Intensively managed monoculture plantations are increasingly replacing natural forests across the tropics resulting in changes in ecological niches of species and communities, and in ecosystem functioning. Collembola are among the most abundant arthropods inhabiting the belowground system sensitively responding to changes in vegetation and soil conditions. However, most studies on the response of Collembola to land-use change were conducted in temperate ecosystems and focused on shifts in community composition or morphological traits, while parameters more closely linked to ecosystem functioning, such as trophic niches, received little attention. Here, we used stable isotope analysis ( $^{13}\text{C}$  and  $^{15}\text{N}$ ) to investigate changes in trophic structure of and use of food resources by Collembola in Jambi province (Sumatra, Indonesia), a region that experienced strong deforestation in the last decades. Isotopic values of Collembola from 32 sites representing four land-use systems were analyzed (rainforest, rubber agroforest, and rubber and oil palm monoculture plantations). Across Collembola species  $\Delta^{13}\text{C}$  values were highest in rainforest, suggesting more pronounced processing of litter resources by microorganisms and consumption of these microorganisms by Collembola in this system. Lower  $\Delta^{13}\text{C}$  values, but high  $\Delta^{13}\text{C}$  variation in Collembola in oil palm plantations indicated that Collembola shifted towards herbivory and used more variable resources in this system. Small range in  $\Delta^{15}\text{N}$  values in Collembola species in monoculture plantations in comparison to rainforest indicated that conversion of rainforest into plantations is associated with simplification in the trophic structure of Collembola communities. This was further confirmed by generally lower isotopic niche differentiation among species in plantations.

Across the studied ecosystems, atmobiotic species (Symphypleona and Paronellidae) occupied the lowest, whereas euedaphic Collembola species occupied the highest trophic position, resembling patterns in temperate forests. Some species of Paronellidae in rainforest and jungle rubber had  $\Delta^{15}\text{N}$  values below those of leaf litter suggesting algivory (*Salina* sp.1, *Callyntrura* sp.1 and *Lepidonella* sp.1), while *Pseudosinella* sp.1 had the highest  $\Delta^{15}\text{N}$  values in most of the land-use systems suggesting that this species at least in part lives as predator or scavenger. Overall, the results suggest that rainforest conversion into plantation systems is associated with marked shifts in the structure of trophic niches in soil and litter Collembola with potential consequences for ecosystem functioning and food-web stability.

### ABSTRACT

18 Intensively managed monoculture plantations are increasingly replacing natural forests across  
19 the tropics resulting in changes in ecological niches of species and communities, and in ecosystem  
20 functioning. Collembola are among the most abundant arthropods inhabiting the belowground  
21 system sensitively responding to changes in vegetation and soil conditions. However, most  
22 studies on the response of Collembola to land-use change were conducted in temperate  
23 ecosystems and focused on shifts in community composition or morphological traits, while  
24 parameters more closely linked to ecosystem functioning, such as trophic niches, received little  
25 attention. Here, we used stable isotope analysis (<sup>13</sup>C and <sup>15</sup>N) to investigate changes in trophic  
26 structure of and use of food resources by Collembola in Jambi province (Sumatra, Indonesia), a  
27 region that experienced strong deforestation in the last decades. Isotopic values of Collembola

28 from 32 sites representing four land-use systems were analyzed (rainforest, rubber agroforest,  
29 and rubber and oil palm monoculture plantations). Across Collembola species  $\Delta^{13}\text{C}$  values were  
30 highest in rainforest, suggesting more pronounced processing of litter resources by  
31 microorganisms and consumption of these microorganisms by Collembola in this system. Lower  
32  $\Delta^{13}\text{C}$  values, but high  $\Delta^{13}\text{C}$  variation in Collembola in oil palm plantations indicated that  
33 Collembola shifted towards herbivory and used more variable resources in this system. Small  
34 range in  $\Delta^{15}\text{N}$  values in Collembola species in monoculture plantations in comparison to  
35 rainforest indicated that conversion of rainforest into plantations is associated with simplification  
36 in the trophic structure of Collembola communities. This was further confirmed by generally  
37 lower isotopic niche differentiation among species in plantations. Across the studied ecosystems,  
38 atmobiotic species (Symphypleona and Paronellidae) occupied the lowest, whereas euedaphic  
39 Collembola species occupied the highest trophic position, resembling patterns in temperate  
40 forests. Some species of Paronellidae in rainforest and jungle rubber had  $\Delta^{15}\text{N}$  values below those  
41 of leaf litter suggesting algivory (*Salina* sp.1, *Callyntrura* sp.1 and *Lepidonella* sp.1), while  
42 *Pseudosinella* sp.1 had the highest  $\Delta^{15}\text{N}$  values in most of the land-use systems suggesting that  
43 this species at least in part lives as predator or scavenger. Overall, the results suggest that  
44 rainforest conversion into plantation systems is associated with marked shifts in the structure of  
45 trophic niches in soil and litter Collembola with potential consequences for ecosystem  
46 functioning and food-web stability.

## 51 Introduction

52 Agricultural intensification in Indonesia is associated with deforestation which increased  
53 strongly in the last 30 years (Koh & Ghazoul, 2010 ; Gatto *et al.*, 2015). Large parts of rainforest  
54 in lowland Sumatra (Indonesia) have been converted into oil palm (16% of total area) and rubber  
55 plantations (12%) (Gatto *et al.*, 2015). These processes are driven by a high global demand for  
56 agricultural products and positively affect income and employment for the local smallholders  
57 (Grass *et al.*, 2020; Qaim *et al.*, 2020). At the same time, conversion of tropical rainforest into  
58 plantation systems is associated with major changes in ecological niches of animal species, loss  
59 of biodiversity, and thereby with changes in ecosystem functioning (Barnes *et al.*, 2014; Clough  
60 *et al.*, 2016; Fitzherbert *et al.*, 2008; Gilbert, 2012). These changes affect both the above- and  
61 belowground system. Complex and diverse microbial and animal communities in soil regulate  
62 important ecosystem functions and support aboveground life (Bardgett & Van Der Putten, 2014),  
63 but knowledge on effects of land-use change on soil life in the tropics is very limited.

64 Studies from Sumatra showed that conversion of rainforest into oil palm and rubber  
65 plantations is associated with a decline in species diversity, population density, biomass, and  
66 energy flux in litter macroinvertebrate communities by approximately 45% (Drescher *et al.*, 2016;  
67 Grass *et al.*, 2020). Uneven decline in energy flux across size classes and trophic levels was  
68 documented for meso- and macrofauna soil communities leading to strong alterations in soil  
69 food-web structure (Potapov *et al.*, 2019). Different basal resources available in different land-  
70 use systems result in changes in trophic niches of decomposer and predatory soil invertebrates,  
71 and results in reduced abundance of primary decomposers and in soil animals shifting their  
72 feeding habits towards herbivory (Klarner *et al.*, 2017; Krause *et al.*, 2019; Susanti *et al.*, 2019).

