpoint for the phylogenetic diversity analysis in QIIME v2. The α - and β -diversity indices for the 16S rRNA were analyzed in the QIIME 2 pipeline. In addition, α -diversity between the termite gut microbiome was compared using the Kruskal-Wallis test, followed by false discovery rate (FDR) correction in Qiime2 pipeline. Weighted and Unweighted UniFrac dissimilarities matrices were also obtained from the QIIME 2 pipeline (*Lozupone et al., 2011*).

Statistical Analysis

The 16S rRNA ASV table was rarefied for 79,256 sequences in 4,882 ASVs (total number of sequences 951,072 for 12 samples). The ITS ASV table was rarefied to 7,418 sequences. The ASV table consists of 149 ASVs (66,762 sequences) for nine samples. α - and β -diversity indexes were calculated and applied in the phyloseq package (*McMurdie and Holmes, 2013*) of R. The test of significance for the ITS ASVs was performed by adonis function (strata = location) of Vegan package (*Dixon, 2003*) in R. The analysis of significant differences based on the groups (termite and diet (wood, mainly soil/grass feeders)). ITS ASV table was Hellinger transformed and Bray-Curtis distances were used to produce a dissimilarity matrix. A p value < 0.05 was set as the cutoff for significance.

Results

Illumina MiSeq sequencing of 16S rRNA gene and ITS amplicons, derived from gut samples from four termite species generated 1,761,565 high quality sequences. The sequences were assigned to 4,882 and 172 amplicon sequence variants (ASVs) for 16S and ITS sequences, respectively.

Bacterial, archaeal and fungal taxonomy

We identified 23 bacterial phyla in the termite guts of the four species tested. The dominant communities in the guts of wood feeding termites (*M. strunckii* and *N. corniger*) were Spirochaetes (51% to 61%), followed by Fibrobacteres (~13%). Both species also showed similar relative abundances of Bacteroidetes (~8%) and Firmicutes (~8% in the case of *N. corniger* and slightly less, ~6%, for *M. strunckii*). Only a few reads (~2%) remained as unclassified bacteria (Fig. 1A). Thus, at the phylum level, gut communities of both wood-feeding species shared similar profiles regarding dominant taxa.

For the grass-feeding termite *C. cumulans*, Spirochaetes was the dominant phylum (~44%), followed by Firmicutes (~23%) and Bacteroidetes (~13%). By contrast, the dominant phylum in the soil/grass-feeding species *T. riograndensis* was Firmicutes (~32%), followed by Spirochaetes (~20%) and Bacteroidetes (~13%). Only 2% of the sequences remained unclassified (Fig. 1A). *Treponema* was the most abundant bacterial genus, but with large variations in its relative abundance among the termite species (*T. riograndensis*, 17.5%; *C. cumulans*, 42.8%; *M. strunckii*, 59.1% and *N. corniger*, 58.3%).

Of the Archaea, the only two phyla detected, Euryarchaeota and Bathyarchaeota accounted for less than 2% of the reads, except for *T. riograndensis*, in which they represented almost 6% on average.

In the ITS data analysis, *C. cumulans* data were excluded from the subsequent ITS sequence assessment because of the low number of reads obtained. Regarding the other three termite species, the absence of matches with the available sequence data (~81%, ~93% and ~99% of unclassified reads for *N. corniger*, *T. riograndensis* and *M. strunckii*, respectively) from the Unite database makes the taxonomical identification of most of the fungal ASVs impossible. The few fungal taxa identified were assigned to the phyla Ascomycota and Basidiomycota, with Eurotiomycetes being the most abundant fungal class (Fig. 1B).

A rarefaction analysis performed for each gut sequence dataset retrieved rarefaction curves that reached a plateau for all samples (except for *C. cumulans* ITS samples). This result suggests that the sample size was large enough to represent the bacterial and fungal diversity present in the communities (Fig. 2).

Diversity of prokaryotic and fungal taxa

The prokaryotic diversity of termite guts was analyzed using α - and β -diversity indices. The different indexes, Shannon, Evenness and Observed, showed no significant differences regarding α -diversities between all four termite species (Fig. S1). However, the α -diversity between diet groups (strict wood -feeders and soil/grass -feeders) significantly differed (Fig. S2). The group of soil/grass feeders displayed higher values of the α -diversity indices and this index was higher for the soil/grass feeders (*T. riograndensis*) in comparison to that for the grass -feeders (*C. Cumulans*) (Fig. 3A; Fig. S2).

The prokaryotic β -diversity of the termite gut microbiome was compared using the Unweighted UniFrac distances. The gut microbiome composition of the polyphagous soil/grass feeders was found to be similar and grouped distantly from that of the wood feeders and both

were separated from each other (Fig. 3B). The PERMANOVA test of Unifrac distances revealed that the β -diversity was significantly different for the four termite species, with a marked variation according to the feeding habit (diet group of termites) (strict wood-feeders and soil/grass -feeders) ($p < 0.05$) (Table 1).

