Running Title: TWO PREDICTED MODELS in LUAD

Abstract

Background It is well accepted that both competitive endogenous RNAs (ceRNAs) and immune microenvironment exert crucial roles in the tumor prognosis. The present study aimed to find prognostic ceRNAs and immune cells in lung adenocarcinoma (LUAD). **Materials and Methods** More specifically, we explored the associations of crucial ceRNAs with the immune microenvironment. The cancer genome atlas (TCGA) database was employed to obtain expression profiles of ceRNAs and clinical data. CIBERSORT was utilized to quantify the proportion of immune cells in LUAD. **Results** We constructed two cox regression models based on crucial ceRNAs and immune cells to predict prognosis in LUAD. Subsequently, seven ceRNAs and seven immune cells were involved in prognostic models. We validated both predicted models via an independent cohort GSE72094. Interestingly, both predicted models proved that the longer patients were smoking, the higher risk scores would be obtained. We further investigated the relationships between seven genes and immune/stromal scores via the ESTIMATE algorithm. The results indicated that CDC14A and H1F0 expression were significantly related to stromal scores/Immune scores in LUAD. Moreover, based on the result of the ceRNA model, single-sample gene set enrichment analysis (ssGSEA) suggested that differences in immune status were evident between high- and low-risk groups.

Introduction

Lung cancer is considered as the most common cause of survival-associated cancer globally (Bray et al. 2018). Besides, lung adenocarcinoma (LUAD) approximately accounts for 50% of all lung cancer types (Imielinski et al. 2012). Although the improvement of diagnosis and the comprehensive treatment in the lung cancer has been made, the 5-year overall survival rate for lung cancer is still approximately 18%, mainly due to invisible early symptoms (Siegel et al. 2018). Thus, it is of great necessity to identify sensitive and accurate biomarkers in the early stage.

Competitive endogenous RNAs (ceRNAs), consisting of a group of regulatory RNA molecules, bind with the specific miRNAs and then affect the protein level (Karthi & Subramanian 2014; Phelps et al. 2016; Shukla et al. 2011). Previous studies have shown that ceRNA regulatory networks play essential roles in tumor progression and migration (Bartel 2009; Qi et al. 2015; Sanchez-Mejias & Tay 2015; Tay et al. 2014). Besides, increasing studies have demonstrated that immune microenvironment (TIME) was also associated with the prognosis in various kinds of tumors, including LUAD (Lavin et al. 2017; Liu et al. 2020a). Stromal cells and immune cells constitute the central part of TIME. Stromal cells participate in the process of tumorigenesis and metastasis and are generally conducive to the movement of cancer cells (Ni et al. 2018). Additionally, various studies revealed that immune cells exhibit large effects on clinical outcomes in many cancers. Donnem et al. summarized that different types of immune cells affected the clinical stage and prognosis in non-small lung cancer (Donnem et al. 2016; Liu et al. 2020b). As a result, to further investigate potential biomarkers based on immune cells and ceRNAs in LUAD,

we constructed Cox proportional hazards models and predicted nomograms.

However, the mechanisms of ceRNAs in the tumor microenvironment still remain unclear in LUAD. It is well accepted that tumor stem cells (CSCs) are tumorigenic cells with self-renewal ability. Besides, CSCs promote tumor immune to escape via expressing a variety of immune factors (Bruttel & Wischhusen 2014). In the current study, RNA stem scores and DNA stem scores were applied to assess tumor stem cell content (Malta et al. 2018). ESTIMATE algorithm was utilized to evaluate the stromal and immune cells in every sample. Thus, we explored the correlation between crucial prognostic genes with RNAss/DNAss scores and stromal/immune scores.

Materials and Methods

Identification of differentially expressed ceRNAs

In the present study, expression profiles of LUAD and the corresponding clinical information were derived from the TCGA database, including lncRNA, miRNA, and mRNA. The R package "DEGseq2" was used to screen the differentially expressed mRNAs, miRNAs and lncRNAs (DEmRNA, DEmiRNA and DElncRNA) between normal and tumor samples (Love et al. 2014). Specifically, a false discovery rate (FDR) < 0.05 and $\log_2 |\text{fold change}| > 1$ were set as cutoff criteria.

ceRNA network construction

Both lncRNA-miRNA and miRNA-mRNA interactions were predicted using, miRcode and

starBase(Chou et al. 2018; Jeggari et al. 2012; Li et al. 2014). DE miRNAs, DE mRNAs, and DE lncRNAs, which presented a significant difference in hypergeometric distribution detection and correlation analysis ($P < 0.05$), were selected to construct a lncRNA-miRNA-mRNA regulatory network and then was visualized by Cytoscape 3.8.0 (Shannon et al. 2003).