73 Land-use change may also result in reduced trophic niche differentiation among species in  
74 belowground communities (Korotkevich *et al.*, 2018), but this has not been investigated in  
75 tropical ecosystems.

76 Collembola are among the most abundant soil decomposer invertebrates, inhabiting  
77 various organic substrates and using a wide range of food resources (Rusek, 1998). Early studies  
78 on food resources of Collembola concluded that the majority of euedaphic and hemiedaphic  
79 species feed unselectively on a wide variety of food materials (Hopkin, 1997). However, stable  
80 isotope analysis showed pronounced trophic niche differentiation among Collembola species in  
81 temperate forests (Chahartagi *et al.*, 2005). This differentiation in large has been explained by  
82 the taxonomic identity and life forms of Collembola (Potapov *et al.*, 2016). Species, living  
83 aboveground and on the litter surface (atmobiote and epedaphic life forms) are mainly  
84 phycophages, feeding on lichens, algae and pollen. Species, living in the litter (hemiedaphic life  
85 form) are detritivores feeding on saprotrophic microorganisms and litter. Species, living in soil  
86 (euedaphic life form) feed on soil organic matter, roots and fungi (Ponge, 2000; Potapov *et al.*,  
87 2016). Further, food resources and trophic levels also vary among high-rank taxa with e.g.,  
88 Poduromorpha occupying higher trophic positions than Entomobryomorpha and Symphypleona,  
89 suggesting evolutionary selection for microbivory in the former (Potapov *et al.*, 2016). Since  
90 lowland tropical forest ecosystems often have a less pronounced organic layer and different plant  
91 and animal community composition than temperate forest ecosystems (Petersen and Luxton,  
92 1982), they provide different ecological niches for Collembola, potentially resulting in a different  
93 trophic structure of communities. To date, information on food resources and trophic niches of

94 Collembola is based on studies from temperate ecosystems, whereas information from tropical  
95 ecosystems is virtually lacking entirely.

96 Over the last two decades, stable isotope analysis has become the most commonly used  
97 tool to assess trophic niches of soil animals (Potapov *et al.*, 2019). Two isotopic ratios,  $^{13}\text{C}/^{12}\text{C}$   
98 (i.e.,  $\delta^{13}\text{C}$  values) and  $^{15}\text{N}/^{14}\text{N}$  (i.e.,  $\delta^{15}\text{N}$  values), typically are used in food-web studies. Trophic  
99 positions and length of trophic chains can be assessed using  $\delta^{15}\text{N}$  values, whereas the range of  
100  $\delta^{13}\text{C}$  values reflects variability in the use of basal resources (Potapov *et al.*, 2019). Stable isotope  
101 composition of consumers follows that in food resources, thus allowing to reveal potential diet  
102 switching with land-use change (Klarner *et al.*, 2017; Krause *et al.*, 2019; Susanti *et al.*, 2019).

103 Here, we use stable isotope analysis to investigate trophic positions and food resources  
104 of soil and litter Collembola in four different land-use systems in Sumatra, Indonesia: rainforest,  
105 rubber agroforest ('jungle rubber'), and monoculture rubber and oil palm plantations. The study  
106 aimed at investigating how trophic positions and food resources of Collembola change after  
107 rainforest conversion into agricultural plantations, such as rubber and oil palm, and, for the first  
108 time, at exploring patterns in trophic niche differentiation among tropical Collembola species. In  
109 more detail we investigated the following hypotheses:

- 110 1) Analogous to other soil invertebrates, Collembola shift their trophic niches towards  
111 herbivory in plantation systems in comparison to rainforest.
- 112 2) Due to reduced food resources (poor litter layer), the trophic niche width of  
113 Collembola is narrower in plantations in comparison to rainforest.
- 114 3) Trophic niche differentiation among Collembola species is more pronounced in  
115 rainforest than in plantation systems.

116 4) Trophic niche differentiation among families and life forms of Collembola in tropical  
117 ecosystems follows similar patterns as in ecosystems of the temperate zone.

118

## 119 **Material and Methods**

### 120 **Site description**

121 Four land-use systems were investigated: lowland rainforest, jungle rubber, rubber  
122 (*Hevea brasiliensis*) and oil palm (*Elaeis guineensis*) plantations, located in Jambi province,  
123 southwest Sumatra, Indonesia. The study sites were located at a similar altitude varying between  
124 50 and 100 m a.s.l. in two landscapes, the Harapan and Bukit Dua Belas landscape; each land-use  
125 system was replicated four times per landscape, resulting in a total of 32 sites (for more details  
126 see Drescher *et al.*, 2016). Lowland rainforest was used as reference, but represents secondary  
127 rainforest, which has been logged once by taking out large trees some 30 years ago. Jungle rubber  
128 represents a rubber agroforest system originating from rainforest enriched with rubber trees;  
129 the age of rubber trees varied between 15-40 years (Kotowska, Leuschner, Triadiati, Meriem, &  
130 Hertel, 2015). Rubber and oil palm plantations were intensively managed monocultures of an  
131 average age of 7 to 16 and 8 to 15 years, respectively (Drescher *et al.*, 2016), and were established  
132 after logging, clearing, and burning of either rainforest or jungle rubber. Soils at the Harapan  
133 landscape are loam Acrisols of low fertility, whereas in Bukit Dua Belas the major soil type is clay  
134 Acrisol (Allen *et al.*, 2015; Kotowska *et al.*, 2015). Management practices in these smallholder  
135 monoculture plantations are described in more detail in Allen *et al.* (2015). Oil palm plantations  
136 typically were fertilized once in the rainy season and once in the dry season. Typically, 300-500  
137 kg NPK complete fertilizer, 300 kg KCl and 138 kg urea ( $\text{CO}(\text{NH}_2)_2$ ) were added per hectare and

138 year. Rubber and oil palm plantations were weeded manually or chemically throughout the year.  
139 The most commonly used herbicides were Gramoxone and Roundup; these were applied at an  
140 average rate of 2 to 5 L ha<sup>-1</sup> y<sup>-1</sup> (Allen *et al.*, 2015; Clough *et al.*, 2016; Kotowska *et al.*, 2015).

141

#### 142 **Sampling procedure**

143 Samples were taken in October 2013 in three 5 x 5 m subplots within 50 x 50 m plots  
144 established at each study site (Drescher *et al.*, 2016). In each subplot soil samples of 16 x 16 cm  
145 were taken including the litter layer and the underlying top soil to a depth of 5 cm. Animals from  
146 both layers were pooled for stable isotope analysis to obtain sufficient amount of animal tissue  
147 for the analyses. Animals were extracted by heat (Kempson *et al.*, 1963) until the substrate was  
148 completely dry (6-8 days) using glycerol : water mixture at a ratio of 1 : 1 as collection solution.  
149 Field collection was conducted under the research permit No. 389/SIP/FRP/SM/X/2013 issued by  
150 the State Ministry of Research and Technology of Indonesia (RISTEK) with collection permit No.  
151 S.07/KKH-2/2013 issued by the Ministry of Forestry (PHKA). We thank the following persons and  
152 organizations for granting us access to and use of their properties: village leaders, local plot  
153 owners, PT Humusindo, PT Perkebunan Nusantara VI, Harapan Rainforest, and Bukit Duabelas  
154 National Park.