The Shannon and Evenness α -diversity indices of fungal communities from *M. strunckii*, *N. corniger* and *T. riograndensis* gut samples differed significantly (Fig. S3). However, Observed-ASVs showed no significant differences in α -diversity. Fungal α -diversity according to the diet group was also significantly different for the Shannon and Evenness indices but not for Observed-ASVs (Fig. S4).

To visualize overall similarities and differences in fungal community structure, we calculated Bray-Curtis distances between *M. strunckii*, *N. corniger* and *T. riograndensis*, and displayed these analyses in the form of two-dimensional NMDS plots (Fig. S5). These analyses revealed that the fungal community composition in the gut samples of the three termite species was significantly different, whereas replicates of the same species were almost identical (Fig. S5). PERMANOVA analysis confirmed significant differences in the fungal communities of the different termite species and diet groups (Table 1).

Core microbiome

In total, 38 bacterial ASVs were shared across the four higher termite species; which represents 28.5 % of all the obtained sequences (Fig. 4A). Furthermore, the termite gut samples grouped according to their feeding habits, shared 23 (wood feeders) and 38 (soil/grass feeders) ASVs (Fig. 4A).

Of the 38 ASVs, 18 were assigned to *Treponema* sp., which represented 19% of all the obtained sequences. These ASVs were present in higher relative abundances in the guts of *C. cumulans*, *M. strunckii* and *M. corniger* than in the gut of *T. riograndensis* (Table 2).

We identified 11 fungal ASVs, which represented an average of 71.3% of all the identified fungal sequences, shared in the gut samples of *M. strunckii*, *N. coringer* and *T. riograndensis* (Fig. 4B). The most abundant shared ASVs were assigned as unclassified fungi in all the termite guts (Table 2).

Discussion

Numerous studies of higher termite gut microbiota have been published in the last two decades (Warnecke et al., 2007; Otani et al., 2014; Mikaelyan et al., 2015; Rahman et al., 2015; Santana et al., 2015; Su et al., 2016). However, in a few proportions of such studies, researchers have investigated the gut community composition in relation to the feeding habits of the host termite species.

This study provides the first description of the intestinal microbiota associated with four Argentinian higher termite species (*C. cumulans*, *M. strunckii*, *N. corniger* and *T. riograndensis*) performed by high-throughput 16S rRNA gene and ITS amplicon sequencing analyses. These termites have different diet preferences ranging from hardwood, softwood, herbaceous materials, soil/grass. In contrast to softwood, the hardwood harbors high amount of carbon content consisting on cellulose, hemicellulose and low proportion of lignin (Demirbas, 2005). Herbaceous plant materials have higher nutritious contents, and lower lignin compared to the wood, whereas soil contains most diverse organic content which are selectively utilized by the

termite species. Based on the diet preferences, we were interested in exploring the differences in the gut microbiota composition of these Argentinian higher termite species.

Overall, Spirochaetes, followed by Fibrobacteres, Bacteroidetes and Firmicutes were the dominant gut phyla in termites feeding on wood or grass (*M. strunckii*, *N. corniger* and *C. cumulans*). By contrast, the dominant phylum in the soil/grass feeder *T. riograndensis* was Firmicutes, followed by Spirochaetes and Bacteroidetes. In accordance with our study, other researchers have reported Spirochaetes as one of the most abundant phylum in wood- and grass-feeding higher termite guts (Hongoh et al., 2005; Warnecke et al., 2007; Köhler et al., 2012; Brune, 2014; Dietrich et al., 2014; Mikaelyan et al., 2015; Rahman et al., 2015).

The high abundance of Spirochaetes (genus *Treponema* sp.), Fibrobacteres and Bacteroidetes in the wood-feeding termites may be related to the nitrogen fixation and lignocellulosic processes (Lilburn et al., 2001; Breznak, 2002; Warnecke et al., 2007; Yamada et al., 2007; Su et al., 2016). In addition, high abundance of phylum Firmicutes (mostly Ruminococcaceae) in the *T. riograndensis* was in accordance with previous reports of soil- and humus-feeding termites (He et al., 2013; Dietrich et al., 2014; Mikaelyan et al., 2015; Santana et al., 2015).

In particular, several studies have reported similar proportion of Spirochaetes which constitutes approximately 50 to 60% of total prokaryotic population, in the gut microbiome of *N. corniger* (Warnecke et al., 2007; He et al., 2013; Dietrich et al., 2014; Santana et al., 2015; Su et al., 2016). However, in one report Köhler et al. (2012) observed lower proportion of Spirochaetes in *N. corniger* and *N. takasagoensis*. This discrepancy could be due to variations in DNA extraction methods (Morgan et al., 2010) and PCR oligonucleotides (different oligonucleotides) performed in the studies (Engelbrektson et al., 2010).

