Conversion of tropical ecosystems is associated with major changes in ecological niches of species and communities, resulting in changes of ecosystem functioning. Collembola are among the most abundant soil arthropods sensitively responding to changes in vegetation and soil conditions at the community level. However, most of the studies to date were conducted in temperate ecosystems and focused on shifts in community composition or morphological traits, while parameters more closely linked to ecosystem functioning, such as trophic niches, received little attention. Here, we investigated changes in trophic structure of and use of food resources by Collembola after conversion of rainforest into rubber and oil palm plantations in Jambi province (Sumatra, Indonesia) using stable isotope analysis (^{13}C and ^{15}N). Across Collembola species $\Delta^{13}\text{C}$ values were highest in rainforest, suggesting more pronounced processing of litter resources by microorganisms in this system. Lower $\Delta^{13}\text{C}$ values, but high $\Delta^{13}\text{C}$ variation in Collembola in oil palm plantations indicated that Collembola shifted towards herbivory and used a wider range of resources in this system. Small range in $\Delta^{15}\text{N}$ values in Collembola species in monoculture plantations in comparison to rainforest indicated that conversion of rainforest into plantations is associated with simplification in the trophic structure of Collembola communities. Across the studied ecosystems, atmobiotic species (Symphypleona and Paronellidae) occupied the lowest, whereas euedaphic species occupied the highest trophic position, resembling patterns in temperate forests. Some species of Paronellidae in rainforest and jungle rubber had $\Delta^{15}\text{N}$ values below those of leaf litter suggesting algivory (*Salina* sp.1, *Callyntrura* sp.1 and *Lepidonella* sp.1), while *Pseudosinella* sp.1 had the

highest $\Delta^{15}\text{N}$ values in most of the land-use systems suggesting that this species at least in part lives as predator / scavenger. Overall, the results suggest that rainforest conversion into plantation systems is associated with marked shifts in the structure of trophic niches in soil and litter Collembola with potential consequences for ecosystem functioning and food-web stability.

ABSTRACT

20 Conversion of tropical ecosystems is associated with major changes in ecological niches of species
21 and communities, resulting in changes of ecosystem functioning. Collembola are among the most
22 abundant soil arthropods sensitively responding to changes in vegetation and soil conditions at
23 the community level. However, most of the studies to date were conducted in temperate
24 ecosystems and focused on shifts in community composition or morphological traits, while
25 parameters more closely linked to ecosystem functioning, such as trophic niches, received little
26 attention. Here, we investigated changes in trophic structure of and use of food resources by
27 Collembola after conversion of rainforest into rubber and oil palm plantations in Jambi province
28 (Sumatra, Indonesia) using stable isotope analysis (¹³C and ¹⁵N). Across Collembola species $\Delta^{13}\text{C}$

29 values were highest in rainforest, suggesting more pronounced processing of litter resources by
30 microorganisms in this system. Lower $\Delta^{13}\text{C}$ values, but high $\Delta^{13}\text{C}$ variation in Collembola in oil
31 palm plantations indicated that Collembola shifted towards herbivory and used a wider range of
32 resources in this system. Small range in $\Delta^{15}\text{N}$ values in Collembola species in monoculture
33 plantations in comparison to rainforest indicated that conversion of rainforest into plantations is
34 associated with simplification in the trophic structure of Collembola communities. Across the
35 studied ecosystems, atmobiotic species (Symphypleona and Paronellidae) occupied the lowest,
36 whereas euedaphic species occupied the highest trophic position, resembling patterns in
37 temperate forests. Some species of Paronellidae in rainforest and jungle rubber had $\Delta^{15}\text{N}$ values
38 below those of leaf litter suggesting algivory (*Salina* sp.1, *Callyntrura* sp.1 and *Lepidonella* sp.1),
39 while *Pseudosinella* sp.1 had the highest $\Delta^{15}\text{N}$ values in most of the land-use systems suggesting
40 that this species at least in part lives as predator / scavenger. Overall, the results suggest that
41 rainforest conversion into plantation systems is associated with marked shifts in the structure of
42 trophic niches in soil and litter Collembola with potential consequences for ecosystem
43 functioning and food-web stability.

47

48 Introduction

49 Agricultural intensification in Indonesia is associated with deforestation which increased
50 strongly in the last 20 years (Koh & Ghazoul, 2010 ; Gatto *et al.*, 2015). Large parts of rainforest
51 in lowland Sumatra have been converted into oil palm (16% of total area) and rubber plantations
52 (12%) (Gatto *et al.*, 2015). The conversion of tropical rainforest into plantation systems is
53 associated with major changes in ecological niches of animal species, loss of biodiversity, and
54 thereby with changes in ecosystem functioning (Barnes *et al.*, 2014; Clough *et al.*, 2016;
55 Fitzherbert *et al.*, 2008; Gilbert, 2012). These changes affect both the above- and belowground
56 system. Complex and diverse microbial and animal communities in soil regulate important
57 ecosystem functions and support aboveground life (Bardgett & Van Der Putten, 2014), but
58 knowledge on effects of land-use change on soil live in the tropics is very limited.

59 Conversion of rainforest into oil palm and rubber plantations in Indonesia is associated
60 with a decline in species diversity, population density, biomass and energy flux in litter
61 macroinvertebrate communities by approximately 45% (Barnes *et al.*, 2014). However, this
62 decline is uneven across size classes and trophic levels, altering the structure of soil food webs
63 (Potapov *et al.*, 2019). Different basal resources available in different land-use systems result in
64 changes in trophic niches of decomposer and predatory soil invertebrates, and results in reduced
65 abundance of primary decomposers and in soil animals shifting their feeding habits towards
66 herbivory (Klarner *et al.*, 2017; Krause *et al.*, 2019; Susanti *et al.*, 2019). Land-use change may
67 also result in reduced trophic niche differentiation among species in belowground communities
68 (Korotkevich, Potapov, Tiunov, & Kuznetsova, 2018), but this has not been investigated in tropical
69 ecosystems.

70 Collembola are among the most abundant soil decomposer invertebrates, inhabiting
71 various organic substrates and using a wide range of food resources (Josef Rusek, 1998). Early
72 studies on food resources of Collembola concluded that the majority of euedaphic and
73 hemiedaphic species feed unselectively on a wide variety of food materials (Hopkin, 1997).
74 However, stable isotope analysis showed pronounced trophic niche differentiation among
75 Collembola species in temperate forests (Chahartagi *et al.*, 2005). This differentiation in large has
76 been explained by the taxonomic identity and life forms of Collembola (Potapov *et al.*, 2016).
77 Species, living aboveground and on the litter surface (atmobiote and epedaphic life forms) are
78 mainly phycophages, feeding on lichens, algae and pollen. Species, living in the litter
79 (hemiedaphic life form) are decomposers which feed on saprotrophic microorganisms and litter.
80 Species, living in soil (euedaphic life form) feed on soil organic matter, roots and fungi (Ponge,
81 2000; Potapov *et al.*, 2016). Further, food resources and trophic levels also vary among taxa with
82 e.g., Poduromorpha occupying higher trophic positions than Entomobryomorpha and
83 Symphypleona, suggesting evolutionary selection for microbivory in the former (Potapov *et al.*,
84 2016). To date, information on food resources and trophic niches of Collembola is based on
85 studies from temperate ecosystems, whereas information from tropical ecosystems is virtually
86 lacking.