155

#### 156 **Species identification**

157           Collembola were sorted in Petri dishes using a dissecting microscope. For species-level  
158 identification, selected individuals were subsequently cleared in Nesbitt solution and mounted  
159 on slides with Hoyer solution. Collembola were identified under a compound light microscope at  
160 400× magnification. The checklist and keys for Indonesian Collembola by Suhardjono *et al.* (2012)  
161 were used along with publications on Southeast Asian Collembola. Due to a relatively poorly  
162 described fauna, in many cases we had to assign individuals to morphospecies without Linnaean  
163 names (in total 72% of all identified species); for simplicity, we refer to both as ‘species’. When  
164 possible, juvenile specimens were ascribed to species of adults or subadults present in the same  
165 sample or in samples from the same plot. After identification, all data on Collembola species and  
166 their identification characters were uploaded to Ecotaxonomy database  
167 (<http://ecotaxonomy.org>). In total 56 species from 13 families and 27 genera were found.

168

### 169 **Bulk stable isotope analyses**

170 Stable isotope ratios were measured from dominant species representing at least 70% of the  
171 individuals on each plot (Supplementary Table S1 ). Dominant species were chosen for each plot  
172 separately to represent the local ‘functional community’. This selection procedure resulted in a  
173 total of 30 out of 56 species being included in the analysis across all land-use systems. For stable  
174 isotope measurements appropriate amounts of animal tissue (ranging from 0.003 to 1.268 mg)  
175 were transferred into tin capsules and dried at 60°C for 24 h, weighed and stored in a desiccator  
176 until analysis. Stable isotope ratios, and total C and N concentration were determined using a  
177 coupled system consisting of an elemental analyzer (Eurovector, Milano, Italy) equipped with a  
178 Blisotec autosampler (Blisotec, Jülich, Germany) and a Thermo Delta Vplus isotope ratio mass

179 spectrometer connected via a ConFlo IV interface (both from Thermo Fisher Scientific, Bremen,  
180 Germany) located at the Centre for Stable Isotope Research and Analysis, Göttingen, Germany  
181 (Langel & Dyckmans, 2014). Isotope signatures were expressed using the  $\delta$  notation as  $\delta X(\text{‰}) =$   
182  $(R_{\text{sample}} - R_{\text{standard}}) / R_{\text{standard}}$ , with X representing the target isotope and R the ratio of heavy to light  
183 isotope ( $^{13}\text{C}/^{12}\text{C}$  or  $^{15}\text{N}/^{14}\text{N}$ ). For  $\delta^{15}\text{N}$  and  $\delta^{13}\text{C}$  analyses, N in atmospheric air and Vienna Pee Dee  
184 Belemnite served as standards, respectively. We use IAEA CH6 (-10.43‰, Sucrose) and IAEA 600  
185 (-27.7‰, Caffein) as C standards, and IAEA N1 (0.4‰) and IAEA N2 (20.3‰) for N (both are  
186 Ammonium sulfates) for internal calibration.

187

188

### 189 **Statistical analysis**

190 To compensate for inter-site variation in the isotopic baseline, prior to the analysis all data were  
191 normalized to the local leaf litter using the following equations (Potapov *et al.*, 2019):

$$192 \quad \Delta^{13}\text{C} = \delta^{13}\text{C}_{\text{Collembola}} - \delta^{13}\text{C}_{\text{litter}}$$

$$193 \quad \Delta^{15}\text{N} = \delta^{15}\text{N}_{\text{Collembola}} - \delta^{15}\text{N}_{\text{litter}}$$

194 Stable isotope values of litter were taken from Klarner *et al.* (2017) who investigated the same  
195 sampling sites.

196 Statistical analyses were performed using R v 3.5.2 (R Core Team, 2018) with R studio  
197 interface (R Studio, Inc.). First, we analyzed the effect of land-use system on the isotopic  
198 composition of Collembola at the community level. Effects of land-use system on the  $\Delta^{13}\text{C}$  and  
199  $\Delta^{15}\text{N}$  values of all measured Collembola individuals were tested using Linear Mixed Effect Models  
200 (LMM) with species identity as random effect. Species identity was coded as random effect for

201 the following reasons: (1) In this first analysis we were not interested in variations in  $\Delta^{13}\text{C}$  and  
202  $\Delta^{15}\text{N}$  values among species but still wanted to account for it, (2) species presence was uneven  
203 across plots and land-use systems preventing the analysis of land-use effects, and (3) including  
204 species as fixed factor would have compromised the analysis of land-use effects on  $\Delta^{13}\text{C}$  and  $\Delta^{15}\text{N}$   
205 values of Collembola by reducing error degrees of freedom. The analysis was conducted using  
206 the *lmer* function in the *lme4* package (Bates *et al.*, 2015). Significance of fixed effects (factors)  
207 was tested using the *Anova* function in the *car* package. Significant differences in stable isotope  
208 values between land-use systems were tested using the *tukey test* in the *emmeans* and  
209 *multcomp* packages. We also analyzed the effect of land use only for one dominant species,  
210 present in sufficient replicates in each land-use system (*Pseudosinella* sp.1) using analysis of  
211 variance implemented in the *avov* function. Additionally, the ranges in  $\Delta^{13}\text{C}$  and  $\Delta^{15}\text{N}$  values in  
212 each land-use system were calculated as difference between minimum and maximum values and  
213 visualized using the Kernel density estimation in the *ggplot 2* package using the *geom\_violin*  
214 function.

215         Second, we assessed trophic niche differentiation among species by assessing the effect  
216 of species identity on stable isotope composition of Collembola with LMM. We used species  
217 identity as factor and either  $\Delta^{13}\text{C}$  or  $\Delta^{15}\text{N}$  values as response variables; sampling plot was included  
218 as random effect to account for site-specific differences in trophic niches. The analysis was done  
219 separately for each land-use system (eight analyses in total). Only species allowing more than  
220 three measurements per land-use system were included.

221         Third, we analyzed the effects of family identity and life form on stable isotope  
222 composition of Collembola using LMM. Here, we used both plot and land-use system as random

223 effects. Significant differences between families and life forms were tested using Tukey contrasts  
224 as implemented in the *glth* function in the *multicomp* package. To display the isotopic niche space  
225 of Collembola species, family, and lifeform, ellipses denoting 60% intervals were plotted using  
226 the *standard.ellipse* function in the *siar* package, and visualized using the *ggplot* and *ggrepel*  
227 packages. We also analyzed interactions between land-use system and life form and between  
228 land-use system and family with plot as random effect. In the analyses, we excluded Neanuridae  
229 and Onychiuridae as they were only represented by a single species not present in each of the  
230 land-use systems. In addition, we also analyzed R square values between species, family, and  
231 lifeform to identify the most important factor. Here, we used plot as random effect The analysis  
232 was done using the *r.squaredGLMM* function in the *lme4* and *MuMin* packages.