The high relative abundance of genus the *Treponema* sp. (phylum Spirochaetes) in the core of *C. cumulans*, *M. strunckii* and *N. corniger*, but not in that of *T. riograndensis*, suggests that this genus have an important impact on the overall physiology and digestive processes in the wood- and grass- feeding higher termites. The presence of Treponema as the principal genus of gut microbiota has been described in several studies of the termite gut microbiota (Warnecke *et al.*, 2007; Köhler *et al.*, 2012; Shi *et al.*, 2013; Benjamino & Graf, 2016). Thus, the differences in their core microbiomes might be related to the phylogeny of the termite and to their diet habits.

A low proportion of archaea was present in the profile of higher termite gut communities. The detected archaeal phyla were Euryarchaeota and Bathyarchaeota. Euryarchaeota include closely related genera known for their methanogenic activity (Rahman *et al.*, 2015). The methanogenic archaeon *Methanimicrococcus* sp. was present in the core microbiome albeit in the different proportions. This genus has been detected in the gut microbiomes of other higher termites and cockroaches (Paul *et al.*, 2012).

In the four species evaluated in this study, the diversity of the fungal community was markedly lower than that of prokaryotes. The high proportion of the taxonomically unclassified fungal ASVs may result from the lack of representative sequences in the SILVA database (Hongoh, 2010; Santana *et al.*, 2015). Although fungi are not as prevalent as bacteria in higher termite guts, an important unresolved issue is to determine the role of fungi in development, cellulolytic process and fitness. Some of these functions could be to provide nitrogen source, degrade high molecular weight molecules and produce pheromones for mating and communication (de León *et al.*, 2016; Zhang *et al.*, 2018). However, the role of fungal microbiota in the digestive process of termites is not clear yet (Brune, 2014).

The fungi classes detected in the core were Eurotiomycetes and Malasseziomycetes. Eurotiomycetidae are producers of secondary metabolites, fermentation agents as well as of xerophile and psychrophile enzymes. They were present in the gut of the litter-feeding termite *Synthermes wheeleri* (Santana et al., 2015). Malasseziomycetes are ecologically diverse and wide spread yeast. The genus *Malassezia* is lipophilic yeast and has been known as a common inhabitant of human skins (Paulino et al., 2008). A report by Zhang et al. (2003) identified this yeast in the gut of beetles.

The presence of a common core microbiota suggests that these taxa are retained despite differences in habitat, geography and food source, and regardless of host phylogeny. This core composition also suggests that these taxa are important in the maintenance of key functions and may serve as the basis for microbial community resistance and/or resilience (Huse et al., 2012; Shade & Handelsman, 2012; Benjamino & Graf, 2016).

The α -diversity of gut bacterial communities in the soil/grass feeder group was significantly higher than that in wood feeders, whereas the gut microbiota in *T. riograndensis* (soil- and grass- feeding termites) was higher than in species that fed on grass only (*C. cummulans*). The lower diversity indexes of gut microbiota associated with the wood- feeding termites may be related to the maintenance of a specialized microbiota that is necessary for performing an efficient lignocellulose metabolism, and therefore for the host survival (Breznak & Brune, 1994; Colman et al., 2012). The studied species of wood- feeding termites have a very limited diet, which includes complex carbohydrates (cellulose, hemicellulose and lignin), and this characteristic may explain the lower α -diversity. Feeding on live trees may expose the host and potentially its microbiota to tree physiological responses (Morewood et al., 2004), which may further shape gut community dynamics of live wood- feeding termites. The high α -diversity

in the soil/grass feeding termites is related to the diverse range of carbon and nitrogen sources available in the soil/grass diets; these more complex substrates require more complex degradative capacity and therefore more complex communities. On the other hand, the host habitat also may influence the relative bacterial abundances of the termite gut microbiota (*Yun et al., 2014*).

An intercommunity analysis showed that the gut microbiomes of soil/grass feeders were clearly separated from that of wood feeders. Soil/grass-feeding termite species grouped closely, whereas the wood -feeders were spatially separated from each other. The replicates of *C. cumulans*, *T. riograndensis* and *M. strunckii* showed little variation, whereas those of the wood feeder *N. corniger* were more disperse. The difference in the β -diversity of the gut from wood feeding termites could be related to the type of wood (hard and soft wood) from which they were collected and, thus, this could help explain the differences in the microbiota composition. The termites *M. strunckii* and *N. corniger* came from live trees of *Astronium balansae* (hardwood) and *Peltrothorum dibium* (softwood), respectively. Even though the relative abundance at the phylum level was similar, microbial species composition was different between them.

The understanding of the termite-microbiome interaction requires the exploration of the composition and structure of the microbiota, as well as of the characterization of its main metabolic activities in different taxonomic groups of termites with different types of diets.