87 Over the last two decades, stable isotope analysis has become the most commonly used
88 tool to assess trophic niches of soil animals (Potapov *et al.*, 2019). Two isotopic ratios, $^{13}\text{C}/^{12}\text{C}$
89 (i.e., $\delta^{13}\text{C}$ values) and $^{15}\text{N}/^{14}\text{N}$ (i.e., $\delta^{15}\text{N}$ values), typically are used in food-web studies. The
90 trophic positions and the length of trophic chains can be assessed using $\delta^{15}\text{N}$ values, whereas the
91 range of $\delta^{13}\text{C}$ values reflects the variability in the use of basal resources (Potapov, *et al.*, 2019).

92 The stable isotope composition of consumers follows that in food resources, thus allowing to
93 reveal potential diet switching with land-use change (Klarner *et al.*, 2017; Krause *et al.*, 2019;
94 Susanti *et al.*, 2019).

95 Here, we use stable isotope analysis to investigate trophic positions and food resources
96 of soil and litter Collembola in four different land-use systems in Sumatra, Indonesia: rainforest,
97 rubber agroforest ('jungle rubber'), and rubber and oil palm plantations. The study aimed at
98 investigating how trophic positions and food resources of Collembola change after rainforest
99 conversion into agricultural plantations, such as rubber and oil palm, and, for the first time, at
100 exploring patterns in trophic niche differentiation among tropical Collembola species. In more
101 detail we investigated the following hypotheses:

- 102 1) Analogous to other soil invertebrates, Collembola shift their trophic niches towards
103 herbivory in plantations systems in comparison to rainforest.
- 104 2) Due to reduced food resources (poor litter layer), the trophic niche width of
105 Collembola is lower in plantations in comparison to rainforest.
- 106 3) Trophic niche differentiation among species is more pronounced in rainforest than in
107 disturbed plantation systems.
- 108 4) Trophic niche differentiation among families and life forms of Collembola in tropical
109 ecosystems follows similar patterns as in ecosystems of the temperate zone.

110

111 **Material and Methods**

112 **Site description**

113 Soil and litter samples were taken in lowland rainforest, jungle rubber, rubber (*Hevea*
114 *brasiliensis*) and oil palm (*Elaeis guineensis*) plantations, located in Jambi province, southwest
115 Sumatra, Indonesia. The study sites are located at similar altitude varying between 50 and 100 m
116 a.s.l. in two landscapes, the Harapan and Bukit Dua Belas landscape; each system was replicated
117 four times (see Drescher *et al.*, 2016 for more details). Lowland rainforest was used as reference,
118 but represents secondary rainforest which has been logged once by taking out large trees some
119 30 years ago. Jungle rubber represents rubber agroforests originating from rainforest enriched
120 with rubber trees; the age of rubber trees varied between 15-40 years (Kotowska, Leuschner,
121 Triadiati, Meriem, & Hertel, 2015). Rubber and oil palm plantations were intensively managed
122 monocultures of an average age of 7 to 16 and 8 to 15 years, respectively (Drescher *et al.*, 2016)
123 and were established after logging, clearing, and burning of either rainforest or jungle rubber.
124 Soils at the Harapan landscape are loam Acrisols of low fertility, whereas in Bukit Dua Belas the
125 major soil type is clay Acrisol (Allen, Corre, Tjoa, & Veldkamp, 2015; Kotowska *et al.*, 2015).
126 Management practices in these smallholder monoculture plantations are described in more
127 detail in Allen *et al.* (2015). Oil palm plantations typically were fertilized once in the rainy season
128 and once in the dry season. Typically, 300-500 kg NPK complete fertilizer, 300 kg KCl and 138 kg
129 urea ($\text{CO}(\text{NH}_2)_2$) were added per hectare and year. Rubber and oil palm plantations were weeded
130 manually or chemically throughout the year. The most commonly used herbicides were
131 Gramoxone and Roundup; these were applied at an average rate of 2 to 5 L ha⁻¹ y⁻¹ (Allen *et al.*,
132 2015; Clough *et al.*, 2016; Kotowska *et al.*, 2015).

133

134 **Sampling procedure**

135 Samples were taken in October 2013 in three 5 x 5 m subplots within 50 x 50 m plots
136 established at each study site (Drescher *et al.*, 2016). A total of 32 plots were investigated (2
137 landscapes x 4 land-use systems x 4 replicates). In each subplot soil samples of 16 x 16 cm were
138 taken including the litter layer and the underlying top soil to a depth of 5 cm. Animals from both
139 layers were pooled for stable isotope analysis to obtain sufficient amount of animal tissue for the
140 analyses. Animals were extracted by heat (Kempson, Lloyd, & Gheraldi, 1963) during 6-8 days
141 using glycerol : water mixture at a ratio of 1 : 1 as collection solution. After extraction animals
142 were transferred into 70% ethanol. Sampling of animals used in this study was based on
143 Collection permits No. S.07/KKH-2/2013 and No. 2841/IPH.1/KS.02.04/X/2016 issued by the
144 Indonesian Ministry of Forestry (PHKA).

145

146 **Species identification**

147 Collembola were sorted in Petri dishes using a dissecting microscope. For
148 (morpho)species identification, selected individuals were subsequently cleared in Nesbitt
149 solution and mounted on slides with Hoyer solution. Collembola were identified under a
150 compound light microscope at 400× magnification. The checklist and keys for Indonesian
151 Collembola by Suhardjono *et al.* (2012) were used along with publications on Southeast Asian
152 Collembola. Juvenile specimens in part were ascribed to morphospecies of adults or subadults
153 present in the same sample or in samples from the same plot. After identification, all data on
154 Collembola species and their identification characters were uploaded to Ecotaxonomy database

155 (<http://ecotaxonomy.org>). In total 56 species/morphospecies from 13 families and 27 genera
156 were found.