233

## 234 **Results**

### 235 *Community-level changes with land use*

236 In rainforest  $\Delta^{13}\text{C}$  values of Collembola ranged between 1.5 and 6.0‰ (total range 4.5‰),  
237 and in oil palm plantations between -1.5 and 8.5‰ (10.0‰), indicating a wider range of  $\Delta^{13}\text{C}$   
238 values in food resources in the latter. In jungle rubber and rubber plantations, the range of  $\Delta^{13}\text{C}$   
239 values was similar to rainforest (between 1.0 and 6.0 ‰). Mean  $\Delta^{13}\text{C}$  values in rainforest were  
240 significantly higher than in plantation systems ( $F_{3,146} = 9.90$ ,  $p = 0.001$ ; Fig. 1A, Supplementary  
241 Material Tables S2, S3). All  $\delta^{13}\text{C}$  values of Collembola species exceeded those of leaf litter except  
242 for one individual of *Isotomiella* cf. *minor* in oil palm plantations (Fig. 2; for details see  
243 Supplementary Material Tables S6-S9).

244 In contrast to  $\Delta^{13}\text{C}$ , the range of  $\Delta^{15}\text{N}$  values was largest in rainforest (-5.0 to 19.0‰),  
245 lowest in oil palm plantations (-1.0 to 8.0‰), and intermediate in rubber plantations (-5.0 to  
246 15.0‰) and in jungle rubber (-7.5 to 16.0‰). Mean  $\Delta^{15}\text{N}$  values of Collembola did not vary  
247 significantly among land-use systems ( $F_{3,153} = 1.46$ ,  $p = 0.228$ ; Fig. 1B, Supplementary Material  
248 Tables S4, S5). Stable isotope values of the most abundant Collembola species present in all land-  
249 use systems, *Pseudosinella* sp.1, did not vary significantly among land-use systems both in  $\Delta^{13}\text{C}$   
250 ( $F_{3,21} = 1.44$ ,  $p = 0.260$ ) and  $\Delta^{15}\text{N}$  ( $F_{3,21} = 0.88$ ,  $p = 0.467$ ).

251

#### 252 *Niche differentiation among species*

253  $\Delta^{13}\text{C}$  values across abundant species (represented by at least three measurements, see  
254 Methods) varied significantly in rainforest ( $F_{4,12} = 6.34$ ,  $p = 0.005$ ) and jungle rubber ( $F_{5,17} = 3.67$ ,  
255  $p = 0.020$ ), but not in rubber ( $F_{5,19} = 1.39$ ,  $p = 0.270$ ) and oil palm plantations ( $F_{2,9} = 1.10$ ,  $p =$   
256 0.370). In rainforest,  $\Delta^{13}\text{C}$  values of *Pseudosinella* sp.1 were highest and differed significantly  
257 from those of *Lepidocyrtus* sp.1 and *Pararrhopalites* sp.1, whereas in jungle rubber they were  
258 highest in *Homidia cingula* and differed significantly from *Callyntrura* sp.1.

259  $\Delta^{15}\text{N}$  values across abundant species varied significantly in rainforest ( $F_{4,14} = 5.00$ ,  $p =$   
260 0.010), jungle rubber ( $F_{5,18} = 4.70$ ,  $p = 0.006$ ) and oil palm plantations ( $F_{2,9} = 23.59$ ,  $p = 0.001$ ), but  
261 not in rubber plantations ( $F_{5,19} = 2.43$ ,  $p = 0.072$ ) (Fig. 3; for details see Supplementary Material  
262 Tables S10-S13). In rainforest *Pseudosinella* sp.1 occupied the highest trophic position, followed  
263 by *Isotomiella* cf. *minor*, whereas *Allacma* sp.1 occupied the lowest trophic position. Similar to  
264 rainforest, in jungle rubber *Pseudosinella* sp.1 also occupied the highest trophic position, but

265  $\Delta^{15}\text{N}$  values were lowest in *Callyntrura* sp.1. Overall, *Pseudosinella* sp.1, the most dominant  
266 species, occupied the highest trophic position across all species. Across all samples analyzed (20  
267 species in rainforest, 17 species jungle rubber, 15 species in rubber plantations, and 13 species  
268 in oil palm plantations) 3% of the measurements had  $\Delta^{15}\text{N}$  values below that of litter (see  
269 Supplementary Material, Fig. 1).

270

#### 271 *Differences among Collembola life forms and families*

272 The  $\Delta^{15}\text{N}$  values of Collembola varied among life forms ( $F_{24,126} = 1.82$ ,  $p = 0.018$ ), but this was not  
273 the case for  $\Delta^{13}\text{C}$  values ( $F_{24,126} = 1.19$ ,  $p = 0.260$ ), with the interaction between lifeform and land-  
274 use system neither being significant for  $\Delta^{15}\text{N}$  ( $F_{9,132} = 0.87$ ,  $p = 0.556$ ) nor for  $\Delta^{13}\text{C}$  ( $F_{9,135} = 0.79$ ,  
275  $p = 0.619$ ). Differences between life forms were more pronounced in rainforest and jungle rubber  
276 and less in rubber and oil palm plantations (Fig. 4). Euedaphic species were generally most  
277 enriched in  $^{15}\text{N}$ , whereas atmobiotic species on average occupied the lowest trophic position  
278 (except in rubber plantations), often having  $\Delta^{15}\text{N}$  values below 5.0‰, with epedaphic and  
279 hemiedaphic species being intermediate.

280 Similar to results of the life form analysis, the  $\Delta^{15}\text{N}$  ( $F_{24,129} = 2.19$ ,  $p = 0.002$ ) but not  $\Delta^{13}\text{C}$   
281 values ( $F_{24,128} = 1.01$ ,  $p = 0.470$ ) of Collembola varied significantly among families (Fig. 5), with the  
282 interaction between family and land-use system neither being significant for  $\Delta^{15}\text{N}$  ( $F_{8,122} = 0.34$ ,  
283  $p = 0.945$ ) nor for  $\Delta^{13}\text{C}$  ( $F_{8,121} = 1.84$ ,  $p = 0.075$ ). Isotomidae and Entomobryidae occupied the  
284 highest trophic positions across land-use systems, Symphypleona occupied the lowest trophic  
285 position in rainforest and oil palm plantations, whereas in jungle rubber and rubber plantations  
286 the lowest trophic position was occupied by Paronellidae. Family and lifeform identity explained

287 approximately two times less variation in  $\Delta^{15}\text{N}$  values than species identity with  $R^2 = 0.29$  in  
288 models based on species, and  $R^2 = 0.13$  in both models based on families and life forms.