Construction of nomogram based on key ceRNAs

Univariate Cox analysis was employed to screen the survival-associated ceRNAs. Lasso regression analysis was applied to ensure that the Cox model was not overfitted. Eventually, the candidate ceRNAs were integrated to establish the multivariate cox regression models. Risk scores were described as following: $\text{risk score} = (\text{Exp RNA1} * \beta_1) + (\text{Exp RNA2} * \beta_2) + \dots + (\text{Exp RNA3} * \beta_3)$. It is worth noting that Exp stands for the expression level, and β denotes the regression coefficient. Based on the risk scores, patients with LUAD were divided into high-risk and low-risk groups. The corresponding Kaplan-Meier survival curves were carried out to reveal the overall survival (OS) within different groups. In addition, we also performed the ROC curve to evaluate the specificity and sensitivity of the model. Finally, according to the multivariate model result, we constructed a nomogram to predict patients' prognostic values. The calibration curve was applied to evaluate the accuracy of the nomogram.

Construction of nomogram based on immune cells

The CIBERSORT was utilized to estimate immune cells in LUAD (Newman et al. 2015). Samples with a CIBERSORT output of $p < 0.05$ presented that the predicted proportion of immune cells

94 were correct.

95 The Wilcoxon test was conducted to examine the significant difference of immune cells between
 96 the tumor samples and healthy samples. We also performed multivariate Cox regression and
 97 produced the corresponding risk scores. Based on the multivariate Cox model results, we finally
 98 built a predicted nomogram. Similar to ceRNAs, patients were also stratified into high-risk and
 99 low-risk groups on the basis of the mean risk score. Subsequently, the prognostic model's
 100 sensitivity and specificity were examined by the ROC curve, and the calibration curve investigated
 101 the accuracy of the nomogram.

102 **Validation of prognostic equations with GEO**

103 To better elucidate the accuracy of both multivariate Cox models, an external validation dataset
 104 GSE72094 (n=442) was applied in the present study. We selected this dataset because it contained
 105 most LUAD patients with clinical data in the Gene Expression Omnibus (GEO) database. Based
 106 on the median risk score generated from TCGA, we also classified patients with high- and low-
 107 risk patients. K-M and ROC curves were applied to evaluate the prognostic efficacy of multivariate
 108 models in TCGA.

109 **Estimation of tumor stemness and microenvironment**

110 Stemness scores of "RNAss" and "DNAss" referred to the result based on mRNA and DNA-
 111 methylation respectively. The larger stemness scores were, the higher likelihood more stem cells
 112 were infiltrating. We utilized the "ESTIMATE" package to assess immune, stromal scores, and

the sum of both in individual patients. The higher scores, the higher proportion of corresponding cells were. Additionally, correlation of hub ceRNAs with above scores was examined by Spearman analysis. By applying the “gsva” package, we calculated infiltrating level of immune cells and immune-associated functions in LUAD samples (Hänzelmann et al. 2013).

Statistical analysis

All statistical analyses were accomplished with R software 4.0.2. The Wilcoxon rank sum tests were conducted for comparisons between two groups. Only a two-sided P-value <0.05 was recognized as statistically significant.

Results

Identification of DEmRNAs, DE miRNAs and DE lncRNAs

Figure1 presents our workflow for the bioinformatic analysis. Among the whole expression profiles, totally 1645 upregulated DEmRNAs, and 1344 downregulated DEmRNA were screened out (Fig. 2A,2B). Furthermore, we also identified 111 upregulated DE miRNA, 87 downregulated DE miRNA (Fig. 2C,2D), 163 upregulated DE lncRNA, and 52 downregulated DE lncRNA (Fig. 2E,2F).

