Intensively managed monoculture plantations are increasingly replacing natural forests across the tropics resulting in changes in ecological niches of species and communities, and in ecosystem functioning. Collembola are among the most abundant arthropods inhabiting the belowground system sensitively responding to changes in vegetation and soil conditions. However, most studies on the response of Collembola to land-use change were conducted in temperate ecosystems and focused on shifts in community composition or morphological traits, while parameters more closely linked to ecosystem functioning, such as trophic niches, received little attention. Here, we used stable isotope analysis ( $^{13}\text{C}$  and  $^{15}\text{N}$ ) to investigate changes in the trophic structure and use of food resources by Collembola in Jambi province (Sumatra, Indonesia), a region that experienced strong deforestation in the last decades. Isotopic values of Collembola from 32 sites representing four land-use systems were analyzed (rainforest, rubber agroforest, rubber (*Hevea brasiliensis*) and oil palm (*Elaeis guineensis*) monoculture plantations). Across Collembola species  $\Delta^{13}\text{C}$  values were highest in rainforest suggesting more pronounced processing of litter resources by microorganisms and consumption of these microorganisms by Collembola in this system. Lower  $\Delta^{13}\text{C}$  values, but high  $\Delta^{13}\text{C}$  variation in Collembola in oil palm plantations indicated that Collembola shifted towards herbivory and used more variable resources in this system. Small range in  $\Delta^{15}\text{N}$  values in Collembola species in monoculture plantations in comparison to rainforest indicated that conversion of rainforest into plantations is associated with simplification in the trophic structure of Collembola communities. This was further confirmed by generally lower isotopic niche differentiation among species in plantations. Across the studied ecosystems, atmobiotic species

(Symphypleona and Paronellidae) occupied the lowest, whereas euedaphic Collembola species occupied the highest trophic position, resembling patterns in temperate forests. Some species of Paronellidae in rainforest and jungle rubber had  $\Delta^{15}\text{N}$  values below those of leaf litter suggesting algivory (*Salina* sp.1, *Callyntrura* sp.1 and *Lepidonella* sp.1), while a dominant species, *Pseudosinella* sp.1, had the highest  $\Delta^{15}\text{N}$  values in most of the land-use systems suggesting that this species at least in part lives as predator or scavenger. Overall, the results suggest that rainforest conversion into plantation systems is associated with marked shifts in the structure of trophic niches in soil and litter Collembola with potential consequences for ecosystem functioning and food-web stability.

### ABSTRACT

18 Intensively managed monoculture plantations are increasingly replacing natural forests across  
19 the tropics resulting in changes in ecological niches of species and communities, and in ecosystem  
20 functioning. Collembola are among the most abundant arthropods inhabiting the belowground  
21 system sensitively responding to changes in vegetation and soil conditions. However, most  
22 studies on the response of Collembola to land-use change were conducted in temperate  
23 ecosystems and focused on shifts in community composition or morphological traits, while  
24 parameters more closely linked to ecosystem functioning, such as trophic niches, received little  
25 attention. Here, we used stable isotope analysis (<sup>13</sup>C and <sup>15</sup>N) to investigate changes in the trophic  
26 structure and use of food resources by Collembola in Jambi province (Sumatra, Indonesia), a  
27 region that experienced strong deforestation in the last decades. Isotopic values of Collembola

28 from 32 sites representing four land-use systems were analyzed (rainforest, rubber agroforest,  
29 rubber (*Hevea brasiliensis*) and oil palm (*Elaeis guineensis*) monoculture plantations). Across  
30 Collembola species  $\Delta^{13}\text{C}$  values were highest in rainforest suggesting more pronounced  
31 processing of litter resources by microorganisms and consumption of these microorganisms by  
32 Collembola in this system. Lower  $\Delta^{13}\text{C}$  values, but high  $\Delta^{13}\text{C}$  variation in Collembola in oil palm  
33 plantations indicated that Collembola shifted towards herbivory and used more variable  
34 resources in this system. Small range in  $\Delta^{15}\text{N}$  values in Collembola species in monoculture  
35 plantations in comparison to rainforest indicated that conversion of rainforest into plantations is  
36 associated with simplification in the trophic structure of Collembola communities. This was  
37 further confirmed by generally lower isotopic niche differentiation among species in plantations.  
38 Across the studied ecosystems, atmobiotic species (*Symphyleona* and *Paronellidae*) occupied  
39 the lowest, whereas euedaphic Collembola species occupied the highest trophic position,  
40 resembling patterns in temperate forests. Some species of *Paronellidae* in rainforest and jungle  
41 rubber had  $\Delta^{15}\text{N}$  values below those of leaf litter suggesting algivory (*Salina* sp.1, *Callyntrura* sp.1  
42 and *Lepidonella* sp.1), while a dominant species, *Pseudosinella* sp.1, had the highest  $\Delta^{15}\text{N}$  values  
43 in most of the land-use systems suggesting that this species at least in part lives as predator or  
44 scavenger. Overall, the results suggest that rainforest conversion into plantation systems is  
45 associated with marked shifts in the structure of trophic niches in soil and litter Collembola with  
46 potential consequences for ecosystem functioning and food-web stability.

## 51 Introduction

52 Agricultural intensification in Indonesia is associated with deforestation which increased  
53 strongly in the last 30 years (Koh & Ghazoul, 2010 ; Gatto *et al.*, 2015). Large parts of rainforest  
54 in lowland Sumatra (Indonesia) have been converted into oil palm (*Elaeis guineensis*) (16% of  
55 total area) and rubber plantations (*Hevea brasiliensis*) (12%) (Gatto *et al.*, 2015). These processes  
56 are driven by the high global demand for agricultural products, and positively affect income and  
57 employment of local smallholders (Grass *et al.*, 2020; Qaim *et al.*, 2020). At the same time,  
58 conversion of tropical rainforest into plantation systems is associated with major changes in  
59 ecological niches of animal species, loss of biodiversity, and thereby with changes in ecosystem  
60 functioning (Barnes *et al.*, 2014; Clough *et al.*, 2016; Fitzherbert *et al.*, 2008; Gilbert, 2012). These  
61 changes affect both the above- and belowground system. Complex and diverse microbial and  
62 animal communities in soil regulate important ecosystem functions and support aboveground  
63 life (Bardgett & Van Der Putten, 2014), but knowledge on effects of land-use change on soil life  
64 in the tropics is very limited.

65 Studies from Sumatra showed that conversion of rainforest into oil palm and rubber  
66 plantations is associated with a decline in species diversity, population density, biomass and  
67 energy flux in litter macroinvertebrate communities by approximately 45% (Drescher *et al.*, 2016;  
68 Grass *et al.*, 2020). Uneven decline in energy flux across size classes and trophic levels was  
69 documented for meso- and macrofauna soil communities leading to strong alterations in soil  
70 food-web structure (Potapov *et al.*, 2019). Different basal resources available in different land-  
71 use systems result in changes in trophic niches of decomposer and predatory soil invertebrates,  
72 and results in reduced abundance of primary decomposers and in soil animals shifting their

73 feeding habits towards herbivory (Klarner *et al.*, 2017; Krause *et al.*, 2019; Susanti *et al.*, 2019).  
74 Land-use change may also result in reduced trophic niche differentiation among species in  
75 belowground communities (Korotkevich *et al.*, 2018), but this has not been investigated in  
76 tropical ecosystems.