289

## 290 Discussion

### 291 *Variations in trophic niches with land-use system*

292 Results of our study indicate that rainforest conversion into agricultural plantations is  
293 associated with changes in basal resources ( $\Delta^{13}\text{C}$  values) of Collembola, but does not significantly  
294 affect their average trophic positions ( $\Delta^{15}\text{N}$  values). These findings are in line with the results of  
295 the study of Krause *et al.* (2019) investigating oribatid mites at the same study sites and showing  
296 that the shift in trophic niches to be mainly due to changes in the use of basal resources rather  
297 than trophic levels. Similar to previous studies on centipedes, oribatid mites and other soil animal  
298 taxa (Klarner *et al.*, 2017; Susanti *et al.*, 2019; Krause *et al.*, 2019), we also found the conversion  
299 of rainforest into plantations to be associated in Collembola with a shift from detritivory towards  
300 herbivory (i.e., lower  $^{13}\text{C}$  enrichment). In rainforest and jungle rubber,  $\delta^{13}\text{C}$  values of Collembola  
301 were 2.0-5.0‰ higher compared to leaf litter, which resembles the shift observed in temperate  
302 forest ecosystems (Pollierer *et al.*, 2009). This “detrital shift” in  $\delta^{13}\text{C}$  (Potapov *et al.*, 2019)  
303 presumably is due to acquiring C from saprotrophic fungi and bacteria (Potapov *et al.*, 2013) that  
304 preferentially use  $^{13}\text{C}$ -rich plant compounds (Pollierer *et al.*, 2009). High  $^{13}\text{C}$  enrichment in most  
305 of the studied Collembola species in more natural ecosystems (rainforest and jungle rubber)  
306 suggests that they predominantly rely on microorganisms decomposing organic matter rather  
307 than on fresh plant material as food source (Potapov *et al.*, 2019). Overall, similar enrichment in  
308  $^{13}\text{C}$  and  $^{15}\text{N}$  in Collembola in temperate and tropical ecosystems suggest that Collembola rely little

309 on fresh plant material or mycorrhizal fungi in both, and this may well apply to soil food webs in  
310 general.

311 As indicated by  $\Delta^{13}\text{C}$  values, Collembola species in oil palm plantations used food  
312 resources of a wide range of  $^{13}\text{C}$  values, which was not the case in the other land-use systems  
313 studied. Variations in  $^{13}\text{C}$  values of food resources in oil palm plantations may be attributed to  
314 the variety of management practices of the smallholder systems studied (Clough *et al.*, 2016).  
315 Potentially, variations in organic inputs due to differences in weeding, herbicide, and fertilization  
316 practices, resulted in an overestimation of the trophic niche width in oil palm plantations

317 The narrow range of  $\Delta^{15}\text{N}$  values in oil palm plantations suggests similar trophic positions  
318 of Collembola species in this land-use system. Notably, the narrow range was due to both the  
319 lack of high trophic level (predators, scavengers) and low trophic level species (primary  
320 decomposers, specialized lichen feeders). This may reflect the dominance of generalist species in  
321 the disturbed habitat of oil palm plantations (Korotkevich *et al.*, 2018). Nematode communities  
322 also indicated oil palm plantations to be the most disturbed of the four land-use systems studied  
323 (Krashevskaya *et al.*, 2019). Further, Klarner *et al.* (2017) found  $\Delta^{15}\text{N}$  values of centipede species to  
324 be lower in oil palm compared to jungle rubber and rubber plantations suggesting that trophic  
325 chains in oil palm plantations are shorter than in the other land-use systems studied. Overall,  
326 these findings suggest that the structure of soil food-webs in monoculture plantations, especially  
327 oil palm, is simplified due to reduced number of trophic levels.

328 The most dominant Collembola species at our study sites, *Pseudosinella* sp.1, occupied a  
329 similar trophic niche in each of the land-use systems studied, suggesting that its diet changes

330 little with the conversion of rainforest into plantation systems. *Pseudosinella* sp.1 colonized both  
331 litter and soil, and, as indicated by  $\Delta^{15}\text{N}$  values, occupied the highest trophic position among all  
332 Collembola species studied. High  $\Delta^{15}\text{N}$  values suggest that this species may either feed on  
333 mycorrhizal fungi, which are enriched in  $^{15}\text{N}$  (Hobbie *et al.*, 2001; Potapov & Tiunov, 2016), and  
334 / or live as predators feeding e.g., on nematodes, which are similarly abundant across the land-  
335 use systems studied (Krashevskaya *et al.*, 2019). Conversion of rainforest may have less affected  
336 the mineral soil- and root-based resources than litter resources, and this may explain the high  
337 abundance of euedaphic *Pseudosinella* sp.1 in plantations. Similarly, Krause *et al.* (2019) found  
338 the trophic niche of dominant species of oribatid mites to change little with the conversion of  
339 rainforest into plantations. This suggests that trophic niches of certain species may be little  
340 affected by land-use change despite strong changes in the overall food-web structure.

341

#### 342 *Trophic differentiation among species*

343 Variations in  $\Delta^{13}\text{C}$  values among Collembola species were more pronounced in rainforest  
344 and jungle rubber than in rubber and oil palm plantations. Korotkevich *et al.* (2018) also found  
345 the interspecific (in contrast to intraspecific) variation in trophic niches of Collembola to be higher  
346 in natural (forest and meadows) than in disturbed habitats (pastures and lawns). Among the  
347 Collembola species studied  $\Delta^{13}\text{C}$  values of *Pseudosinella* sp.1 in rainforest, and *Callyntrura* sp.1  
348 and *Sphyroteca* sp.1 in jungle rubber differed significantly from those of other Collembola species  
349 indicating that these species are able to exploit resources not available to the other Collembola  
350 species in the respective land-use system.

351 Similar to  $\Delta^{13}\text{C}$  values, Collembola species in each land-use system, except rubber  
352 plantations, also differed in  $\Delta^{15}\text{N}$  values. In jungle rubber *Callyntrura* sp.1 was most depleted in  
353  $\delta^{15}\text{N}$  among the studied Collembola species indicating that this species occupied the lowest  
354 trophic position pointing to phycophagy (Potapov *et al.*, 2018). In rainforest *Pseudosinella* sp.1  
355 had the highest  $\delta^{15}\text{N}$  values followed by *Isotomiella* cf. *minor* and *Acrocyrtus* sp. suggesting that  
356 these species act as microbivores in undisturbed ecosystems. Overall, based on  $\Delta^{13}\text{C}$  and  $\Delta^{15}\text{N}$   
357 values, trophic niche differentiation among species was most pronounced in rainforest,  
358 presumably due to the availability of a wider spectrum of food resources and more stable  
359 environmental conditions than in plantations. This is likely to result in more efficient food-web  
360 functioning in natural ecosystems due to species complementarity (Loreau and Hector 2001),  
361 which is partly lost in plantation systems.