Construct Nomogram of ceRNAs

To investigate the endogenously competitive relationships between the lncRNA and mRNA, we

constructed an intersected ceRNA network. Seven lncRNAs (H19, AC074117.1, FBXL19-AS1, MAGI2-AS3, SNHG3, PVT1 and SNHG1), 94mRNA, and 15miRNA were involved in the network (Supplementary Table.S1). Hsa-miR-130b-3p and hsa-miR-29b-3p were the top 2 regulated miRNA in the ceRNA network (Fig. 3). In addition, the initial univariate Cox regression (Supplementary Fig. S1) and Lasso regression analysis were further conducted to investigate the key biomarkers (Fig. 4B,4C). Seven survival-associated biomarkers were finally involved in a new multiple Cox regression analysis (Fig. 4A). According to the result, all biomarkers belonged to protein-coding RNAs. Consequently, the corresponding risk score was generated (Table 1): risk score = (Exp CDC14A * 0.281888)+(Exp LOXL2*0.114969) + (Exp CCT6A * 0.174244)+(Exp E2F7 *0.187164)+(Exp GPR37*0.099737)+(Exp H1F0 *0.197590)+(Exp SMOC1 * 0.068385).

As shown in Fig.4D, the prognostic score could be a promising indicator to distinguish the LUAD patients according to the individual prognosis ($P=5.701e-8$). The area under ROC reflected the predictive efficacy of the prognostic signature (AUC of 3-year survival:0.772) (Fig.4E). By the GEO validation set, the AUC of gene signature at 3-year was 0.711 (Supplementary Fig. S3A). Additionally, K-M analysis further confirmed the difference between high- and low-risk groups ($P=9.963e-05$) (Supplementary Fig. S3B). Eventually, we assessed the prognosis of patients with LUAD by a nomogram (Fig. 5A), and the accuracy of the nomogram was confirmed by the calibration curve (Fig. 5C). As shown in Fig.5E, based on this prognostic model, the risk score in the group with fewer smoking years (≤ 20)was lower than the group with more smoking years (> 20) ($P=0.025$).

Construct Nomogram of immune Cells

By applying the CIBERSORT, we estimated the percentages of 22 immune cell types in LUAD (Supplementary Fig. S2B,2C) (Chen et al. 2018). The violin plot indicated that 13 immune cell types showed a significant difference in percentages of immune cells between tumor samples and healthy samples by the Wilcoxon test (Supplementary Fig. S2D). The correlation analysis of immune cells could be found in Supplementary Fig.2A. Subsequently, after the analysis of univariate cox regression and lasso regression, seven immune cells were taken as prognostic biomarkers and eventually integrated into a new multivariate model (Fig. 6A,6B,6C). The formula was presented as following (Table 2): risk score = $[\text{Exp CD8} * (-3.425649)] + (\text{Exp Tregs} * 9.175062) + [\text{Exp Monocytes} * (-5.318492)] + (\text{Exp M1} * 6.134551) + (\text{Exp Dendritic cells activated} * 5.539130) + (\text{Exp Mast cells activated} * 24.611110) + (\text{Exp Eosinophils} * 37.351722)$. The K-M analysis results showed a significant difference in overall survival between high- and low-risk groups ($P=3.342e-05$) (Fig. 6D). The ROC curve (AUC of 3-years: 0.766) demonstrated that the multivariate model was recognized as a fair potential to monitor the prognostic efficacy (Fig. 6E). In the external validation set, the model also carried out adequate predicted capacity. The AUC of immune cell signature was 0.738 at 3-years (Supplementary Fig. S3C). K-M curves reflected that low-risk group had longer overall survival than the high-risk group ($P=2.922e-04$) (Supplementary Fig. S3D). A predicted nomogram was also performed, and the discrimination was conducted to test the calibration quality (Fig. 5B,5D). Similarly, we could also found that more smoking group had more risk score based on the predicted model of immune cells ($P=0.0046$)

171 (Fig.5F)

172 **Correlation of hub ceRNAs expression with tumor stemness and microenvironment**

173 As shown in Fig.7, CCT6A, H1F0 and E2F7 were positively related to RNAss and DNAss ($R=0.22$
174 to 0.53). A significant negative association was detected between CDC14A and RNAss ($R=-0.25$,
175 $P=7.5e-8$). Nevertheless, we did not find a significant correlation between LOXL2, GPR37 and
176 SMOC1 with tumor stemness. In addition, H1F0 displayed a negative association with stromal
177 scores, immune scores and estimate scores ($R=-0.34$ to -0.27). However, CDC14A showed a
178 positive association with the microenvironment-related scores ($R=0.31$ to 0.35).