77         Collembola are among the most abundant soil decomposer invertebrates, inhabiting  
78 various organic substrates and using a wide range of food resources (Rusek, 1998). Early studies  
79 on food resources of Collembola concluded that the majority of euedaphic and hemiedaphic  
80 species feed unselectively on a wide variety of food materials (Hopkin, 1997). However, stable  
81 isotope analysis showed pronounced trophic niche differentiation among Collembola species in  
82 temperate forests (Chahartagi *et al.*, 2005). This differentiation in large has been explained by  
83 the taxonomic identity and life forms of Collembola (Potapov *et al.*, 2016). Species, living  
84 aboveground and on the litter surface (atmobiote and epedaphic life forms) are mainly  
85 phycophages, feeding on lichens, algae and pollen. Species, living in the litter (hemiedaphic life  
86 form) are detritivores feeding on saprotrophic microorganisms and litter. Species, living in soil  
87 (euedaphic life form) feed on soil organic matter, roots and fungi (Ponge, 2000; Potapov *et al.*,  
88 2016). Further, food resources and trophic levels also vary among high-rank taxa with e.g.,  
89 Poduromorpha occupying higher trophic positions than Entomobryomorpha and Symphypleona,  
90 suggesting evolutionary selection for microbivory in the former (Potapov *et al.*, 2016). Since  
91 lowland tropical forest ecosystems often have a less pronounced organic layer and different plant  
92 and animal community composition than temperate forest ecosystems (Petersen and Luxton,  
93 1982), they provide different ecological niches for Collembola, potentially resulting in a different  
94 trophic structure of communities. To date, information on food resources and trophic niches of

95 Collembola is based on studies from temperate ecosystems, whereas information from tropical  
96 ecosystems is virtually lacking entirely.

97 Over the last two decades, stable isotope analysis has become the most commonly used  
98 tool to assess trophic niches of soil animals (Potapov *et al.*, 2019). Two isotopic ratios,  $^{13}\text{C}/^{12}\text{C}$   
99 (i.e.,  $\delta^{13}\text{C}$  values) and  $^{15}\text{N}/^{14}\text{N}$  (i.e.,  $\delta^{15}\text{N}$  values), typically are used in food-web studies. Trophic  
100 positions and length of trophic chains can be assessed using  $\delta^{15}\text{N}$  values, whereas the range of  
101  $\delta^{13}\text{C}$  values reflects variability in the use of basal resources (Potapov *et al.*, 2019). Stable isotope  
102 composition of consumers follows that in food resources, thus allowing to reveal potential diet  
103 switching with land-use change (Klarner *et al.*, 2017; Krause *et al.*, 2019; Susanti *et al.*, 2019).

104 Here, we use stable isotope analysis to investigate trophic positions and food resources  
105 of soil and litter Collembola in four different land-use systems in Sumatra, Indonesia: rainforest,  
106 rubber agroforest ('jungle rubber'), and monoculture rubber and oil palm plantations. The study  
107 aimed at investigating how trophic positions and food resources of Collembola change after  
108 rainforest conversion into agricultural plantations, such as rubber and oil palm, and, for the first  
109 time, at exploring patterns in trophic niche differentiation among tropical Collembola species. In  
110 more detail we investigated the following hypotheses:

- 111 1) Analogous to other soil invertebrates, Collembola shift their trophic niches towards  
112 herbivory in plantation systems in comparison to rainforest.
- 113 2) Due to reduced food resources (poor litter layer), the trophic niche width of  
114 Collembola is narrower in plantations in comparison to rainforest.
- 115 3) Trophic niche differentiation among Collembola species is more pronounced in  
116 rainforest than in plantation systems.

117 4) Trophic niche differentiation among families and life forms of Collembola in tropical  
118 ecosystems follows similar patterns as in ecosystems of the temperate zone.

119

## 120 **Material and Methods**

### 121 **Site description**

122 Four land-use systems were investigated: lowland rainforest, jungle rubber, rubber and  
123 oil palm plantations, located in Jambi province, southwest Sumatra, Indonesia. The study sites  
124 were located at a similar altitude varying between 50 and 100 m a.s.l. in two landscapes, the  
125 Harapan and Bukit Dua Belas landscape; each land-use system was replicated four times per  
126 landscape, resulting in a total of 32 sites (for more details see Drescher *et al.*, 2016). Lowland  
127 rainforest was used as reference, but represents secondary rainforest, which has been logged  
128 once by taking out large trees some 30 years ago. Jungle rubber represents a rubber agroforest  
129 system originating from rainforest enriched with rubber trees; the age of rubber trees varied  
130 between 15-40 years (Kotowska, Leuschner, Triadiati, Meriem, & Hertel, 2015). Rubber and oil  
131 palm plantations were intensively managed monocultures of an average age of 7 to 16 and 8 to  
132 15 years, respectively (Drescher *et al.*, 2016), and were established after logging, clearing, and  
133 burning of either rainforest or jungle rubber. Soils at the Harapan landscape are loam Acrisols of  
134 low fertility, whereas in Bukit Dua Belas the major soil type is clay Acrisol (Allen *et al.*, 2015;  
135 Kotowska *et al.*, 2015). Management practices in these smallholder monoculture plantations are  
136 described in more detail in Allen *et al.* (2015). Oil palm plantations typically were fertilized once  
137 in the rainy season and once in the dry season. Typically, 300-500 kg NPK complete fertilizer, 300  
138 kg KCl and 138 kg urea ( $\text{CO}(\text{NH}_2)_2$ ) were added per hectare and year. Rubber and oil palm

139 plantations were weeded manually or chemically throughout the year. The most commonly used  
140 herbicides were paraquat and glyphosate; these were applied at an average rate of 2 to 5 L ha<sup>-1</sup>  
141 y<sup>-1</sup> (Allen *et al.*, 2015; Clough *et al.*, 2016; Kotowska *et al.*, 2015).

142

### 143 **Sampling procedure**

144 Samples were taken in October 2013 in three 5 x 5 m subplots within 50 x 50 m plots  
145 established at each study site (Drescher *et al.*, 2016). In each subplot soil samples of 16 x 16 cm  
146 were taken including the litter layer and the underlying top soil to a depth of 5 cm. Animals from  
147 both layers were pooled for stable isotope analysis to obtain sufficient amount of animal tissue  
148 for the analyses. Animals were extracted by heat (Kempson *et al.*, 1963) until the substrate was  
149 completely dry (6-8 days) using glycerol : water mixture at a ratio of 1 : 1 as collection solution.  
150 Field collection was conducted under the research permit No. 389/SIP/FRP/SM/X/2013 issued by  
151 the State Ministry of Research and Technology of Indonesia (RISTEK) with collection permit No.  
152 S.07/KKH-2/2013 issued by the Ministry of Forestry (PHKA) and support from the following  
153 persons and organizations who granting us to access and use their properties: village leaders,  
154 local plot owners, PT Humusindo, PT Perkebunan Nusantara VI, Harapan Rainforest, and Bukit  
155 Duabelas National Park.

156

### 157 **Species identification**

158 Collembola were sorted in Petri dishes using a dissecting microscope. For species-level  
159 identification, selected individuals were subsequently cleared in Nesbitt solution and mounted  
160 on slides with Hoyer solution. Collembola were identified under a compound light microscope at  
161 400× magnification. The checklist and keys for Indonesian Collembola by Suhardjono *et al.* (2012)  
162 were used along with publications on Southeast Asian Collembola. Due to a relatively poorly  
163 described fauna, in many cases we had to assign individuals to morphospecies without Linnaean  
164 names (in total 72% of all identified species); for simplicity, we refer to both as ‘species’. When  
165 possible, juvenile specimens were ascribed to species of adults or subadults present in the same  
166 sample or in samples from the same plot. After identification, all data on Collembola species and  
167 their identification characters were uploaded to Ecotaxonomy database  
168 (<http://ecotaxonomy.org>). In total 56 species from 13 families and 27 genera were found.