362

### 363 *Variations in isotopic niches of Collembola taxa and life forms with land-use systems*

364 Collembola taxa such as Symphypleona and Paronellidae typically had low  $\Delta^{15}\text{N}$  values,  
365 indicating that these taxa feed on algae or lichens (Chahartaghi *et al.*, 2005; Potapov *et al.*, 2018).  
366 Symphypleona as well as Paronellidae are well adapted to aboveground live, both are large-sized  
367 and possess well-developed visual systems. Such 'atmobiotic' Collembola have been assumed to  
368 live at least in part as herbivores on vascular plants or algae (Rusek, 2007). This suggestion is in  
369 line with studies from temperate forests investigating variations in stable isotope ratios in  
370 Symphypleona (Chahartaghi *et al.*, 2005; Potapov *et al.*, 2016). Paronellidae predominantly occur  
371 in tropical regions also living above the ground suggesting that the microhabitat they live in

372 defines feeding preferences of Collembola across different phylogenetic lineages (see life form  
373 discussion below). Entomobryidae and Isotomidae occupied high trophic positions and this also  
374 is consistent with earlier studies based on variations in stable isotope ratios suggesting that they  
375 predominantly feed on microorganisms colonizing decomposing litter materials (Chahartaghi *et*  
376 *al.*, 2005; Potapov *et al.*, 2016). Some species of these two families occupied very high trophic  
377 positions resembling those of Onychiuridae and Neanuridae in temperate ecosystems suggesting  
378 that at least in part they live as predators or scavengers, presumably including nematodes as prey  
379 (Heidemann *et al.*, 2014). Since Onychiuridae and Neanuridae were rare at our study sites,  
380 species from other families might have been able to occupy their trophic niches.

381       Trophic niches of Collembola in our study varied with life form as shown previously for  
382 temperate ecosystems (Ponge, 2000; Potapov *et al.*, 2016). Conform to the patterns in  
383 Collembola families, the results suggest that atmobiotic and epedaphic species occupied the  
384 lowest trophic position across land-use systems, whereas euedaphic species such as  
385 *Pseudosinella* sp.1 occupied the highest trophic position. This is in line with the results of the  
386 study of Potapov *et al.* (2016) indicating that species inhabiting deeper soil layers (hemiedaphic  
387 and euedaphic) are more enriched in  $^{15}\text{N}$  than those living in litter and above the ground  
388 (epedaphic and atmobiotic). High  $\delta^{15}\text{N}$  values may result from feeding on ectomycorrhizal fungi  
389 which are enriched in  $^{15}\text{N}$  (see above; Hobbie *et al.*, 2001; Potapov and Tiunov, 2016), however,  
390 this unlikely applies to tropical forests where trees predominantly form mutualistic interactions  
391 with arbuscular mycorrhizal fungi. We attributed low  $\delta^{15}\text{N}$  values in epedaphic and atmobiotic  
392 Collembola to algae or lichen feeding, which is widespread in Collembola in temperate forests  
393 (Potapov *et al.*, 2018), but in our study only few species had  $\delta^{15}\text{N}$  values below those of litter.

394 This contradicts results based on fatty acid analysis suggesting that Collembola feed more on  
395 algae in tropical than in temperate ecosystems (Susanti *et al.*, 2019). To clarify the contribution  
396 of algae in soil food webs in tropical and temperate ecosystems, more data on stable isotope  
397 composition of various food resources in tropical forests, or direct experimentation, are needed.  
398 Differences between life forms were more pronounced in rainforest and jungle rubber and less  
399 in plantation systems, which may reflect the more pronounced litter layer in the former than the  
400 latter (Krashevskaya *et al.* 2015). Overall, the results suggest that similar to oribatid mites (Tsurikov  
401 *et al.*, 2019) the trophic niche structure in Collembola communities in temperate and tropical  
402 forests is generally similar and this is partly explained by taxonomic affiliation and life form.

403

#### 404 **Conclusion**

405 We showed that the conversion of rainforest into agricultural plantations, such as rubber and oil  
406 palm, is associated with changes in trophic niches of Collembola. The use of food resources  
407 shifted towards herbivory, with the range of food resources of Collembola in oil palm plantations  
408 being the highest, likely due to the heterogeneity in management. By contrast, the range of  
409 trophic positions in oil palm plantations was low suggesting that the trophic structure is simplified  
410 lacking high but also low trophic levels. This is further supported by the less pronounced trophic  
411 niche differentiation among species in monoculture plantations. Similar to the pattern in oribatid  
412 mites (Tsurikov *et al.*, 2019), the structure of trophic niches in tropical Collembola communities  
413 resembled that in temperate forests. Life form and family identity explained about half of the  
414 species-level variation; atmobiotic species occupied the lowest and eudaphic species occupied

415 the highest trophic position, but the difference was less pronounced in plantations. Overall, the  
416 results document that changes in community composition associated with the conversion of  
417 rainforest into plantation systems are followed by shifts in the trophic structure and trophic  
418 niches in Collembola communities, potentially compromising ecosystem functions and food-web  
419 stability in plantations.

# Figure 1

Variations in  $\Delta^{13}\text{C}$  and  $\Delta^{15}\text{N}$  values of Collembola among the studied land-use systems (rainforest, jungle rubber, rubber and oil palm plantations)