157

158 **Bulk stable isotope analyses**

159 Stable isotope ratios were measured from dominant species representing at least 70% of the
160 individuals on each plot. Dominant species were chosen for each plot separately to represent the
161 local 'functional community'. This selection procedure resulted in a total of 30 out of 56 species
162 being included in the analysis. For stable isotope measurements appropriate amounts of animal
163 tissue (ranging from 0.003 to 1.268 mg) were transferred into tin capsules and dried at 60°C for
164 24 h, weighed and stored in a desiccator until analysis. Stable isotope and C-to-N ratios were
165 determined using a coupled system consisting of an elemental analyzer (Eurovector, Milano,
166 Italy) equipped with a Blisotec autosampler (Blisotec, Jülich, Germany) and a Thermo Delta Vplus
167 isotope ratio mass spectrometer connected via a ConFlo IV interface (both from Thermo Fisher
168 Scientific, Bremen, Germany) located at the Centre for Stable Isotope Research and Analysis,
169 Göttingen, Germany (Langel & Dyckmans, 2014). Isotope signatures are expressed using the δ
170 notation as $\delta X(\text{‰}) = (R_{\text{sample}} - R_{\text{standard}}) / R_{\text{standard}} \times 1000$, with X representing the target isotope and
171 R the ratio of heavy to light isotope ($^{13}\text{C}/^{12}\text{C}$ or $^{15}\text{N}/^{14}\text{N}$). For $\delta^{15}\text{N}$ and $\delta^{13}\text{C}$ analyses, N in
172 atmospheric air and Vienna PD Belemnite served as standards, respectively. Acetanilide ($\text{C}_8\text{H}_9\text{NO}$,
173 Merck, Darmstadt) was used for internal calibration.

174

175 **Statistical analysis**

176 To compensate for inter-site variation in the isotopic baseline, all data were normalized to the
177 local leaf litter using the following equations (Potapov *et al.*, 2019):

$$178 \Delta^{13}\text{C} = \delta^{13}\text{C}_{\text{Collembola}} - \delta^{13}\text{C}_{\text{litter}}$$

$$179 \Delta^{15}\text{N} = \delta^{15}\text{N}_{\text{Collembola}} - \delta^{15}\text{N}_{\text{litter}}$$

180 Stable isotope values of litter were taken from Klarner *et al.* (2017) who investigated the same
181 sampling sites. Statistical analyses were performed using R v 3.5.2 (R Core Team, 2018) with R
182 studio interface (R Studio, Inc.).

183 First, we analyzed the effect of land-use system on the isotopic composition of Collembola
184 at the community level. Effects of land-use system on the $\Delta^{13}\text{C}$ and $\Delta^{15}\text{N}$ values of all measured
185 Collembola individuals were tested using Linear Mixed Effect Models (LMM) with species identity
186 as random effect. The analysis was conducted using the *lmer* function in the *lme4* package (Bates
187 *et al.*, 2015). Significance of fixed effects (factors) was tested using the *Anova* function from the
188 package *car*. Significant differences in stable isotope values between land-use systems were
189 tested using the *tukey test* in the *emmeans* and *multcomp* packages. In addition, we analyzed
190 the effect of land use only for one dominant species, present in sufficient replicates of each land-
191 use systems (*Pseudosinella* sp.1) using analysis of variance implemented in the *aov* function.
192 Additionally, the ranges of $\Delta^{13}\text{C}$ and $\Delta^{15}\text{N}$ values in each land-use system were visualized using
193 the Kernel density estimation in the *ggplot 2* package using the *geom_violin* function.

194 Second, we assessed trophic niche differentiation among species using LMM. We used
195 species identity as factor and either $\Delta^{13}\text{C}$ or $\Delta^{15}\text{N}$ values as response variables; sampling plot was
196 included as random effect. The analysis was done separately for each land-use system (eight

197 analyses in total). In each case, only species with more than three measurements in the given
198 land-use system were included.

199 Third, we analyzed the effects of family identity and life form on stable isotope
200 composition using LMM. Here, we used both plot and land-use system as random effects.
201 Significant differences between families and life forms were tested using Tukey contrasts as
202 implemented in the *glth* function in the *multicomp* package. To display the isotopic niche space
203 of Collembola species, family and lifeform, standard ellipses were plotted using the
204 *standard.ellipses* function in the *siar* package, and visualized using the *ggplot* and *ggrepel*
205 packages. We also analyzed interactions between lifeform and family and land-use system with
206 species as random effects. In the analyses, we excluded Neanuridae and Onychiuridae as they
207 were only represented by a single species not present in each of the land-use systems.

208

209 **Results**

210 *Community-level changes with land use*

211 In rainforest $\Delta^{13}\text{C}$ values of Collembola ranged between 1.5 and 6.0‰ (4.5‰) and in oil
212 palm plantations between -1.5 and 8.5‰ (10.0‰), indicating that Collembola species in oil palm
213 plantations used a wider range of food resources compared to rainforest. In jungle rubber and
214 rubber plantations, the range of $\Delta^{13}\text{C}$ values was similar to rainforest (between 1.0 and 6.0 ‰).
215 Mean $\Delta^{13}\text{C}$ values in rainforest were significantly higher than in plantation systems ($F_{3,146} = 9.90$,
216 $p = 0.001$; Fig. 1A, Supplementary Material Table S1,S2). All Collembola species were enriched in

217 $\delta^{13}\text{C}$ relative to leaf litter except for one individual of *Isotomiella* cf. *minor* in oil palm plantations
218 (Fig. 2; for details see Supplementary Material Table S5-S8).

219 In contrast to $\Delta^{13}\text{C}$, the range of $\Delta^{15}\text{N}$ values was largest in rainforest (-5.0 to 19.0‰),
220 lowest in oil palm plantations (-1.0 to 8.0‰) and intermediate in rubber plantations (-5.0 to
221 15.0‰) and in jungle rubber (-7.5 to 16.0‰). The mean $\Delta^{15}\text{N}$ values of Collembola did not vary
222 significantly among land-use systems ($F_{3,153} = 1.46$, $p = 0.228$; Fig. 1B, Supplementary Material
223 Table S3, S4). Stable isotope values of the most abundant Collembola species present in all land-
224 use systems, *Pseudosinella* sp.1, did not vary significantly among land-use systems both in $\Delta^{13}\text{C}$
225 ($F_{3,21} = 1.44$, $p = 0.260$) and $\Delta^{15}\text{N}$ ($F_{3,21} = 0.88$, $p = 0.467$).

226

227

228 Figure 1. Variations in $\Delta^{13}\text{C}$ and $\Delta^{15}\text{N}$ values of Collembola among the studied land-use systems
229 (rainforest, jungle rubber, rubber and oil palm plantations). Violin plots show mirrored Kernel
230 density estimation, all individual measurements are displayed together, independently of the
231 taxonomic identity. * $\Delta^{13}\text{C}$ values in rainforest were significantly higher than in other three land-
232 use systems ($P < 0.05$).

233

234

235 *Trophic niche differentiation among species*

236 $\Delta^{13}\text{C}$ values of the species analyzed (with at least three replicates per species; see
237 Methods) varied significantly in rainforest ($F_{4,12} = 6.34$, $p = 0.005$) and jungle rubber ($F_{5,17} = 3.67$,
238 $p = 0.020$), but not in rubber ($F_{5,19} = 1.39$, $p = 0.270$) and oil palm plantations ($F_{2,9} = 1.10$, $p =$
239 0.370). In rainforest $\Delta^{13}\text{C}$ values of *Pseudosinella* sp.1 were highest and differed significantly from
240 those of *Lepidocyrtus* sp.1 and *Pararrhopalites* sp.1, whereas in jungle rubber they were highest
241 in *Homidia cingula* and differed significantly from *Callyntrura* sp.1.