Altogether, the results obtained in this study showed that, except for the relative abundance of bacterial phyla (in the case of strict wood- feeders), no obvious pattern was observed in mutual comparisons of any of the four analyzed termite species. The relationship between the diet and diversity of microorganisms present in the termite digestive system warns

about the consequences environment changes could have on them. Indeed, this could lead to a reduction in the food supply, which could result in turn in a loss of microbial gut diversity.

Figure 1

Relative abundance of bacteria, archaea (phyla level) and fungi (class level) in the gut of Neotropical termites

(A) 16S rRNA gene (B) ITS sequence based taxonomic distribution in triplicate gut samples.

Figure 2

Rarefaction curves for the prokaryotic and fungi observed ASVs at 97% sequence identity

(A) 16S rRNA gene. (B) ITS sequences.

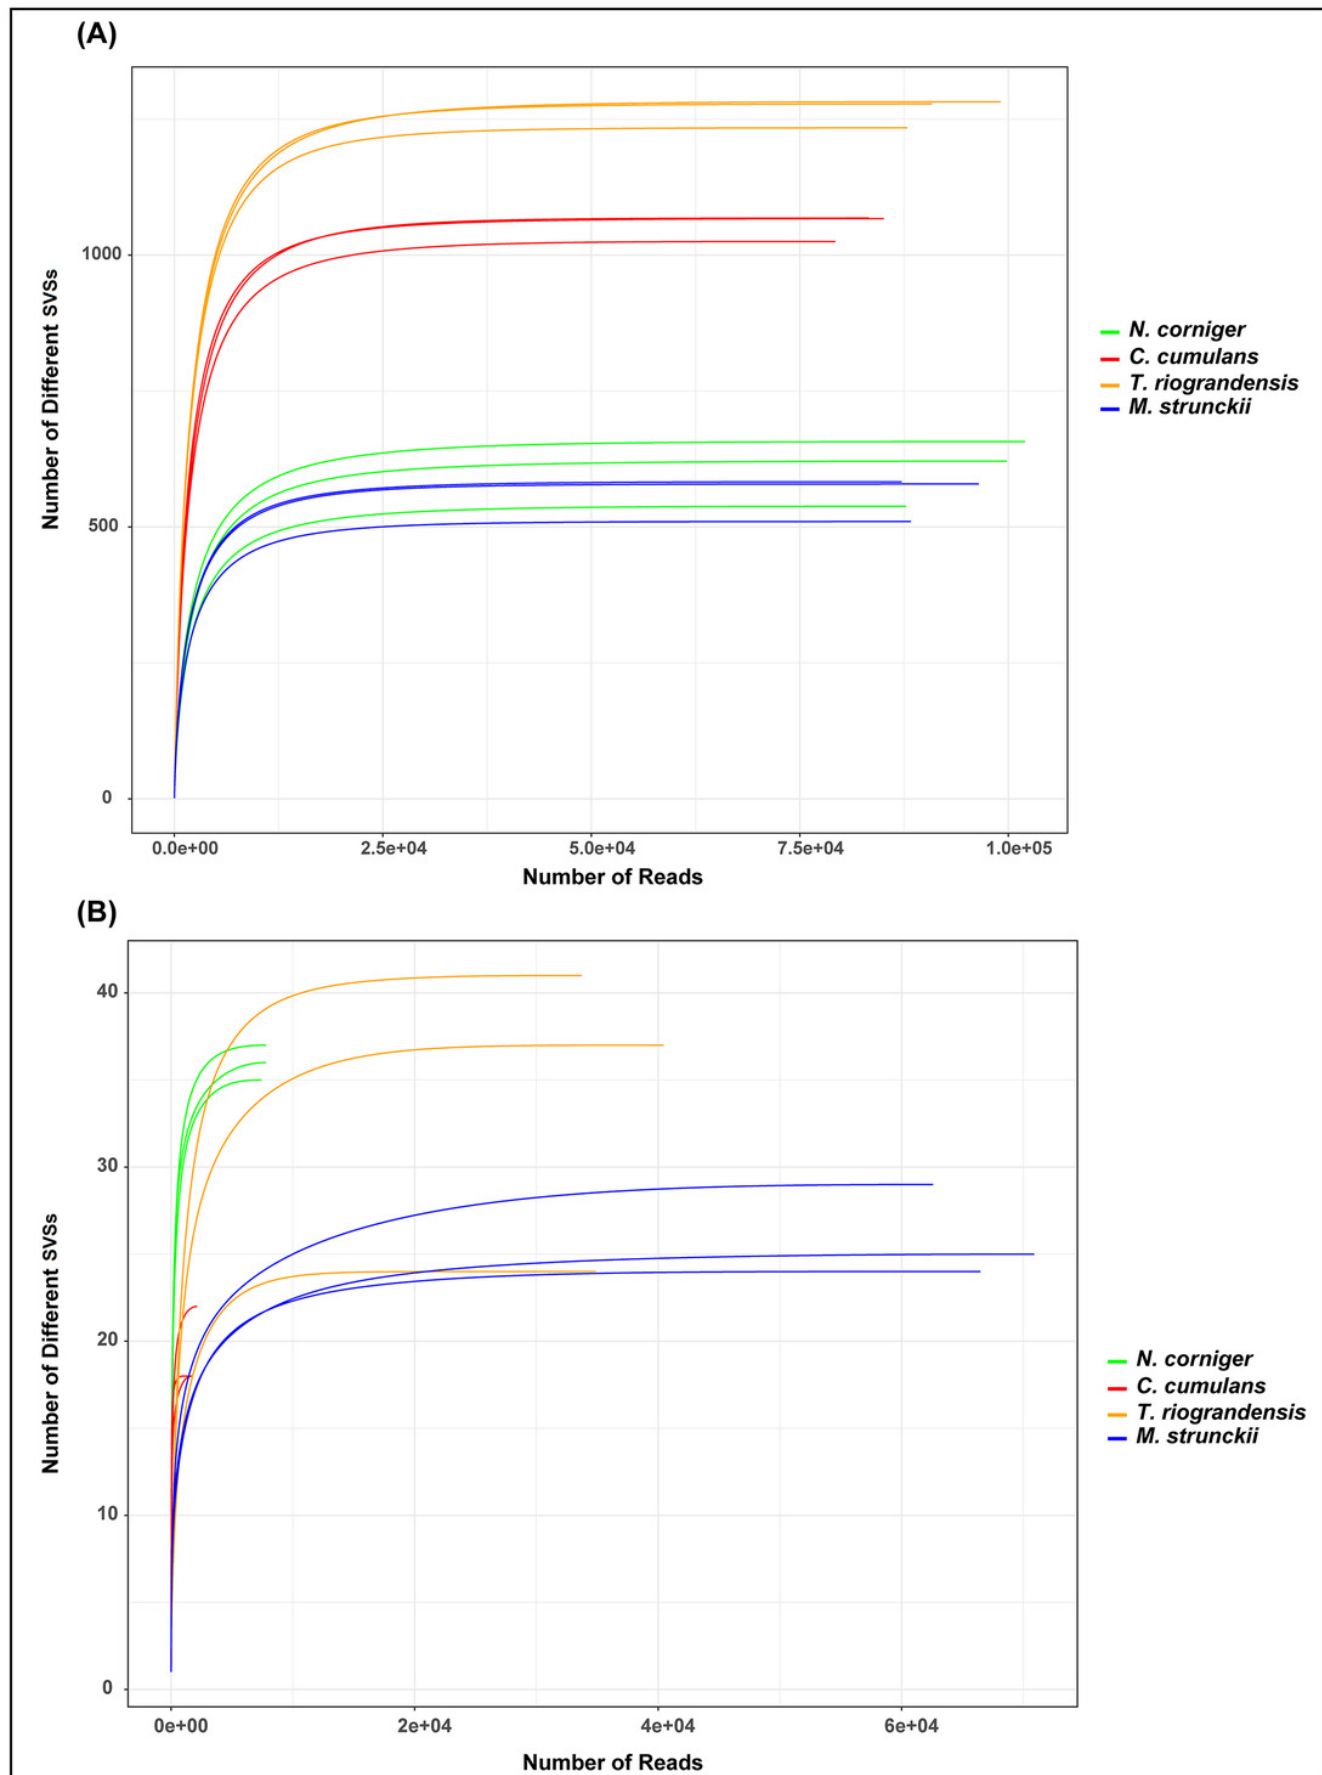

Figure 3

α - and β -diversity indexes of prokaryotes

(A) Shannon diversity index (B) Unweighted Unifrac distance plot. The red, blue, green and orange dots represent the gut microbiome of *C. cumulans*, *M. strunckii*, *N. corniger* and *T. riograndensis*, respectively. The circle and triangle denote the soil/grass and wood feeders, respectively. The first and second principal components explain 34% (PC1) and 24% (PC2) of variations, respectively.