169

#### 170 **Bulk stable isotope analyses**

171 Stable isotope ratios were- measured from dominant species representing at least 70% of the  
172 individuals on each plot (Supplementary Table S1 ). A number of rare species were observed only  
173 on few sites and such data would be not suitable for a proper analysis of the species and land-  
174 use effects and also for analytical facilities in the laboratory. Dominant species were chosen for  
175 each plot separately to represent the local ‘functional community’. This selection procedure  
176 resulted in a total of 30 out of 56 species being included in the analysis across all land-use  
177 systems. For stable isotope measurements appropriate amounts of animal tissue (ranging from  
178 0.003 to 1.268 mg) were transferred into tin capsules and dried at 60°C for 24 h, weighed and  
179 stored in a desiccator until analysis. Stable isotope ratios, and total C and N concentration were

180 determined using a coupled system consisting of an elemental analyzer (Eurovector, Milano,  
181 Italy) equipped with a Blisotec autosampler (Blisotec, Jülich, Germany) and a Thermo Delta Vplus  
182 isotope ratio mass spectrometer connected via a ConFlo IV interface (both from Thermo Fisher  
183 Scientific, Bremen, Germany) located at the Centre for Stable Isotope Research and Analysis,  
184 Göttingen, Germany (Langel & Dyckmans, 2014). Isotope signatures were expressed using the  $\delta$   
185 notation as  $\delta X(\text{‰}) = (R_{\text{sample}} - R_{\text{standard}}) / R_{\text{standard}}$ , with X representing the target isotope and R the  
186 ratio of heavy to light isotope ( $^{13}\text{C}/^{12}\text{C}$  or  $^{15}\text{N}/^{14}\text{N}$ ). For  $\delta^{15}\text{N}$  and  $\delta^{13}\text{C}$  analyses, N in atmospheric  
187 air and Vienna Pee Dee Belemnite served as standards, respectively. We use IAEA CH6 (-10.43‰,  
188 Sucrose) and IAEA 600 (-27.7‰, Caffein) as C standards, and IAEA N1 (0.4‰) and IAEA N2  
189 (20.3‰) for N (both are Ammonium sulfates) for internal calibration.

190

191

## 192 **Statistical analysis**

193 To compensate for inter-site variation in the isotopic baseline, prior to the analysis all data were  
194 normalized to the local leaf litter using the following equations (Potapov *et al.*, 2019):

$$195 \quad \Delta^{13}\text{C} = \delta^{13}\text{C}_{\text{Collembola}} - \delta^{13}\text{C}_{\text{litter}}$$

$$196 \quad \Delta^{15}\text{N} = \delta^{15}\text{N}_{\text{Collembola}} - \delta^{15}\text{N}_{\text{litter}}$$

197 Stable isotope values of litter were taken from Klarner *et al.* (2017) who investigated the same  
198 sampling sites.

199 Statistical analyses were performed using R v 3.5.2 (R Core Team, 2018) with R studio  
200 interface (R Studio, Inc.). First, we analyzed the effect of land-use system on the isotopic  
201 composition of Collembola at the community level. Effects of land-use system on the  $\Delta^{13}\text{C}$  and

202  $\Delta^{15}\text{N}$  values of all measured Collembola individuals were tested using Linear Mixed Effect Models  
203 (LMM) with species identity as random effect. Species identity was coded as random effect for  
204 the following reasons: (1) In this first analysis we were not interested in variations in  $\Delta^{13}\text{C}$  and  
205  $\Delta^{15}\text{N}$  values among species but still wanted to account for it, (2) species presence was uneven  
206 across plots and land-use systems preventing the analysis of land-use effects, and (3) including  
207 species as fixed factor would have compromised the analysis of land-use effects on  $\Delta^{13}\text{C}$  and  $\Delta^{15}\text{N}$   
208 values of Collembola by reducing error degrees of freedom. The analysis was conducted using  
209 the *lmer* function in the *lme4* package (Bates *et al.*, 2015). Significance of fixed effects (factors)  
210 was tested using the *Anova* function in the *car* package. Significant differences in stable isotope  
211 values between land-use systems were tested using the *tukey test* in the *emmeans* and  
212 *multcomp* packages. We also analyzed the effect of land use only for one dominant species,  
213 present in sufficient replicates in each land-use system (*Pseudosinella* sp.1) using analysis of  
214 variance implemented in the *aov* function. Additionally, the ranges in  $\Delta^{13}\text{C}$  and  $\Delta^{15}\text{N}$  values in  
215 each land-use system were calculated as difference between minimum and maximum values and  
216 visualized using the Kernel density estimation in the *ggplot 2* package using the *geom\_violin*  
217 function.

218         Second, we assessed trophic niche differentiation among species by assessing the effect  
219 of species identity on stable isotope composition of Collembola with LMM. We used species  
220 identity as factor and either  $\Delta^{13}\text{C}$  or  $\Delta^{15}\text{N}$  values as response variables; sampling plot was included  
221 as random effect to account for site-specific differences in trophic niches. The analysis was done  
222 separately for each land-use system (eight analyses in total). Only species allowing more than  
223 three measurements per land-use system were included.

224 Third, we analyzed the effects of family identity and life form on stable isotope  
225 composition of Collembola using LMM. Here, we used both plot and land-use system as random  
226 effects. Significant differences between families and life forms were tested using Tukey contrasts  
227 as implemented in the *glth* function in the *multicomp* package. To display the isotopic niche space  
228 of Collembola species, family, and lifeform, ellipses denoting 60% intervals were plotted using  
229 the *standard.ellipse* function in the *siar* package, and visualized using the *ggplot* and *ggrepel*  
230 packages. We also analyzed interactions between land-use system and life form and between  
231 land-use system and family with plot as random effect. In the analyses, we excluded Neanuridae  
232 and Onychiuridae as they were only represented by a single species not present in each of the  
233 land-use systems. In addition, we also analyzed R square values between species, family, and  
234 lifeform to identify the most important factor. Here, we used plot as random effect The analysis  
235 was done using the *r.squaredGLMM* function in the *lme4* and *MuMin* packages.

236

## 237 Results

### 238 *Community-level changes with land use*

239 In rainforest  $\Delta^{13}\text{C}$  values of Collembola ranged between 1.5 and 6.0‰ (total range 4.5‰),  
240 and in oil palm plantations between -1.5 and 8.5‰ (10.0‰), indicating a wider range of  $\Delta^{13}\text{C}$   
241 values in food resources in the latter. In jungle rubber and rubber plantations, the range of  $\Delta^{13}\text{C}$   
242 values was similar to rainforest (between 1.0 and 6.0 ‰). Mean  $\Delta^{13}\text{C}$  values in rainforest were  
243 significantly higher than in plantation systems ( $F_{3,146} = 9.90$ ,  $p = 0.001$ ; Fig. 1A, Supplementary  
244 Material Tables S2, S3). All  $\delta^{13}\text{C}$  values of Collembola species exceeded those of leaf litter except

245 for one individual of *Isotomiella* cf. *minor* in oil palm plantations (Fig. 2; for details see  
246 Supplementary Material Tables S6-S9).