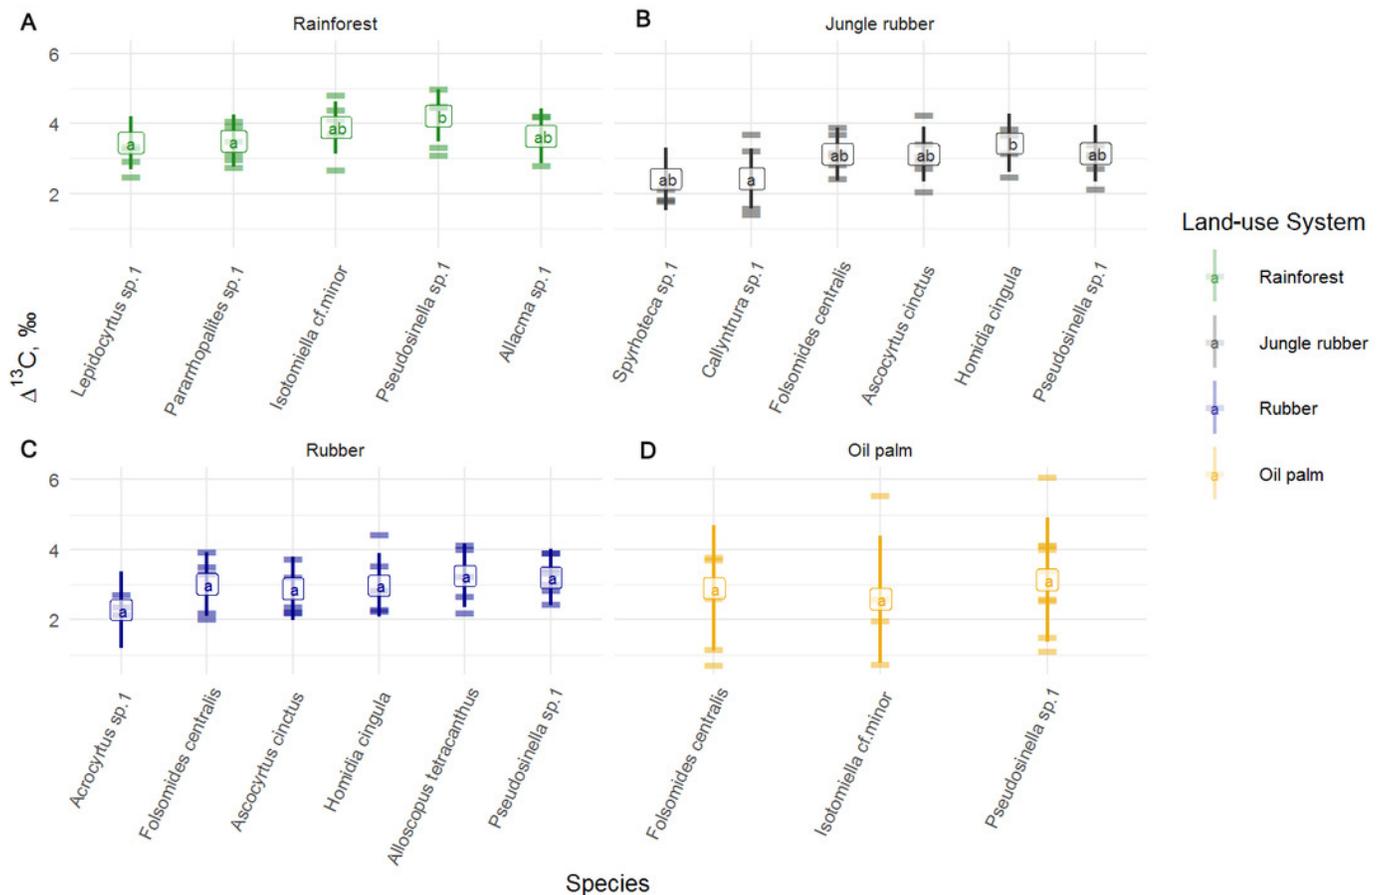

Variations in  $\Delta^{13}\text{C}$  and  $\Delta^{15}\text{N}$  values of Collembola among the studied land-use systems: (A) rainforest, (B) jungle rubber, (C) rubber and (D) oil palm plantations. Violin plots show frequency distribution of values (mirrored Kernel density estimation), all individual measurements are displayed together independent of taxonomic identity. \*Average  $\Delta^{13}\text{C}$  values in rainforest were significantly higher than in the other three land-use systems ( $P < 0.05$ )

## Figure 2

$\Delta^{13}\text{C}$  values of Collembola species in different land-use systems (rainforest, jungle rubber, rubber and oil palm plantations)

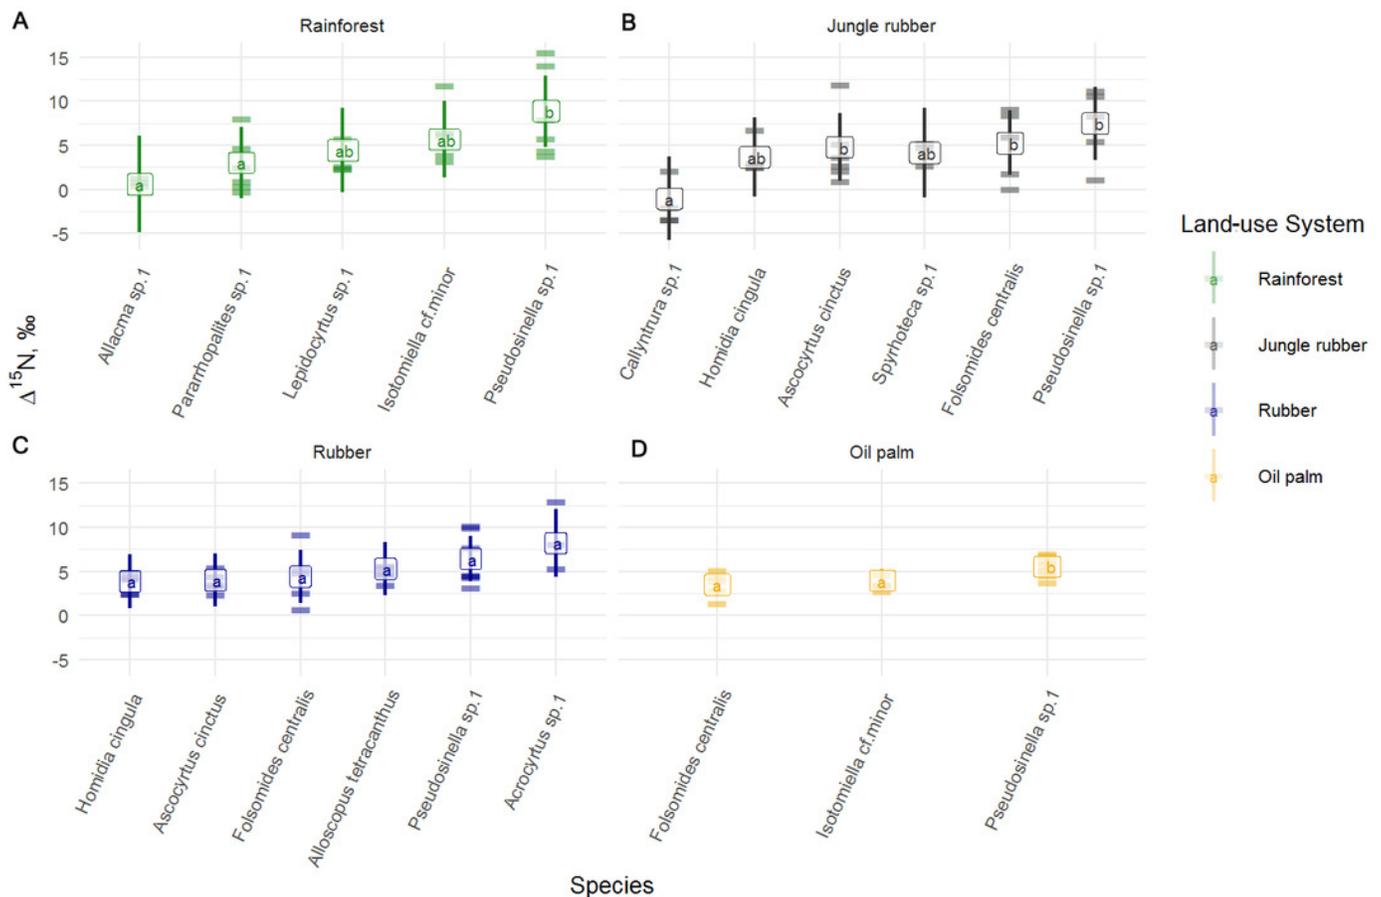

$\Delta^{13}\text{C}$  values of Collembola species in different land-use systems: (A) rainforest, (B) jungle rubber, (C) rubber and (D) oil palm plantations; model-estimated means (Ismeans) with standard deviation. Horizontal stripes represent individual measurements. Only species with more than three replicates per land-use system were analyzed (see Methods). Isotope values of each species in each land-use system with the same letter are not significantly different according to Tukey's honestly significant difference test ( $p > 0.05$ )