179 **Multiple databases validation**

180 To validate CDC14A and H1F0 expression in LUAD, we utilized multiple databases. Based on
181 the result of UCLAN, GEPIA and TIMER, it could be concluded that H1F0 was highly expressed
182 while CDC14A was weakly expressed in LUAD (Supplementary Fig.4). Furthermore, the
183 CDC14A and H1F0 protein expression were obtained from The Human Protein Atlas data (HPA),
184 indicating that H1F0 was high staining in tumor cells, while it was medium staining in normal
185 tissues (Supplementary Fig.S5A, S5B). The opposite trend was observed in CDC14A. Besides,
186 the association of H1F0 and CDC14A with immune cells were validated in TISIDB. CDC14A
187 expression was positively associated with Immature B cell ($R=0.345$), NK cell ($R=0.308$),
188 Eosinophils ($R=0.357$), and Mast cell ($R=0.332$) (Supplementary Fig.S6A-S6E).
189 Controversially, H1F0 expression was negatively related to Eosinophil ($R=-0.34$),

190 Macrophage($R=-0.359$), NKT($R=-0.323$), Tem_CD8 ($R=-0.323$) and Th1($R=-0.407$)
191 (Supplementary Fig.S6F-S6J).

192 Differences in ssGSEA scores in TCGA/GEO cohort

193 To further elucidate the immune status in risk- and low groups of ceRNA signatures, we performed
194 the ssGSEA algorithm to estimate the immune infiltrating between two groups (Supplementary
195 Fig.7).Of note, low-risk group were associated with higher scores of aDCs, B_cells,
196 CD8+_T_cells,iDCs, Mast_cells, Neutrophils, pDCs, T_helper_cells and TIL
197 (Fig.8A,8B).Similarly, in lower-risk group, the scores of Check-point, HLA, T_cell_co-
198 stimulation and Type_II_IFN_Reponse in still higher in the low-risk group.Additionally, the
199 differences above were confirmed by the GEO cohort (Fig. 8C,8D).

200 Discussion

201 With the reduced overall survival rate, lung adenocarcinoma is the most common pathological
202 type since most patients were diagnosed at an advanced stage. Currently, there is a general
203 consensus that both molecular and cellular characteristics play an imposing role in oncogenesis
204 and metastasis, and thus they were suggested as underlying prognostic signatures. However, the
205 integrative analysis of ceRNAs and microenvironments has yet to be fully explored. In the present
206 study, we constructed nomogram survival models of both ceRNAs and immune cells. GSE72094
207 dataset further proved the feasibility of predicted equations. Besides, we stratified TCGA patients
208 with smoking history into two groups and calculated risk scores in each sample via both predicted

formulas, respectively. Not unexpectedly, both predicted formulas confirmed that the more extended smoking group (smoking years >20) have a higher risk than the shorter smoking group (smoking years ≤20). Thus, it could be concluded that smoking was an adverse factor for prognosis in both models.

E2F7, a member of EF transcription factors, was known as a transcriptional repressor that influences the prognosis in a lot of tumors, such as breast cancer, endometrial carcinoma, gallbladder cancer, and colon cancer. Previous studies have proved that miR-30a-5p prevents tumor migration and metastasis by targeting E2F7 in gallbladder cancer (Ye et al. 2018). Liu et al. have revealed that E2F7 was reported significantly overexpressed in ER-positive breast cancer than healthy breast tissues and then led to tamoxifen resistance in breast cancer cells (Liu et al. 2018). Additionally, overexpressed E2F7 could be suggested as a significant biomarker to identify the high-risk and low-risk groups of patients with lung cancer, which is also in consistence with our report (Sun et al. 2018).