247 In contrast to  $\Delta^{13}\text{C}$ , the range of  $\Delta^{15}\text{N}$  values was largest in rainforest (-5.0 to 19.0‰),  
248 lowest in oil palm plantations (-1.0 to 8.0‰), and intermediate in rubber plantations (-5.0 to  
249 15.0‰) and in jungle rubber (-7.5 to 16.0‰). Mean  $\Delta^{15}\text{N}$  values of Collembola did not vary  
250 significantly among land-use systems ( $F_{3,153} = 1.46$ ,  $p = 0.228$ ; Fig. 1B, Supplementary Material  
251 Tables S4, S5). Stable isotope values of the most abundant Collembola species present in all land-  
252 use systems, *Pseudosinella* sp.1, did not vary significantly among land-use systems both in  $\Delta^{13}\text{C}$   
253 ( $F_{3,21} = 1.44$ ,  $p = 0.260$ ) and  $\Delta^{15}\text{N}$  ( $F_{3,21} = 0.88$ ,  $p = 0.467$ ).

254

#### 255 *Niche differentiation among species*

256  $\Delta^{13}\text{C}$  values across abundant species (represented by at least three measurements, see  
257 Methods) varied significantly in rainforest ( $F_{4,12} = 6.34$ ,  $p = 0.005$ ) and jungle rubber ( $F_{5,17} = 3.67$ ,  
258  $p = 0.020$ ), but not in rubber ( $F_{5,19} = 1.39$ ,  $p = 0.270$ ) and oil palm plantations ( $F_{2,9} = 1.10$ ,  $p =$   
259  $0.370$ ). In rainforest,  $\Delta^{13}\text{C}$  values of *Pseudosinella* sp.1 were highest and differed significantly  
260 from those of *Lepidocyrtus* sp.1 and *Pararrhopalites* sp.1, whereas in jungle rubber they were  
261 highest in *Homidia cingula* and differed significantly from *Callyntrura* sp.1.

262  $\Delta^{15}\text{N}$  values across abundant species varied significantly in rainforest ( $F_{4,14} = 5.00$ ,  $p =$   
263  $0.010$ ), jungle rubber ( $F_{5,18} = 4.70$ ,  $p = 0.006$ ) and oil palm plantations ( $F_{2,9} = 23.59$ ,  $p = 0.001$ ), but  
264 not in rubber plantations ( $F_{5,19} = 2.43$ ,  $p = 0.072$ ) (Fig. 3; for details see Supplementary Material  
265 Tables S10-S13). In rainforest *Pseudosinella* sp.1 occupied the highest trophic position, followed

266 by *Isotomiella* cf. *minor*, whereas *Allacma* sp.1 occupied the lowest trophic position. Similar to  
267 rainforest, in jungle rubber *Pseudosinella* sp.1 also occupied the highest trophic position, but  
268  $\Delta^{15}\text{N}$  values were lowest in *Callyntrura* sp.1. Overall, *Pseudosinella* sp.1, the most dominant  
269 species, occupied the highest trophic position across all species. Across all samples analyzed (20  
270 species in rainforest, 17 species jungle rubber, 15 species in rubber plantations, and 13 species  
271 in oil palm plantations) 3% of the measurements had  $\Delta^{15}\text{N}$  values below that of litter (see  
272 Supplementary Material, Fig. 1).

273

#### 274 *Differences among Collembola life forms and families*

275 The  $\Delta^{15}\text{N}$  values of Collembola varied among life forms ( $F_{24,126} = 1.82$ ,  $p = 0.018$ ), but this was not  
276 the case for  $\Delta^{13}\text{C}$  values ( $F_{24,126} = 1.19$ ,  $p = 0.260$ ), with the interaction between lifeform and land-  
277 use system neither being significant for  $\Delta^{15}\text{N}$  ( $F_{9,132} = 0.87$ ,  $p = 0.556$ ) nor for  $\Delta^{13}\text{C}$  ( $F_{9,135} = 0.79$ ,  
278  $p = 0.619$ ). Differences between life forms were more pronounced in rainforest and jungle rubber  
279 and less in rubber and oil palm plantations (Fig. 4). Euedaphic species were generally most  
280 enriched in  $^{15}\text{N}$ , whereas atmobiotic species on average occupied the lowest trophic position  
281 (except in rubber plantations), often having  $\Delta^{15}\text{N}$  values below 5.0‰, with epedaphic and  
282 hemiedaphic species being intermediate.

283 Similar to results of the life form analysis, the  $\Delta^{15}\text{N}$  ( $F_{24,129} = 2.19$ ,  $p = 0.002$ ) but not  $\Delta^{13}\text{C}$   
284 values ( $F_{24,128} = 1.01$ ,  $p = 0.470$ ) of Collembola varied significantly among families (Fig. 5), with the  
285 interaction between family and land-use system neither being significant for  $\Delta^{15}\text{N}$  ( $F_{8,122} = 0.34$ ,  
286  $p = 0.945$ ) nor for  $\Delta^{13}\text{C}$  ( $F_{8,121} = 1.84$ ,  $p = 0.075$ ). Isotomidae and Entomobryidae occupied the  
287 highest trophic positions across land-use systems, Symphypleona occupied the lowest trophic

288 position in rainforest and oil palm plantations, whereas in jungle rubber and rubber plantations  
289 the lowest trophic position was occupied by Paronellidae. Family and lifeform identity explained  
290 approximately two times less variation in  $\Delta^{15}\text{N}$  values than species identity with  $R^2 = 0.29$  in  
291 models based on species, and  $R^2 = 0.13$  in both models based on families and life forms.

292

## 293 **Discussion**

### 294 *Variations in trophic niches with land-use system*

295 Results of our study indicate that rainforest conversion into agricultural plantations is  
296 associated with changes in basal resources ( $\Delta^{13}\text{C}$  values) of Collembola, but does not significantly  
297 affect their average trophic positions ( $\Delta^{15}\text{N}$  values). These findings are in line with the results of  
298 the study of Krause *et al.* (2019) investigating oribatid mites at the same study sites and showing  
299 that the shift in trophic niches to be mainly due to changes in the use of basal resources rather  
300 than trophic levels. Similar to previous studies on centipedes, oribatid mites and other soil animal  
301 taxa (Klarner *et al.*, 2017; Susanti *et al.*, 2019; Krause *et al.*, 2019), we also found the conversion  
302 of rainforest into plantations to be associated in Collembola with a shift from detritivory towards  
303 herbivory (i.e., lower  $^{13}\text{C}$  enrichment). In rainforest and jungle rubber,  $\delta^{13}\text{C}$  values of Collembola  
304 were 2.0-5.0‰ higher compared to leaf litter, which resembles the shift observed in temperate  
305 forest ecosystems (Pollierer *et al.*, 2009). This “detrital shift” in  $\delta^{13}\text{C}$  (Potapov *et al.*, 2019)  
306 presumably is due to acquiring C from saprotrophic fungi and bacteria (Potapov *et al.*, 2013) that  
307 preferentially use  $^{13}\text{C}$ -rich plant compounds (Pollierer *et al.*, 2009). High  $^{13}\text{C}$  enrichment in most  
308 of the studied Collembola species in more natural ecosystems (rainforest and jungle rubber)  
309 suggests that they predominantly rely on microorganisms decomposing organic matter rather

310 than on fresh plant material as food source (Potapov *et al.*, 2019). Overall, similar enrichment in  
311  $^{13}\text{C}$  and  $^{15}\text{N}$  in Collembola in temperate and tropical ecosystems suggest that Collembola rely little  
312 on fresh plant material or mycorrhizal fungi in both, and this may well apply to soil food webs in  
313 general.