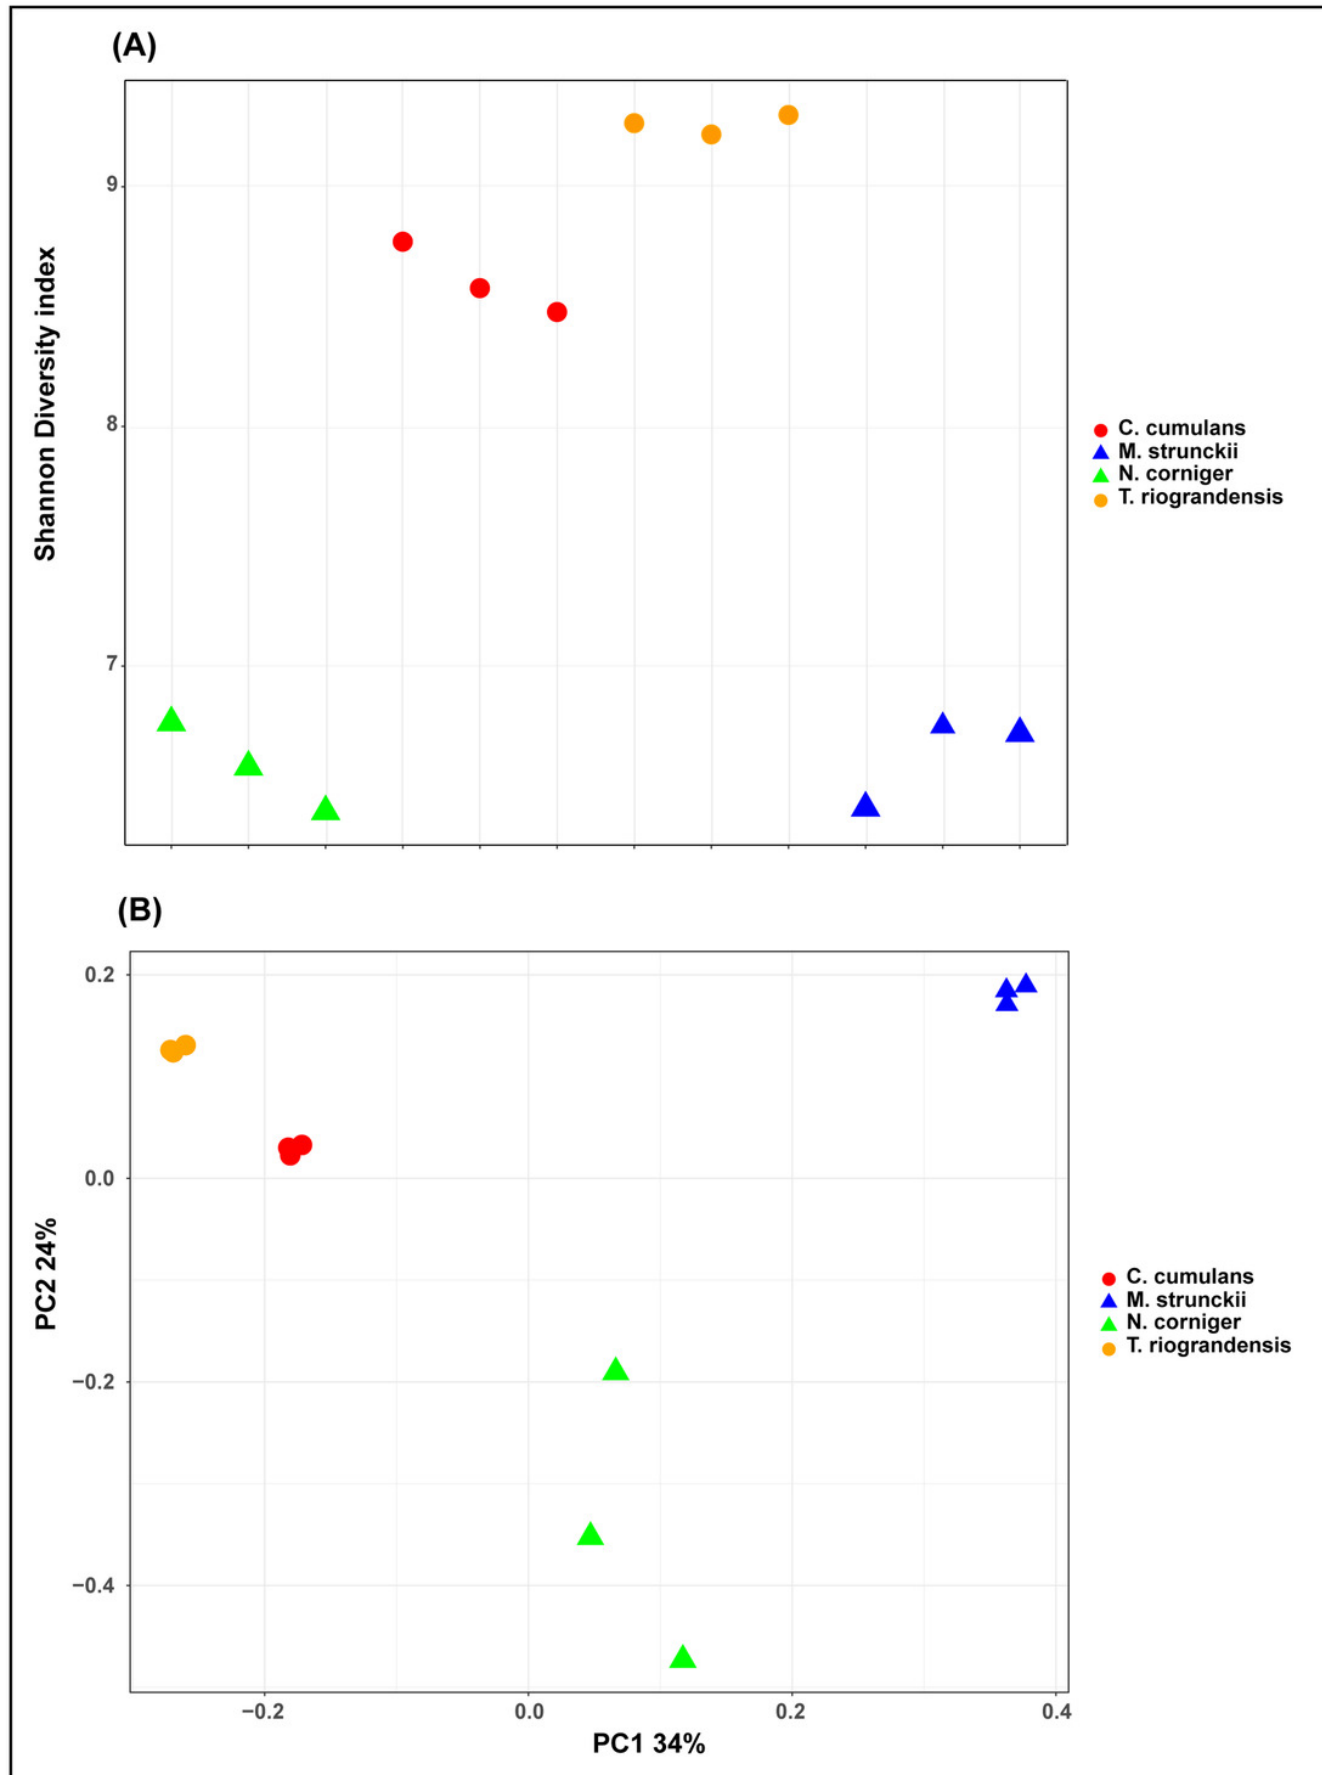

Figure 4

Venn diagram showing the distribution of shared ASVs across the termite gut

(A) Shared prokaryotic ASVs between four gut microbiomes and (B) Shared fungal ASVs between the three termites.