SMOC1 is a cancer-associated protein, identified as an extracellular glycoprotein of the SPARC-related modular calcium-binding protein family. SMOC1 was overexpressed in brain cancer, including oligodendrogliomas, astrocytomas, and glioblastomas (Brellier et al. 2011; Fackler et al. 2011). However, till now, there is no enough evidence for the impact of SMOC1 in LUAD reported in the literature. Moreover, the current study may provide a study direction for researches of SMOC1 in the LUAD. Additionally, CCTA6 is reported to encode a molecular chaperone and play critical roles in damaged proteins repair, cytoskeletal organization, and the cell

cycle (Van Hove et al. 2015; Yam et al. 2008). Ying et al. found that CCTA6 served as a SMAD2-binding protein, which could inhibit the function of SMAD2, and promote metastasis (Ying et al. 2017).

CDC14A, which is of considerable significance to regulate the actin, was reported downregulated in many tumors and then reduced CDC14A was associated with the poor clinical outcomes (Chen et al. 2016). Our results indicated that CDC14A was a protective biomarker in LUAD (HR=0.75, P=0.0066), which corresponded well with previous studies. Similarly, based on the correlation with stemness scores and immune scores, we could also draw inferences that CDC14A suppressed tumor progression.

As one of H1 histone genes, H1F0 (known as H1.0) is heterogeneous in many tumors (Di Liegro et al. 2018). Knockdown of H1.0 influenced the differentiation of embryonic stem cells (Terme et al. 2011). Recent studies revealed that H1F0 were prognostic indicators in many cancers, such as breast cancer, liver cancer, and kidney cancer (Torres et al. 2016). In the current study, the relationships of H1F0 expression with stemness scores and Estamine scores suggested that H1F0 might promote LUAD.

T cells regulatory (Tregs) account for 5%-10% of peripheral CD4⁺ T cells in humans. Increasing evidence demonstrated that the immunosuppression mediated by Tregs is one of the essential mechanisms of immune evasion in tumors (Dunn et al. 2004; Shevach 2002; Zou 2005). Mast cells are increased in several tumors, and their accumulation was associated with a low survival rate in many cancers, such as pancreatic adenocarcinoma (Strouch et al. 2010) and

melanoma (Ribatti et al. 2003). Macrophages M1 was historically recognized as the proinflammatory subgroup, expressing a series of chemokines and consequently play antitumor roles (Hao et al. 2012). Controversially, our results suggested that M1 was highly expressed in LUAD (Fig.8). Actually, heterogeneity of environment signals could influence TAM development, and comprehensive nomenclatures of TAM have consequently been suggested (Ostuni et al. 2015).

Additionally, our study found that there were Obviously differences in immune status between high- and low risk groups in both TCGA and GEO cohorts. This indicated that decreased risk scores of ceRNAs were related to the enhancement of antitumor immunity. Furthermore, we could say that diminished immune function is responsible for poor prognosis in LUAD patients. However, there are inevitably some disadvantages in our study that should be taken into consideration. Firstly, considering the limit data from the TCGA and GEO, it could result in large analysis deviation and be verified by other large cohorts. Secondly, our follow-up experiment will explore the molecular mechanisms of prognostic signatures in the present study.

Conclusion

To conclude, the present study firstly provided a combined analysis of ceRNA and immune cells and then established nomograms to predict the prognosis in LUAD reliably. Based on the present study result, we will carry out the biological experiments to validate key ceRNAs and mechanisms of immune cells in the future.