242 $\Delta^{15}\text{N}$ values of the species analyzed varied significantly in rainforest ($F_{4,14} = 5.00$, $p =$
243 0.010), jungle rubber ($F_{5,18} = 4.70$, $p = 0.006$) and oil palm plantations ($F_{2,9} = 23.59$, $p = 0.001$), but
244 not in rubber plantations ($F_{5,19} = 2.43$, $p = 0.072$) (Fig. 3; for details see Supplementary Material
245 Table S9-S12). In rainforest *Pseudosinella* sp.1 occupied the highest trophic position, followed by
246 *Isotomiella* cf. *minor*, whereas *Allacma* sp.1 occupied the lowest trophic position. Similar to
247 rainforest, in jungle rubber *Pseudosinella* sp.1 also occupied the highest trophic position, but
248 $\Delta^{15}\text{N}$ values were lowest in *Callyntrura* sp.1. Overall, *Pseudosinella* sp.1, the most dominant
249 species, occupied the highest trophic position across all species. Across all samples analyzed (20
250 species in rainforest, 17 species jungle rubber, 15 species in rubber plantations, and 13 species
251 in oil palm plantations) 3.0% had $\Delta^{15}\text{N}$ values below that of litter (see Supplementary Material,
252 Figure 1).

253

254

255 Figure 2. $\Delta^{13}\text{C}$ values of Collembola species in different land-use systems (rainforest, jungle
256 rubber, rubber and oil palm plantations); model-estimated means (lsmeans) with standard
257 deviation. Horizontal stripes represent individual measurements. Only species with more than
258 three replicates per land-use system were analyzed (see Methods). Isotope values of each species
259 in each land-use system with the same letter are not significantly different according to Tukey's
260 honestly significant difference test ($p > 0.05$).

261

262 Figure 3. Differences of $\Delta^{15}\text{N}$ values of Collembola in different land-use systems (rainforest, jungle
263 rubber, rubber and oil palm plantations); model-estimated means (lsmeans) with standard
264 deviation. Horizontal stripes represent individual measurements. Only species with more than
265 three replicates per land-use system were analyzed (see Methods). Isotope values of each species
266 in each land-use system with the same letter are not significantly different according to Tukey's
267 honestly significant difference test ($p > 0.05$).

268

269

270 *Stable isotope niches of Collembola life forms and families*

271 $\Delta^{15}\text{N}$ values of Collembola varied among life forms ($F_{24,126} = 1.82$, $p = 0.018$), but this was not the
272 case for $\Delta^{13}\text{C}$ values ($F_{24,126} = 1.19$, $p = 0.260$), with the interaction between lifeform and land-use
273 system neither being significant for $\Delta^{15}\text{N}$ ($F_{9,131.60} = 0.87$, $p = 0.556$) nor for $\Delta^{13}\text{C}$ ($F_{9,135.05} = 0.79$,
274 $p = 0.619$). Differences between life forms were more pronounced in rainforest and jungle rubber
275 and less in rubber and oil palm plantations (Figure 4). Euedaphic species were generally most
276 enriched in ^{15}N , whereas atmobiotic species on average occupied the lowest trophic position
277 (except in rubber plantations), often having $\Delta^{15}\text{N}$ values below 5.0‰, with epedaphic and
278 hemiedaphic species being intermediate.

279 $\Delta^{15}\text{N}$ ($F_{24,128.87} = 2.19$, $p = 0.002$) but not $\Delta^{13}\text{C}$ values ($F_{24,127.86} = 1.01$, $p = 0.470$) of
280 Collembola also varied significantly among families (Figure 5), with the interaction between
281 family and land-use system neither being significant for $\Delta^{15}\text{N}$ ($F_{8,121.94} = 0.34$, $p = 0.945$) nor for
282 $\Delta^{13}\text{C}$ ($F_{8,120.67} = 1.84$, $p = 0.075$). Across all land-use systems Isotomidae and Entomobryidae
283 occupied the highest trophic positions, but in rainforest and oil palm plantations Symphypleona
284 occupied the lowest trophic position, whereas in jungle rubber and rubber plantations the lowest
285 trophic position was occupied by Paronellidae.

286

287

288 Figure 4. Stable isotope niches of four Collembola life forms in rainforest, jungle rubber, rubber
289 and oil palm plantations. Ellipses denote 60% confidence intervals, different life forms are shown
290 with colors (eudaphic = dark blue, epedaphic = grey, hemiedaphic = dark goldenrod, atmobiotic
291 = forest green). Large colored dots represent means of land-use systems, small points represent
292 individual measurements.

293

295 Figure 5. Stable isotope niche of Collembola families in rainforest, jungle rubber, rubber and oil
296 palm plantations. Ellipses denote 60% intervals, different families are shown with colors
297 (Paronellidae = blue, Isotomidae = green, Symphypleona = purple, Entomobryidae = light red;
298 Symphypleona comprises the families Sminthuridae, Sminthurididae, Dycirtomidae and
299 Katiannidae). Large colored dots represent means of land-use systems, small points represent
300 individual measurements.

301

302

303 Discussion

304 *Variations in trophic niches with land-use system*

305 Results of the present study indicate that rainforest conversion into agricultural
306 plantations is associated with changes in basal resources ($\Delta^{13}\text{C}$ values) of Collembola, but does
307 not significantly affect their average trophic positions ($\Delta^{15}\text{N}$ values). These findings are in line
308 with the results of the study of Krause *et al.* (2019) investigating oribatid mites at the same study
309 sites and showing that the shift in trophic niches to be mainly due to changes in the use of basal
310 resources rather than trophic levels. Similar to previous studies on centipedes, oribatid mites and
311 other soil animal taxa (Klarner *et al.*, 2017; Susanti *et al.*, 2019; Krause *et al.*, 2019), we also found
312 the conversion of rainforest into plantations to be associated in Collembola with a shift from
313 detritivory towards herbivory (i.e. lower ^{13}C enrichment). In rainforest and jungle rubber,

314 Collembola were enriched in $\delta^{13}\text{C}$ by about 2.0-5.0‰ compared to leaf litter, which resembles
315 the shift observed in temperate forest ecosystems (Pollierer *et al.*, 2009). This “detrital shift” in
316 $\delta^{13}\text{C}$ (Potapov *et al.*, 2019) presumably is due to acquiring C from saprotrophic fungi and bacteria
317 (Potapov *et al.*, 2013). High $\delta^{13}\text{C}$ enrichment in most of the studied Collembola species in the two
318 more natural ecosystems (rainforest and jungle rubber) suggests that they predominantly rely on
319 microorganisms decomposing organic matter rather than on fresh plant material as the food
320 source (Potapov *et al.*, 2019). Overall, similar enrichment in ^{13}C and ^{15}N in Collembola in
321 temperate and tropical ecosystems suggest that Collembola rely little on fresh plant material or
322 mycorrhizal fungi in both and this may well apply to the soil food web in general.