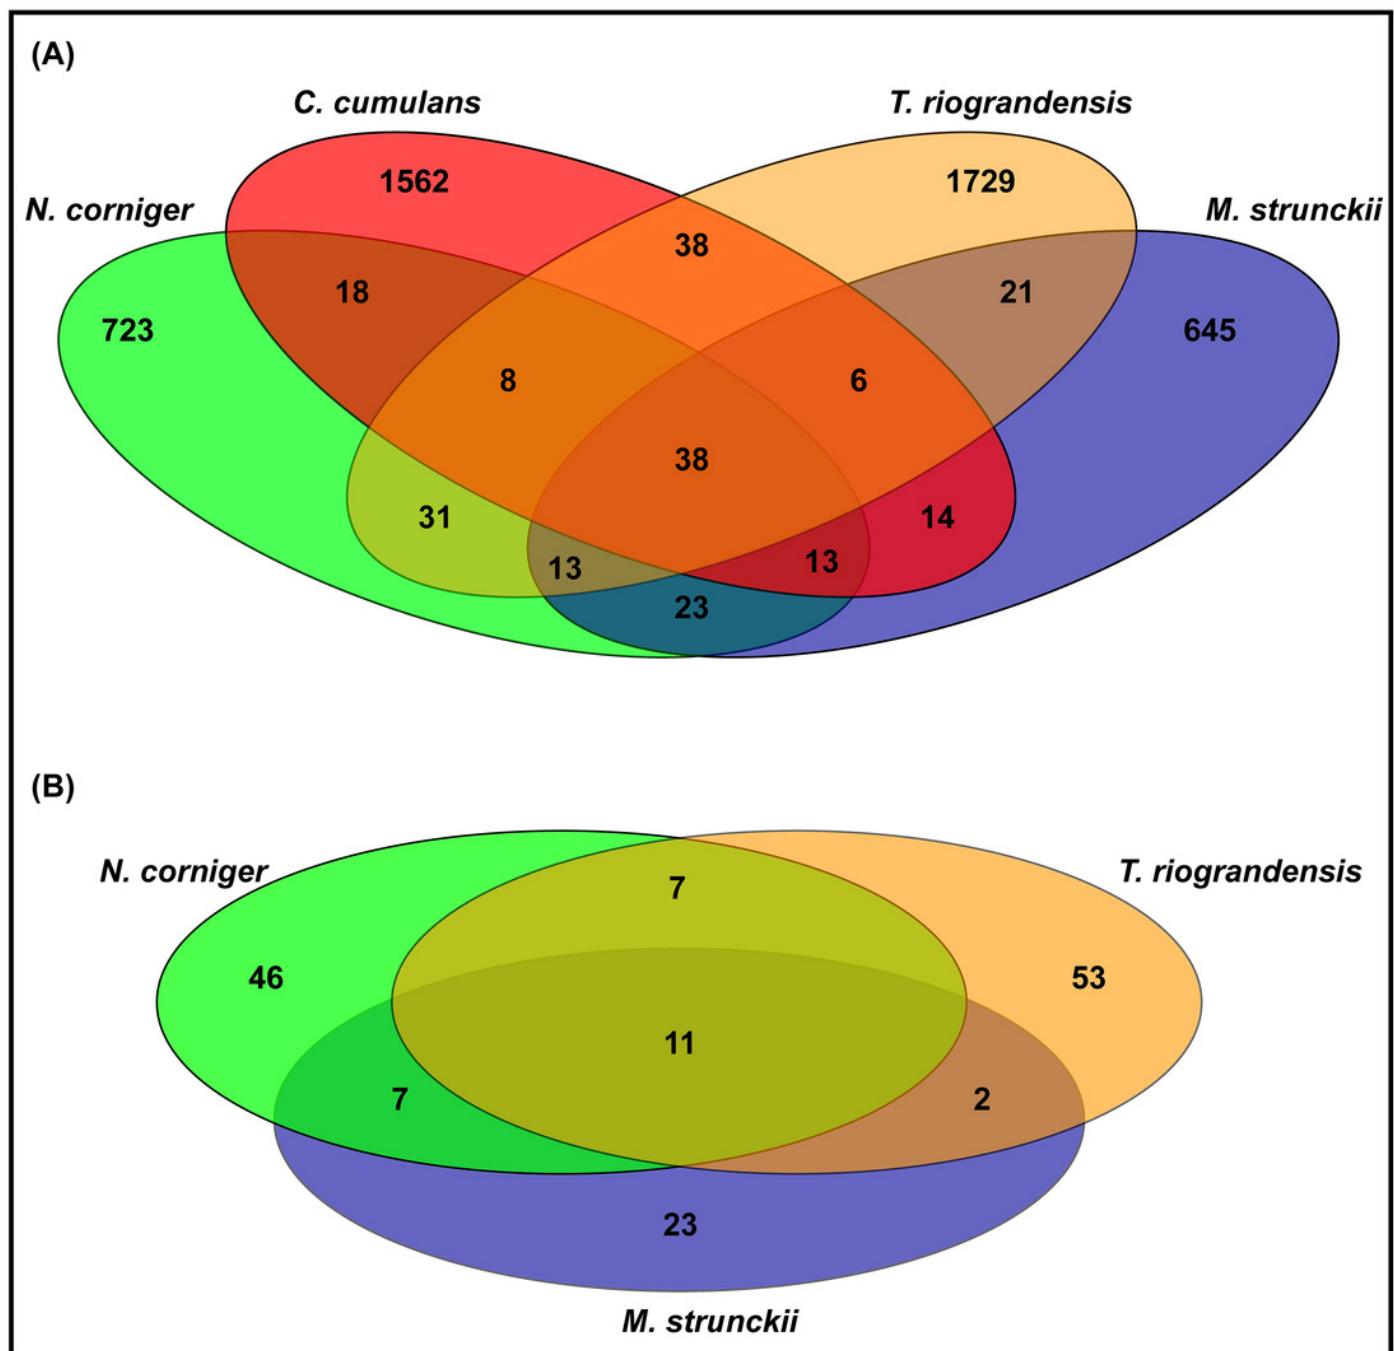

Table 1 (on next page)

PERMANOVA analysis of bacteria/archaea and fungi

The statistical analysis of ITS sequence data were performed based on the Hellinger transformation and Bray-Curtis distance-based dissimilarity matrix.

16S rRNA		
	Based on termite species	
	Unweighted Unifrac	Weighted Unifrac
Pseudo F	8.5445	67.0377
<i>p</i> value	0.001	0.001
	Based on diet groups	
Pseudo F	4.5241	12.4488
<i>p</i> value	0.002	0.002
ITS (Bray-Curtis distance dissimilarity matrix)		
	Based on termite species	
Pseudo F	13.1240	
<i>p</i> value	0.005	
	Based on diet groups	
Pseudo F	3.8839	
<i>p</i> value	0.03	

Table 2(on next page)

Relative abundance (%) of *C. cumulans*, *M. strunckii*, *N. corniger* and *T. riograndensis* core microbiota

1