314 As indicated by  $\Delta^{13}\text{C}$  values, Collembola species in oil palm plantations used food  
315 resources of a wide range of  $^{13}\text{C}$  values, which was not the case in the other land-use systems  
316 studied. Variations in  $^{13}\text{C}$  values of food resources in oil palm plantations may be attributed to  
317 the variety of management practices of the smallholder systems studied (Clough *et al.*, 2016).  
318 Potentially, variations in organic inputs due to differences in weeding, herbicide, and fertilization  
319 practices, resulted in an overestimation of the trophic niche width in oil palm plantations

320 The narrow range of  $\Delta^{15}\text{N}$  values in oil palm plantations suggests similar trophic positions  
321 of Collembola species in this land-use system. Notably, the narrow range was due to both the  
322 lack of high trophic level (predators, scavengers) and low trophic level species (primary  
323 decomposers, specialized lichen feeders). This may reflect the dominance of generalist species in  
324 the disturbed habitat of oil palm plantations (Korotkevich *et al.*, 2018). Nematode communities  
325 also indicated oil palm plantations to be the most disturbed of the four land-use systems studied  
326 (Krashevskaya *et al.*, 2019). Further, Klarner *et al.* (2017) found  $\Delta^{15}\text{N}$  values of centipede species to  
327 be lower in oil palm compared to jungle rubber and rubber plantations suggesting that trophic  
328 chains in oil palm plantations are shorter than in the other land-use systems studied. Overall,  
329 these findings suggest that the structure of soil food-webs in monoculture plantations, especially  
330 oil palm, is simplified due to reduced number of trophic levels.

331 The most dominant Collembola species at our study sites, *Pseudosinella* sp.1, occupied a  
332 similar trophic niche in each of the land-use systems studied, suggesting that its diet changes  
333 little with the conversion of rainforest into plantation systems. *Pseudosinella* sp.1 colonized both  
334 litter and soil, and, as indicated by  $\Delta^{15}\text{N}$  values, occupied the highest trophic position among all  
335 Collembola species studied. High  $\Delta^{15}\text{N}$  values suggest that this species may either feed on  
336 mycorrhizal fungi, which are enriched in  $^{15}\text{N}$  (Hobbie *et al.*, 2001; Potapov & Tiunov, 2016), and  
337 / or live as predators feeding e.g., on nematodes, which are similarly abundant across the land-  
338 use systems studied (Krashevskaya *et al.*, 2019). Conversion of rainforest may have less affected  
339 the mineral soil- and root-based resources than litter resources, and this may explain the high  
340 abundance of euedaphic *Pseudosinella* sp.1 in plantations. Similarly, Krause *et al.* (2019) found  
341 the trophic niche of dominant species of oribatid mites to change little with the conversion of  
342 rainforest into plantations. This suggests that trophic niches of certain species may be little  
343 affected by land-use change despite strong changes in the overall food-web structure.

344

#### 345 *Trophic differentiation among species*

346 Variations in  $\Delta^{13}\text{C}$  values among Collembola species were more pronounced in rainforest  
347 and jungle rubber than in rubber and oil palm plantations. Korotkevich *et al.* (2018) also found  
348 the interspecific (in contrast to intraspecific) variation in trophic niches of Collembola to be higher  
349 in natural (forest and meadows) than in disturbed habitats (pastures and lawns). Among the  
350 Collembola species studied  $\Delta^{13}\text{C}$  values of *Pseudosinella* sp.1 in rainforest, and *Callyntrura* sp.1  
351 and *Sphyroteca* sp.1 in jungle rubber differed significantly from those of other Collembola species

352 indicating that these species are able to exploit resources not available to the other Collembola  
353 species in the respective land-use system.

354         Similar to  $\Delta^{13}\text{C}$  values, Collembola species in each land-use system, except rubber  
355 plantations, also differed in  $\Delta^{15}\text{N}$  values. In jungle rubber *Callyntrura* sp.1 was most depleted in  
356  $\delta^{15}\text{N}$  among the studied Collembola species indicating that this species occupied the lowest  
357 trophic position pointing to phycophagy (Potapov *et al.*, 2018). In rainforest *Pseudosinella* sp.1  
358 had the highest  $\delta^{15}\text{N}$  values followed by *Isotomiella* cf. *minor* and *Acrocyrtus* sp. suggesting that  
359 these species are as microbivores in undisturbed ecosystems. Overall, based on  $\Delta^{13}\text{C}$  and  $\Delta^{15}\text{N}$   
360 values, trophic niche differentiation among species was most pronounced in rainforest,  
361 presumably due to the availability of a wider spectrum of food resources and more stable  
362 environmental conditions than in plantations. This is likely to result in more efficient food-web  
363 functioning in natural ecosystems due to species complementarity (Loreau and Hector 2001),  
364 which is partly lost in plantation systems.

365

366 *Variations in isotopic niches of Collembola taxa and life forms with land-use systems*

367         Collembola taxa such as Symphypleona and Paronellidae typically had low  $\Delta^{15}\text{N}$  values,  
368 indicating that these taxa feed on algae or lichens (Chahartaghi *et al.*, 2005; Potapov *et al.*, 2018).  
369 Symphypleona as well as Paronellidae are well adapted to aboveground life, both are large-sized  
370 and possess well-developed visual systems. Such 'atmobiotic' Collembola have been assumed to  
371 live at least in part as herbivores on vascular plants or algae (Rusek, 2007). This suggestion is in  
372 line with studies from temperate forests investigating variations in stable isotope ratios in

373 Symphypleona (Chahartaghi *et al.*, 2005; Potapov *et al.*, 2016). Paronellidae predominantly occur  
374 in tropical regions also living above the ground suggesting that the microhabitat they live in  
375 defines feeding preferences of Collembola across different phylogenetic lineages (see life form  
376 discussion below). Entomobryidae and Isotomidae occupied high trophic positions and this also  
377 is consistent with earlier studies based on variations in stable isotope ratios suggesting that they  
378 predominantly feed on microorganisms colonizing decomposing litter materials (Chahartaghi *et*  
379 *al.*, 2005; Potapov *et al.*, 2016). Some species of these two families occupied very high trophic  
380 positions resembling those of Onychiuridae and Neanuridae in temperate ecosystems suggesting  
381 that at least in part they live as predators or scavengers, presumably including nematodes as prey  
382 (Heidemann *et al.*, 2014). Since Onychiuridae and Neanuridae were rare at our study sites,  
383 species from other families might have been able to occupy their trophic niches.