323 As indicated by $\Delta^{13}\text{C}$ values, Collembola species in oil palm plantations used the widest
324 range of food resources compared to the other land-use systems studied, but occupied a
325 narrower range of trophic positions. The wide range in food resources in oil palm plantations may
326 be attributed to the large variety of management practices of the smallholder systems studied
327 (Clough *et al.*, 2016), potentially associated with different organic inputs depending on weeding
328 and fertilization practices. The narrow range of trophic positions in oil palm plantations was due
329 to both the absence of high (predators, scavengers) and low trophic level species (primary
330 decomposers, specialized lichen feeders). This may reflect trophic generalization in the disturbed
331 and unstable habitat of oil palm plantations (Korotkevich *et al.*, 2018). In fact, among the studied
332 land-use systems nematode communities were shown to be most unstable in monoculture
333 plantations (Krashevskaya, *et al.*, 2019). Further, Klarner *et al.* (2017) showed that certain species
334 of centipedes had lower $\Delta^{15}\text{N}$ values in oil palm compared to jungle rubber and rubber

335 plantations suggesting that trophic chains in oil palm plantations are shorter than in the other
336 land-use systems studied.

337 The most dominant Collembola species at our study sites, *Pseudosinella* sp.1, occupied a
338 similar trophic niche in each of the land-use systems studied, suggesting that its diet changes
339 little with the conversion of rainforest into plantation systems. *Pseudosinella* sp.1 colonized both
340 litter and soil, and, as indicated by $\Delta^{15}\text{N}$ values, occupied the highest trophic position among all
341 Collembola species studied. High $\Delta^{15}\text{N}$ values suggest that this species may either feed on
342 mycorrhizal fungi, which are enriched in ^{15}N (Potapov & Tiunov, 2016), and / or on nematodes,
343 which are similarly abundant across the land-use systems studied (Krashevskaya *et al.*, 2019).
344 Conversion of rainforest may have little affected the mineral soil- and root-based resources and
345 this may explain the high abundance of *Pseudosinella* sp.1 in plantations. Similarly, Krause *et al.*
346 (2019) found the trophic niche of some dominant species of oribatid mites to change little with
347 the conversion of rainforest into plantations.

348

349 *Trophic differentiation among species*

350 Variations in $\Delta^{13}\text{C}$ values among Collembola species were more pronounced in rainforest
351 and jungle rubber than in rubber and oil palm plantations. Korotkevich *et al.* (2018) also found
352 the interspecific (in contrast to intraspecific) variation in trophic niches of Collembola
353 communities to be higher in natural (forest and meadows) than in disturbed habitats (pastures
354 and lawns). Among the Collembola species studied $\Delta^{13}\text{C}$ values of *Pseudosinella* sp.1 in rainforest
355 and *Callyntrura* sp.1 and *Sphyroteca* sp.1 in jungle rubber differed significantly from those of the

356 other species indicating that these species are able to exploit resources not available to the other
357 Collembola species in the respective land-use system.

358 Similar to $\Delta^{13}\text{C}$ values, Collembola species in each of the land-use system studied, except
359 rubber plantations, also differed in $\Delta^{15}\text{N}$ values. *Callyntrura* sp.1 in jungle rubber was most
360 depleted in $\delta^{15}\text{N}$ among the studied Collembola species indicating that this species occupied the
361 lowest trophic position. *Pseudosinella* sp. 1 in rainforest was most enriched in $\delta^{15}\text{N}$ values
362 compared the litter substrate and followed by *Isotomiella cf. minor* and *Acrocyrtus* sp. Overall,
363 based on $\Delta^{13}\text{C}$ and $\Delta^{15}\text{N}$ values, trophic niche differentiation among species was most
364 pronounced in rainforest, presumably due to the availability of a wider spectrum of food
365 resources and more stable environmental conditions. This is likely to result in more efficient food-
366 web functioning in natural ecosystems due to species complementarity (Loreau and Hector
367 2001), which is partly lost in plantation systems.

368

369 *Variations in isotopic niches of Collembola taxa and life forms with land-use systems*

370 Collembola taxa such as Symphypleona and Paronellidae typically had low $\Delta^{15}\text{N}$ values,
371 indicating that these taxa feed on algae or lichens (Chahartaghi *et al.*, 2005; Potapov *et al.*, 2018).
372 Symphypleona as well as Paronellidae are well adapted to living above the ground, both are large
373 and possess well-developed visual systems. Such 'atmobiotic' Collembola have been assumed to
374 live at least in part as herbivores on vascular plants or algae (Rusek, 2007) and this is in line with
375 studies from temperate forests investigating variations in stable isotope ratios in Symphypleona
376 (Chahartaghi *et al.*, 2005; Potapov *et al.*, 2016). Paronellidae predominantly occur in tropical

377 regions and also are adapted to living above the ground. Entomobryidae and Isotomidae
378 occupied high trophic positions and this also is consistent with earlier studies based on variations
379 in stable isotope ratios suggesting that they predominantly feed on litter as well as
380 microorganisms colonizing decomposing litter materials (Chahartaghi *et al.*, 2005; Potapov *et al.*,
381 2016). However, some species of these two families also occupied very high trophic positions
382 resembling those of Onychiuridae and Neanuridae in temperate ecosystems suggesting that at
383 least in part they live as predators / scavengers presumably including nematodes as prey
384 (Heidemann *et al.*, 2014). Since Onychiuridae and Neanuridae were extremely rare on our
385 sampling sites, species from other families might have been able to occupy their trophic niches.