## Figure 3

Differences of  $\Delta^{15}\text{N}$  values of Collembola in different land-use systems (rainforest, jungle rubber, rubber and oil palm plantations)

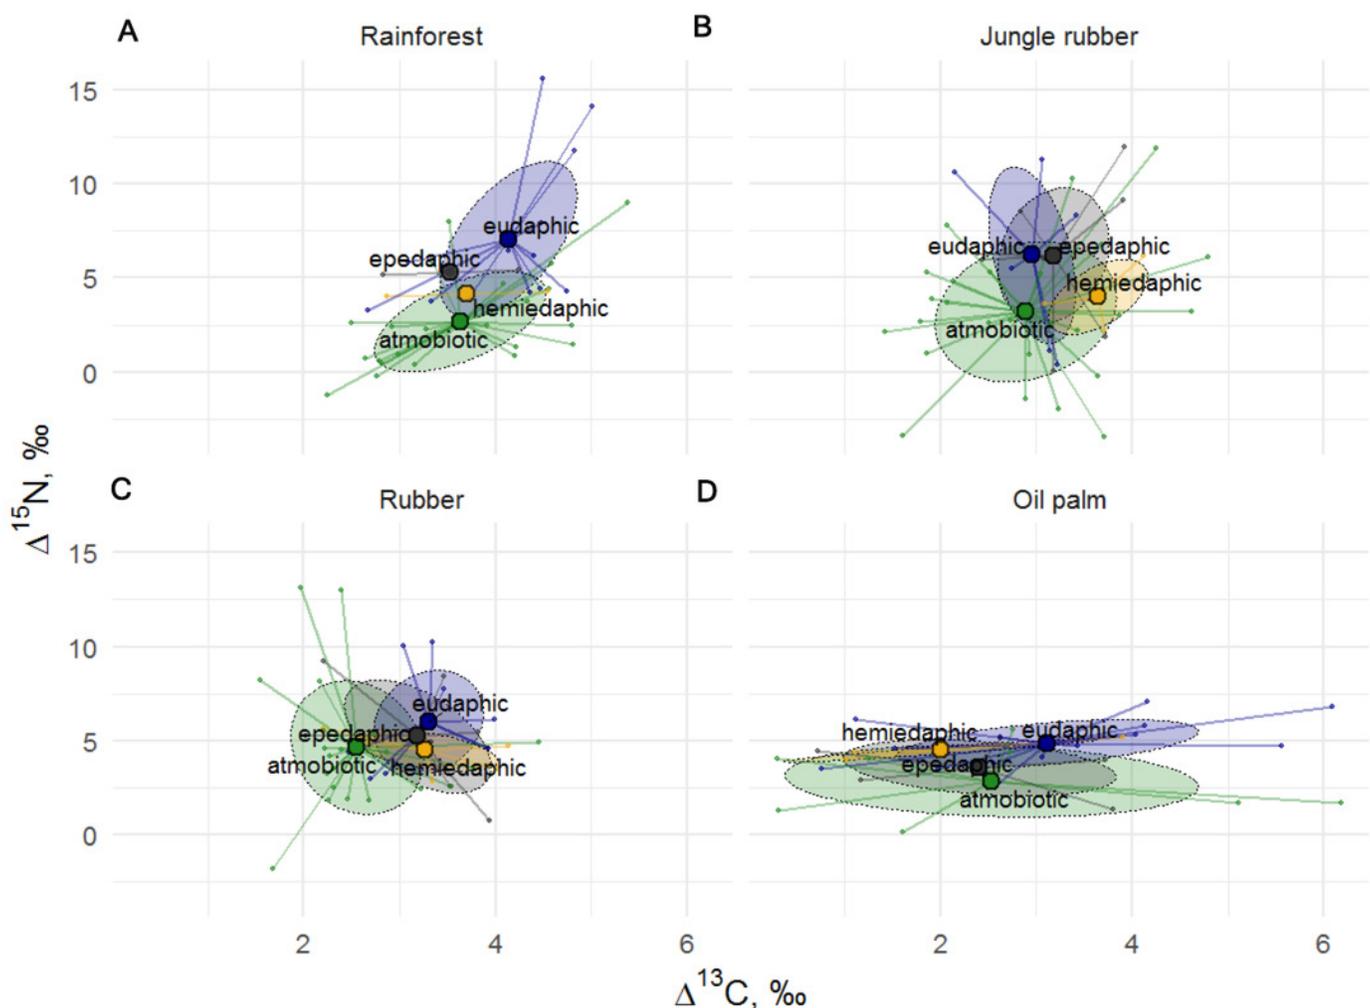

Differences of  $\Delta^{15}\text{N}$  values of Collembola in different land-use systems: (A) rainforest, (B) jungle rubber, (C) rubber and (D) oil palm plantation; model-estimated means (Ismeans) with standard deviation. Horizontal stripes represent individual measurements. Only species with more than three replicates per land-use system were analyzed (see Methods). Isotope values of each species in each land-use system with the same letter are not significantly different according to Tukey's honestly significant difference test ( $p > 0.05$ )

## Figure 4

Stable isotope niches of four Collembola life forms in rainforest, jungle rubber, rubber, and oil palm plantations

Stable isotope niches of four Collembola life forms in (A) rainforest, (B) jungle rubber, (C) rubber, and (D) oil palm plantations. Ellipses denote 60% confidence intervals, different life forms are shown in color (eudaphic = blue, epedaphic = grey, hemiedaphic = yellow, atmobiotic = green). Large colored dots represent means of land-use systems, small points represent individual measurements

## Figure 5

Stable isotope niche of Collembola families in rainforest, jungle rubber, rubber, and oil palm plantations

Stable isotope niche of Collembola families in (A) rainforest, (B) jungle rubber, (C) rubber, and (D) oil palm plantations. Ellipses denote 60% intervals, different families are shown in color (Paronellidae = blue, Isotomidae = green, Symphypleona = purple, Entomobryidae = red; Symphypleona comprises the families Sminthuridae, Sminthurididae, Dycirtomidae and Katiannidae). Large colored dots represent means of land-use systems, small points represent individual measurements