384         Trophic niches of Collembola in our study varied with life form as shown previously for  
385 temperate ecosystems (Ponge, 2000; Potapov *et al.*, 2016). Conform to the patterns in  
386 Collembola families, the results suggest that atmobiotic and epedaphic species occupied the  
387 lowest trophic position across land-use systems, whereas euedaphic species such as  
388 *Pseudosinella* sp.1 occupied the highest trophic position. This is in line with the results of the  
389 study of Potapov *et al.* (2016) indicating that species inhabiting deeper soil layers (hemiedaphic  
390 and euedaphic) are more enriched in  $^{15}\text{N}$  than those living in litter and above the ground  
391 (epedaphic and atmobiotic). High  $\delta^{15}\text{N}$  values may result from feeding on ectomycorrhizal fungi  
392 which are enriched in  $^{15}\text{N}$  (see above; Hobbie *et al.*, 2001; Potapov and Tiunov, 2016), however,  
393 this unlikely applies to tropical forests where trees predominantly form mutualistic interactions  
394 with arbuscular mycorrhizal fungi. We attributed low  $\delta^{15}\text{N}$  values in epedaphic and atmobiotic

395 Collembola to algae or lichen feeding, which is widespread in Collembola in temperate forests  
396 (Potapov et al., 2018), but in our study only few species had  $\delta^{15}\text{N}$  values below those of litter.  
397 This contradicts results based on fatty acid analysis suggesting that Collembola feed more on  
398 algae in tropical than in temperate ecosystems (Susanti *et al.*, 2019). To clarify the contribution  
399 of algae in soil food webs in tropical and temperate ecosystems, more data on stable isotope  
400 composition of various food resources in tropical forests, or direct experimentation, are needed.  
401 Differences between life forms were more pronounced in rainforest and jungle rubber and less  
402 in plantation systems, which may reflect the more pronounced litter layer in the former than the  
403 latter (Krashevskaya et al. 2015). Overall, the results suggest that similar to oribatid mites (Tsurikov  
404 *et al.*, 2019) the trophic niche structure in Collembola communities in temperate and tropical  
405 forests is generally similar and this is partly explained by taxonomic affiliation and life form.

406

#### 407 **Conclusion**

408 We showed that the conversion of rainforest into agricultural plantations, such as rubber and oil  
409 palm, is associated with changes in trophic niches of Collembola. The use of food resources  
410 shifted towards herbivory, with the range of food resources of Collembola in oil palm plantations  
411 being the highest, likely due to the heterogeneity in management. By contrast, the range of  
412 trophic positions in oil palm plantations was low suggesting that the trophic structure is simplified  
413 lacking high but also low trophic levels. This is further supported by the less pronounced trophic  
414 niche differentiation among species in monoculture plantations. Similar to the pattern in oribatid  
415 mites (Tsurikov *et al.*, 2019), the structure of trophic niches in tropical Collembola communities

416 resembled that in temperate forests. Life form and family identity explained about half of the  
417 species-level variation; atmobiotic species occupied the lowest and euedaphic species the  
418 highest trophic position, but the difference was less pronounced in plantations. Overall, the  
419 results document that changes in community composition associated with the conversion of  
420 rainforest into plantation systems are followed by shifts in the trophic structure and trophic  
421 niches in Collembola communities, potentially compromising ecosystem functions and food-web  
422 stability in plantations.

# Figure 1

Variations in  $\Delta^{13}\text{C}$  and  $\Delta^{15}\text{N}$  values of Collembola among the studied land-use systems (rainforest, jungle rubber, rubber and oil palm plantations)