386 Trophic niches of Collembola also varied with life form as shown previously for temperate
387 ecosystems (Ponge, 2000; Potapov *et al.*, 2016). Conform to the patterns in Collembola families,
388 the results suggest that atmobiotic and epedaphic species occupied the lowest trophic position
389 across land-use systems, whereas eudaphic species such as *Pseudosinella* sp.1 occupied the
390 highest trophic position. This is in line with the results of the study of Potapov *et al.* (2016)
391 indicating that species inhabiting deeper soil layers (hemiedaphic and euedaphic) are more
392 enriched in $\delta^{15}\text{N}$ than those living in litter and above the ground (epedaphic and atmobiotic).
393 Possibly, high $\delta^{15}\text{N}$ values resulted from feeding on ectomycorrhizal fungi which are enriched in
394 $\delta^{15}\text{N}$ (see above; Potapov and Tiunov, 2016), however, this unlikely applies to tropical forests
395 where trees predominantly form mutualistic interactions with arbuscular mycorrhizal fungi. Low
396 $\delta^{15}\text{N}$ values in epedaphic and atmobiotic Collembola were attributed to algae or lichen feeding.
397 This is widespread in Collembola in temperate forests (Potapov *et al.*, 2018), but in our study only
398 few species had $\delta^{15}\text{N}$ values below those of litter. This contradicts results based on fatty acid

399 analysis suggesting that Collembola feed more on algae in tropical than in temperate ecosystems
400 (Susanti *et al.*, 2019). To clarify the contribution of algae in soil food webs in tropical and
401 temperate ecosystems, more data on stable isotope composition of various food resources in
402 tropical forests, or direct experimentation, are needed. Overall, the results suggest that similar
403 to oribatid mites (Tsurikov, Ermilov, & Tiunov, 2019) the trophic niche structure in Collembola
404 communities is generally similar in temperate and tropical forests and this is partly explained by
405 taxonomic affiliation and life form.

406

407 **Conclusion**

408 We showed that the conversion of rainforest into agricultural plantations, such as rubber and oil
409 palm, is associated with changes in trophic niches of Collembola. We observed a shift in the use
410 of food resources towards herbivory, with the range of food resources of Collembola in oil palm
411 plantations being the highest, likely due to the heterogeneity in management. By contrast, the
412 range of trophic positions in oil palm plantations was low suggesting simplified trophic structure.
413 This is further supported by the less pronounced trophic niche differentiation among species in
414 monoculture plantations. Trophic niche variation of Collembola life forms and families was
415 generally in line with data from temperate forests (although less pronounced), with atmobiotic
416 species occupying the lowest and eudaphic species occupying the highest trophic position.
417 Overall, the results document that the conversion of rainforest into plantation systems not only
418 is associated with shifts in Collembola community composition, but also in shifts in the trophic

419 organization of Collembola communities and species, potentially compromising ecosystem
420 functions and food-web stability in plantations.

Figure 1

Variations in $\Delta^{13}\text{C}$ and $\Delta^{15}\text{N}$ values of Collembola among the studied land-use systems (rainforest, jungle rubber, rubber and oil palm plantations).

Variations in $\Delta^{13}\text{C}$ and $\Delta^{15}\text{N}$ values of Collembola among the studied land-use systems (rainforest, jungle rubber, rubber and oil palm plantations). Violin plots show mirrored Kernel density estimation, all individual measurements are displayed together, independently of the taxonomic identity. * $\Delta^{13}\text{C}$ values in rainforest were significantly higher than in other three land-use systems ($P < 0.05$).

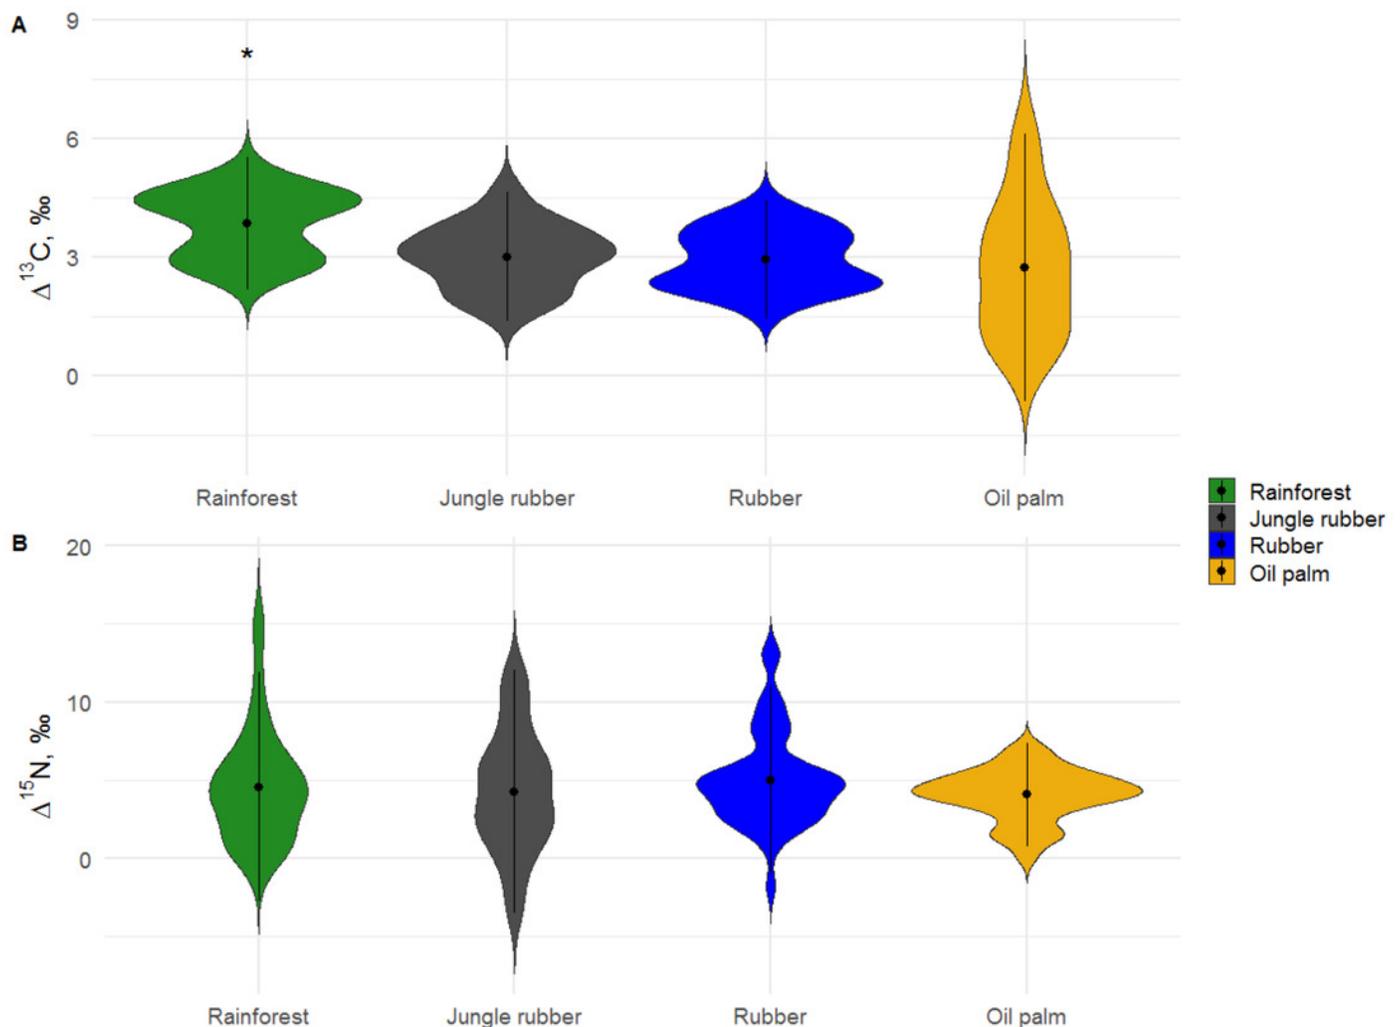

Figure 2

$\Delta^{13}\text{C}$ values of Collembola species in different land-use systems (rainforest, jungle rubber, rubber and oil palm plantations)

$\Delta^{13}\text{C}$ values of Collembola species in different land-use systems (rainforest, jungle rubber, rubber and oil palm plantations); model-estimated means (lsmeans) with standard deviation. Horizontal stripes represent individual measurements. Only species with more than three replicates per land-use system were analyzed (see Methods). Isotope values of each species in each land-use system with the same letter are not significantly different according to Tukey's honestly significant difference test ($p > 0.05$).

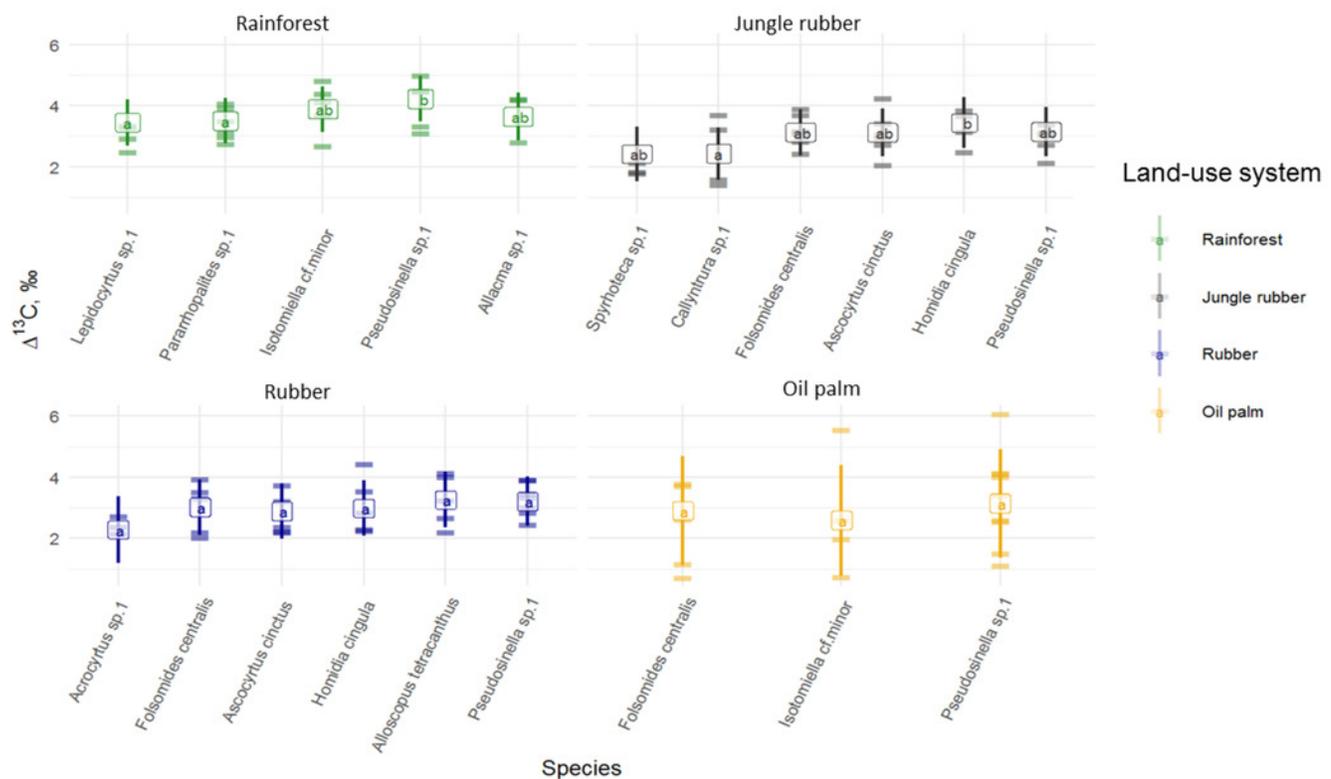

Figure 3

Differences of $\Delta^{15}\text{N}$ values of Collembola in different land-use systems (rainforest, jungle rubber, rubber and oil palm plantations)

Differences of $\Delta^{15}\text{N}$ values of Collembola in different land-use systems (rainforest, jungle rubber, rubber and oil palm plantations); model-estimated means (Ismeans) with standard deviation. Horizontal stripes represent individual measurements. Only species with more than three replicates per land-use system were analyzed (see Methods). Isotope values of each species in each land-use system with the same letter are not significantly different according to Tukey's honestly significant difference test ($p > 0.05$).