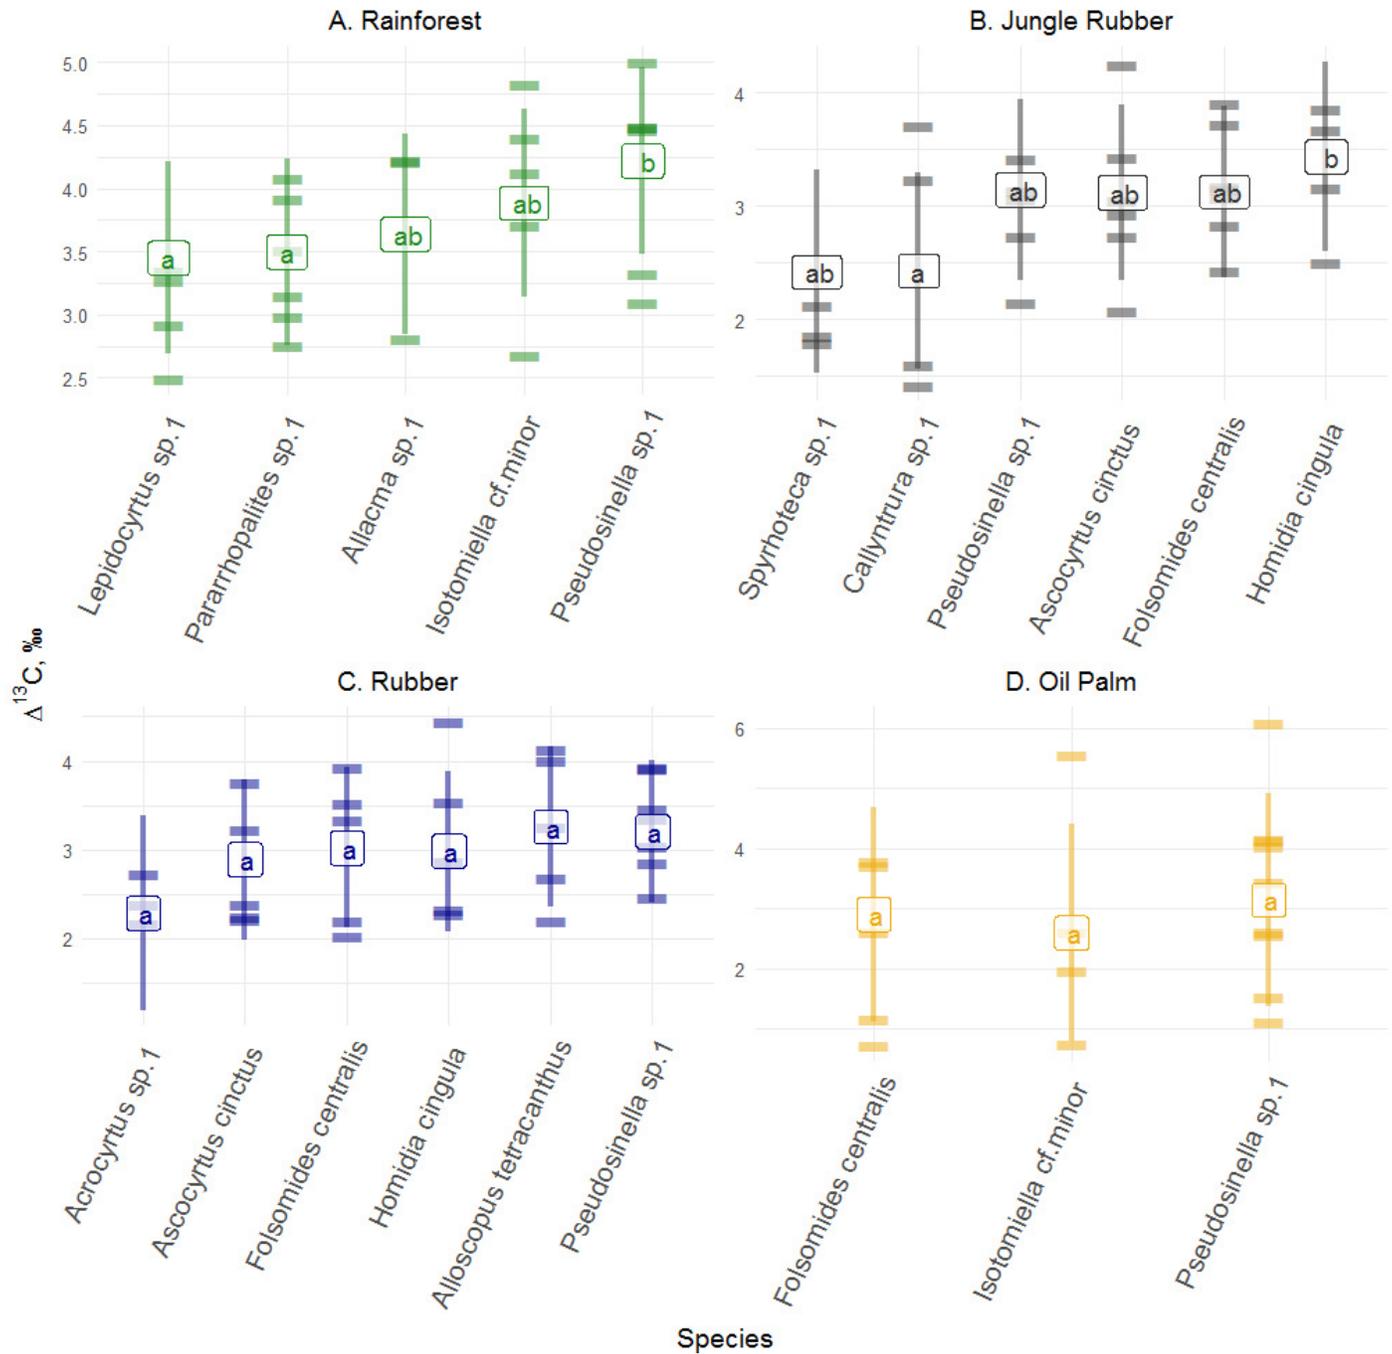

Variations in  $\Delta^{13}\text{C}$  and  $\Delta^{15}\text{N}$  values of Collembola among the studied land-use systems: (A) rainforest, (B) jungle rubber, (C) rubber and (D) oil palm plantations. Violin plots show frequency distribution of values (mirrored Kernel density estimation), all individual measurements are displayed together independent of taxonomic identity. \*Average  $\Delta^{13}\text{C}$  values in rainforest were significantly higher than in the other three land-use systems ( $P < 0.05$ )

## Figure 2

Differences of  $\Delta^{13}\text{C}$  values of Collembola species in different land-use systems (rainforest, jungle rubber, rubber and oil palm plantations)