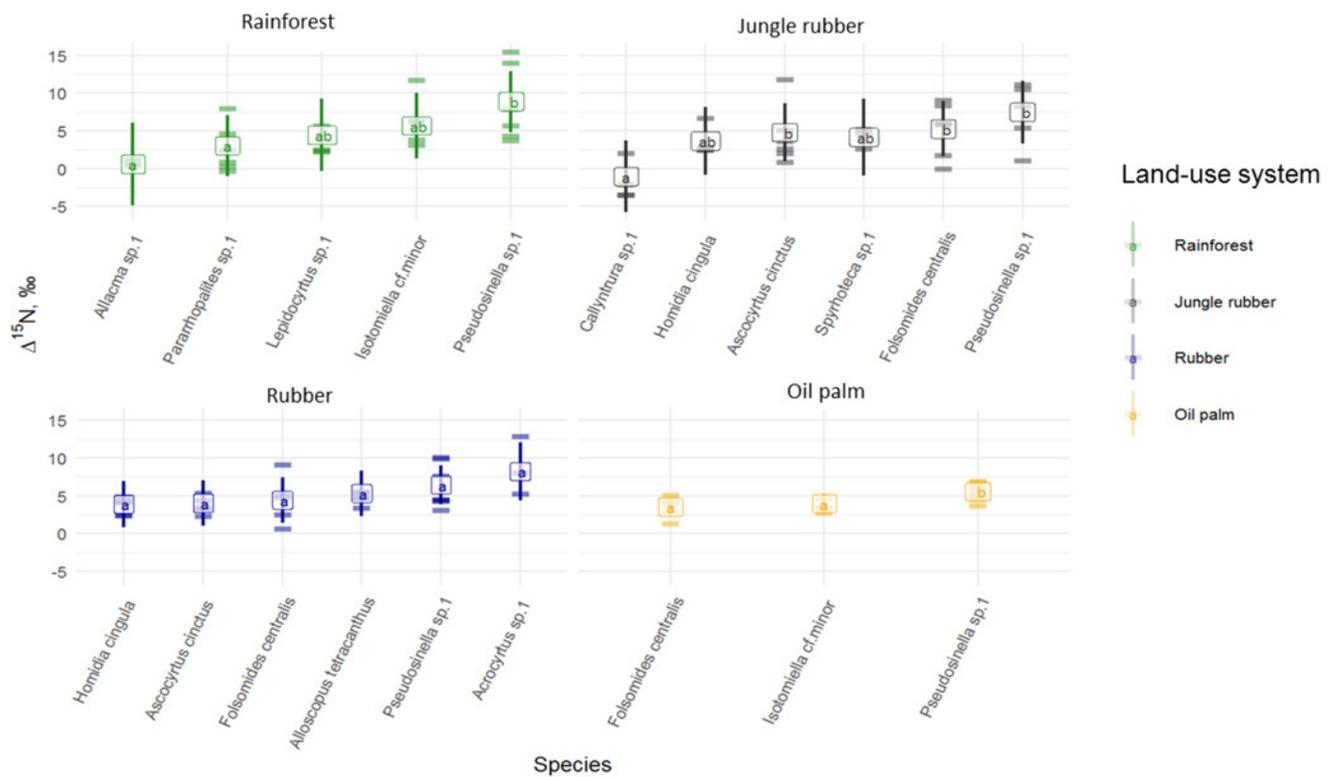

Figure 4

Stable isotope niches of four Collembola life forms in rainforest, jungle rubber, rubber and oil palm plantations.

Stable isotope niches of four Collembola life forms in rainforest, jungle rubber, rubber and oil palm plantations. Ellipses denote 60% confidence intervals, different life forms are shown with colors (eudaphic = dark blue, epedaphic = grey, hemiedaphic = dark goldenrod, atmobiotic = forest green). Large colored dots represent means of land-use systems, small points represent individual measurements.

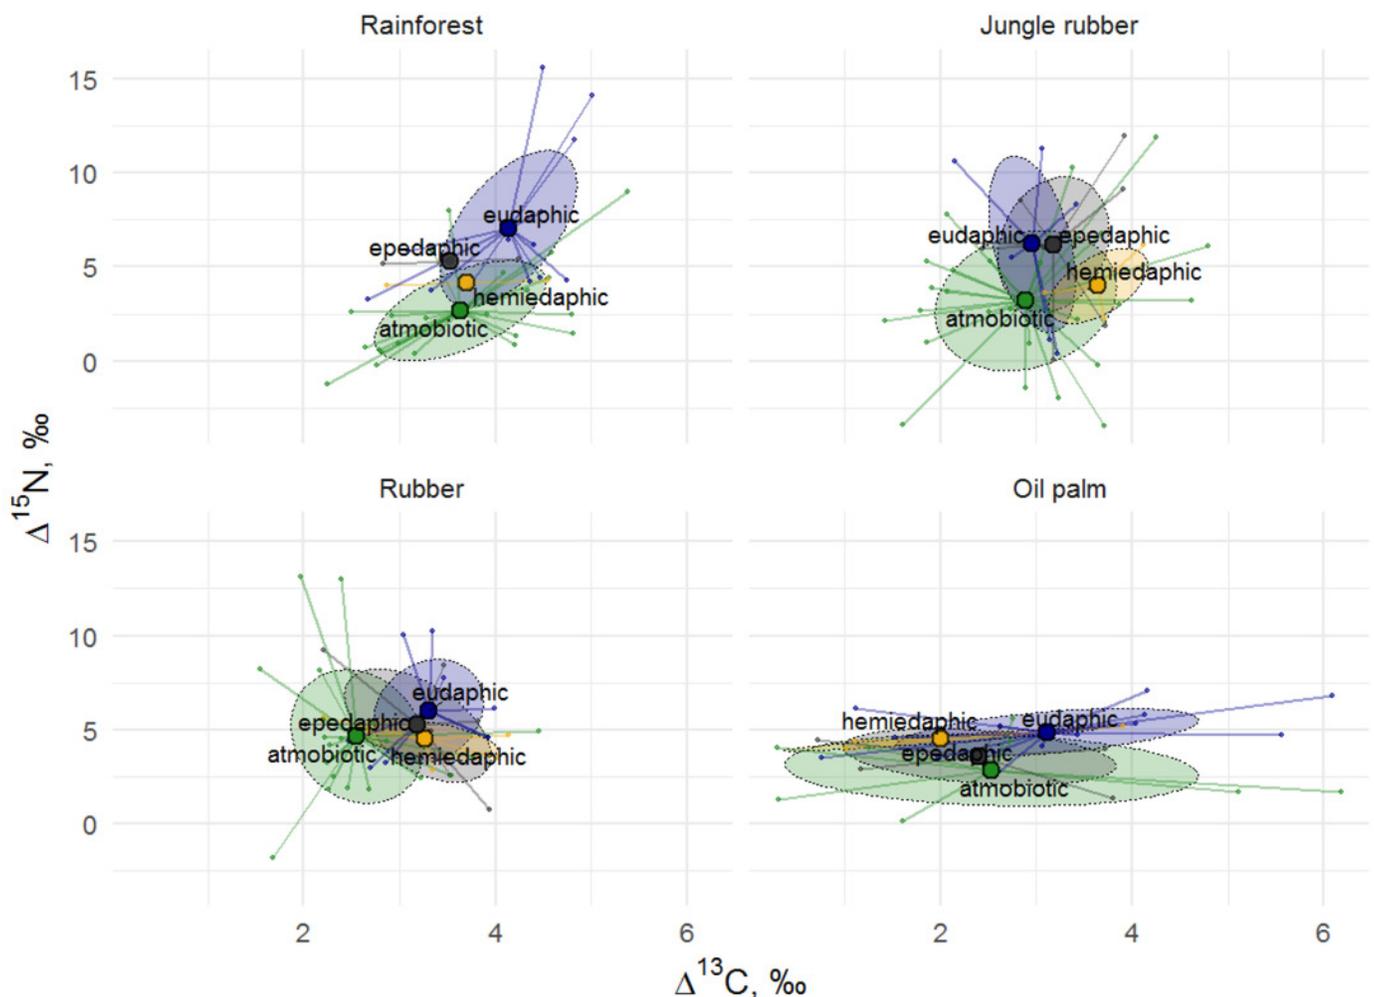

Figure 5

Stable isotope niche of Collembola families in rainforest, jungle rubber, rubber and oil palm plantations.

Stable isotope niche of Collembola families in rainforest, jungle rubber, rubber and oil palm plantations. Ellipses denote 60% intervals, different families are shown with colors (Paronellidae = blue, Isotomidae = green, Symphypleona = purple, Entomobryidae = light red; Symphypleona comprises the families Sminthuridae, Sminthurididae, Dycirtomidae and Katiannidae). Large colored dots represent means of land-use systems, small points represent individual measurements.