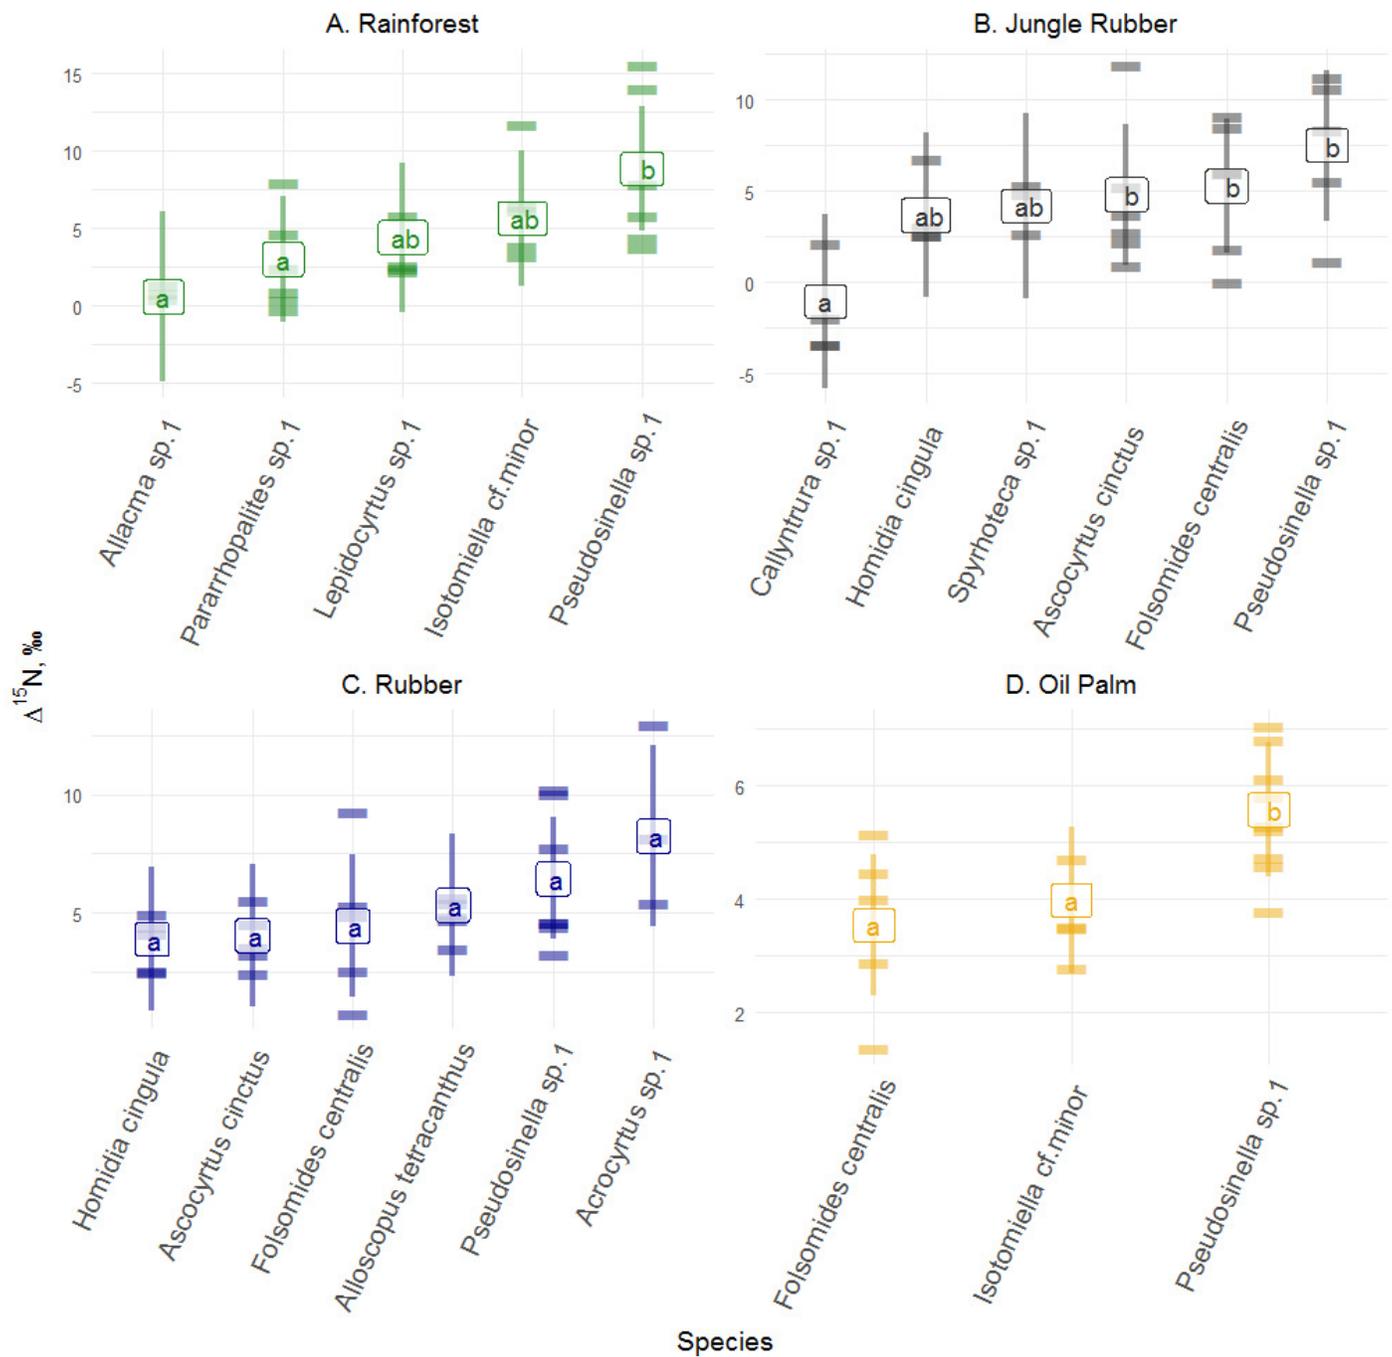

Differences of  $\Delta^{13}\text{C}$  values of Collembola species in different land-use systems: (A) rainforest, (B) jungle rubber, (C) rubber and (D) oil palm plantations; model-estimated means (Ismeans) with standard deviation. Horizontal stripes represent individual measurements. Only species with more than three replicates per land-use system were analyzed (see Methods). Isotope values of each species in each land-use system with the same letter are not significantly different according to Tukey's honestly significant difference test ( $p > 0.05$ )

## Figure 3

Differences of  $\Delta^{15}\text{N}$  values of Collembola in different land-use systems (rainforest, jungle rubber, rubber and oil palm plantations)

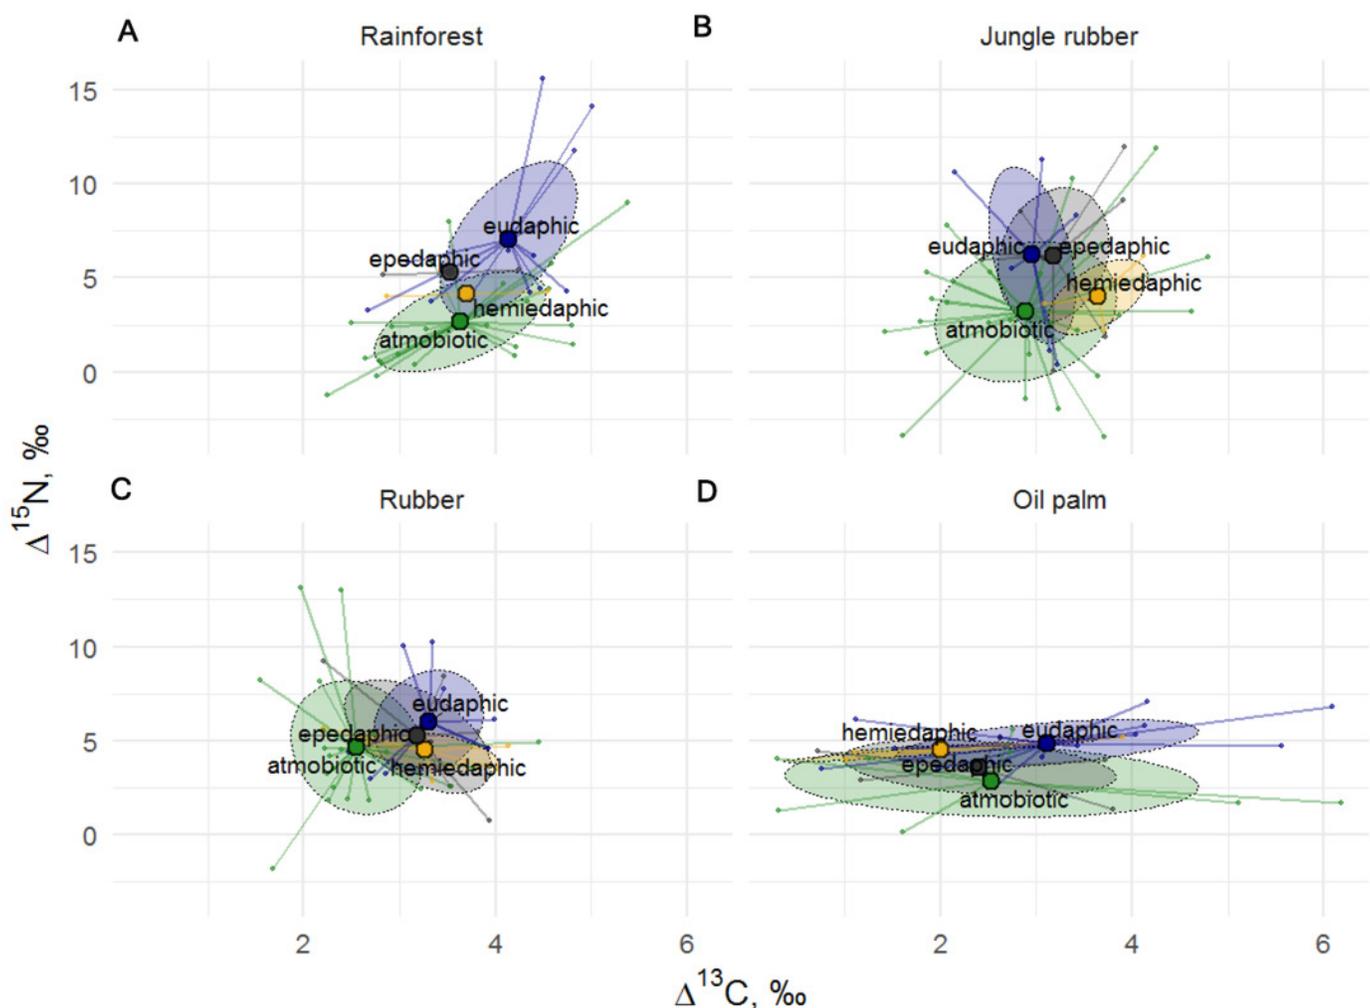

Differences of  $\Delta^{15}\text{N}$  values of Collembola in different land-use systems: (A) rainforest, (B) jungle rubber, (C) rubber and (D) oil palm plantation; model-estimated means (Ismeans) with standard deviation. Horizontal stripes represent individual measurements. Only species with more than three replicates per land-use system were analyzed (see Methods). Isotope values of each species in each land-use system with the same letter are not significantly different according to Tukey's honestly significant difference test ( $p > 0.05$ )

## Figure 4

Stable isotope niches of four Collembola life forms in rainforest, jungle rubber, rubber, and oil palm plantations

Stable isotope niches of four Collembola life forms in (A) rainforest, (B) jungle rubber, (C) rubber, and (D) oil palm plantations. Ellipses denote 60% confidence intervals, different life forms are shown in color (eudaphic = blue, epedaphic = grey, hemiedaphic = yellow, atmobiotic = green). Large colored dots represent means of land-use systems, small points represent individual measurements

## Figure 5

Stable isotope niche of Collembola families in rainforest, jungle rubber, rubber, and oil palm plantations

Stable isotope niche of Collembola families in (A) rainforest, (B) jungle rubber, (C) rubber, and (D) oil palm plantations. Ellipses denote 60% intervals, different families are shown in color (Paronellidae = blue, Isotomidae = green, Symphypleona = purple, Entomobryidae = red; Symphypleona comprises the families Sminthuridae, Sminthurididae, Dycirtomidae and Katiannidae). Large colored dots represent means of land-use systems, small points represent individual measurements