Figure 1

Figure 1 The workflow for bioinformatic analysis

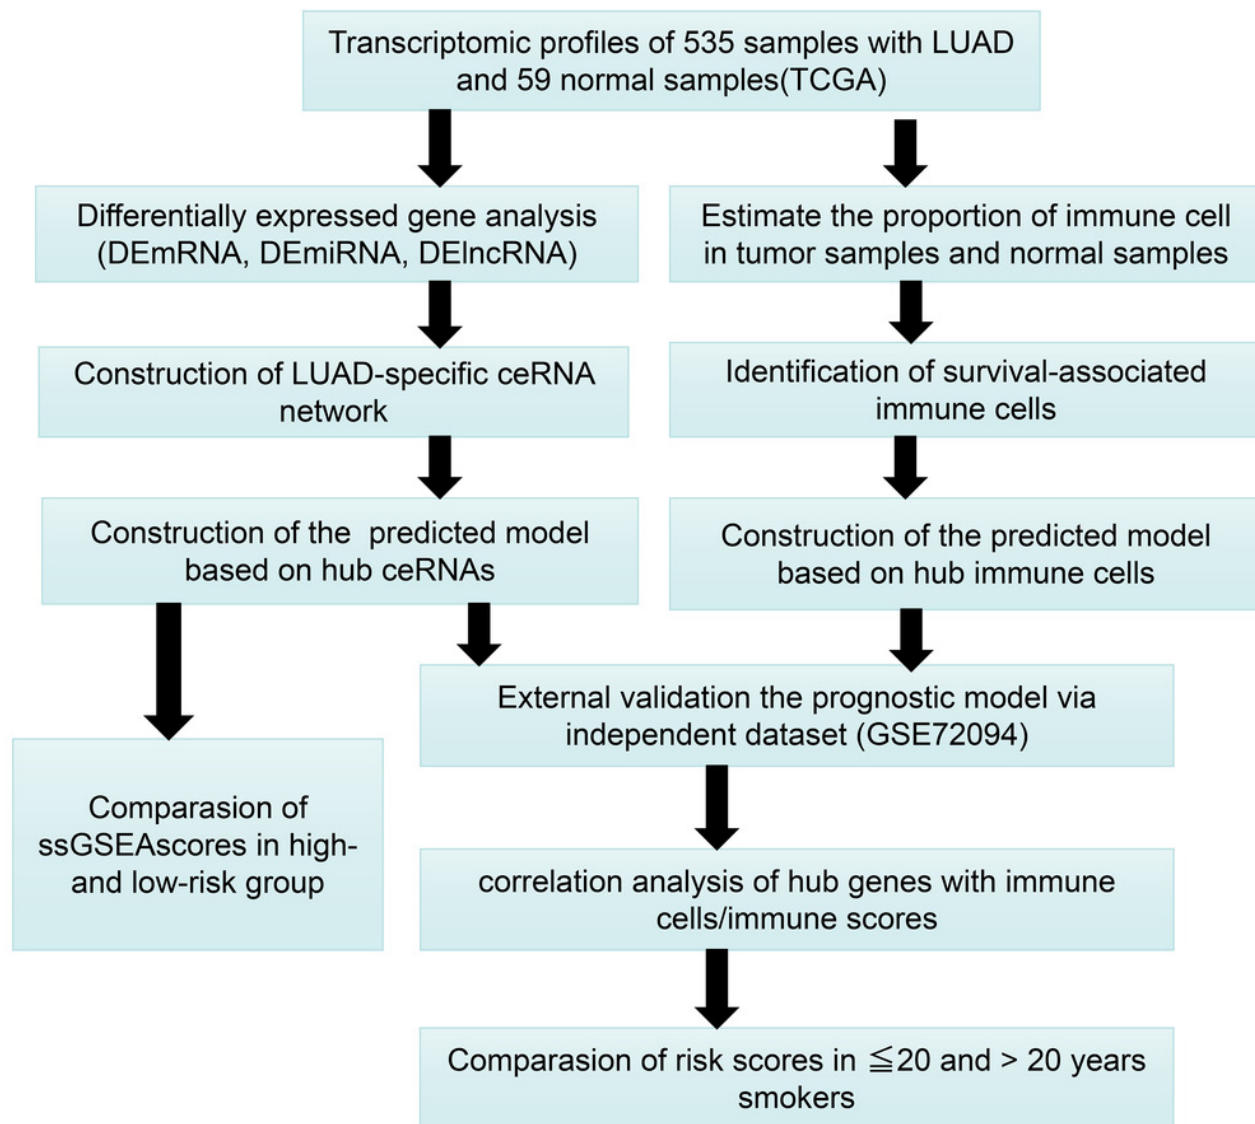

Figure 2

Figure 2 Differentially expressed genes.

Heatmap (**A**) and volcano plot (**B**) of DEmRNA. Heatmap (**C**) and volcano plot (**D**) of DEmiRNA. Heatmap (**E**) and volcano plot (**F**) of DElncRNA. Red dots and green dots represent up-regulated, down-regulated differentially expressed genes, respectively. DEmRNA, DEmiRNA and DElncRNA represent differentially expressed mRNA, miRNA and lncRNA, respectively.

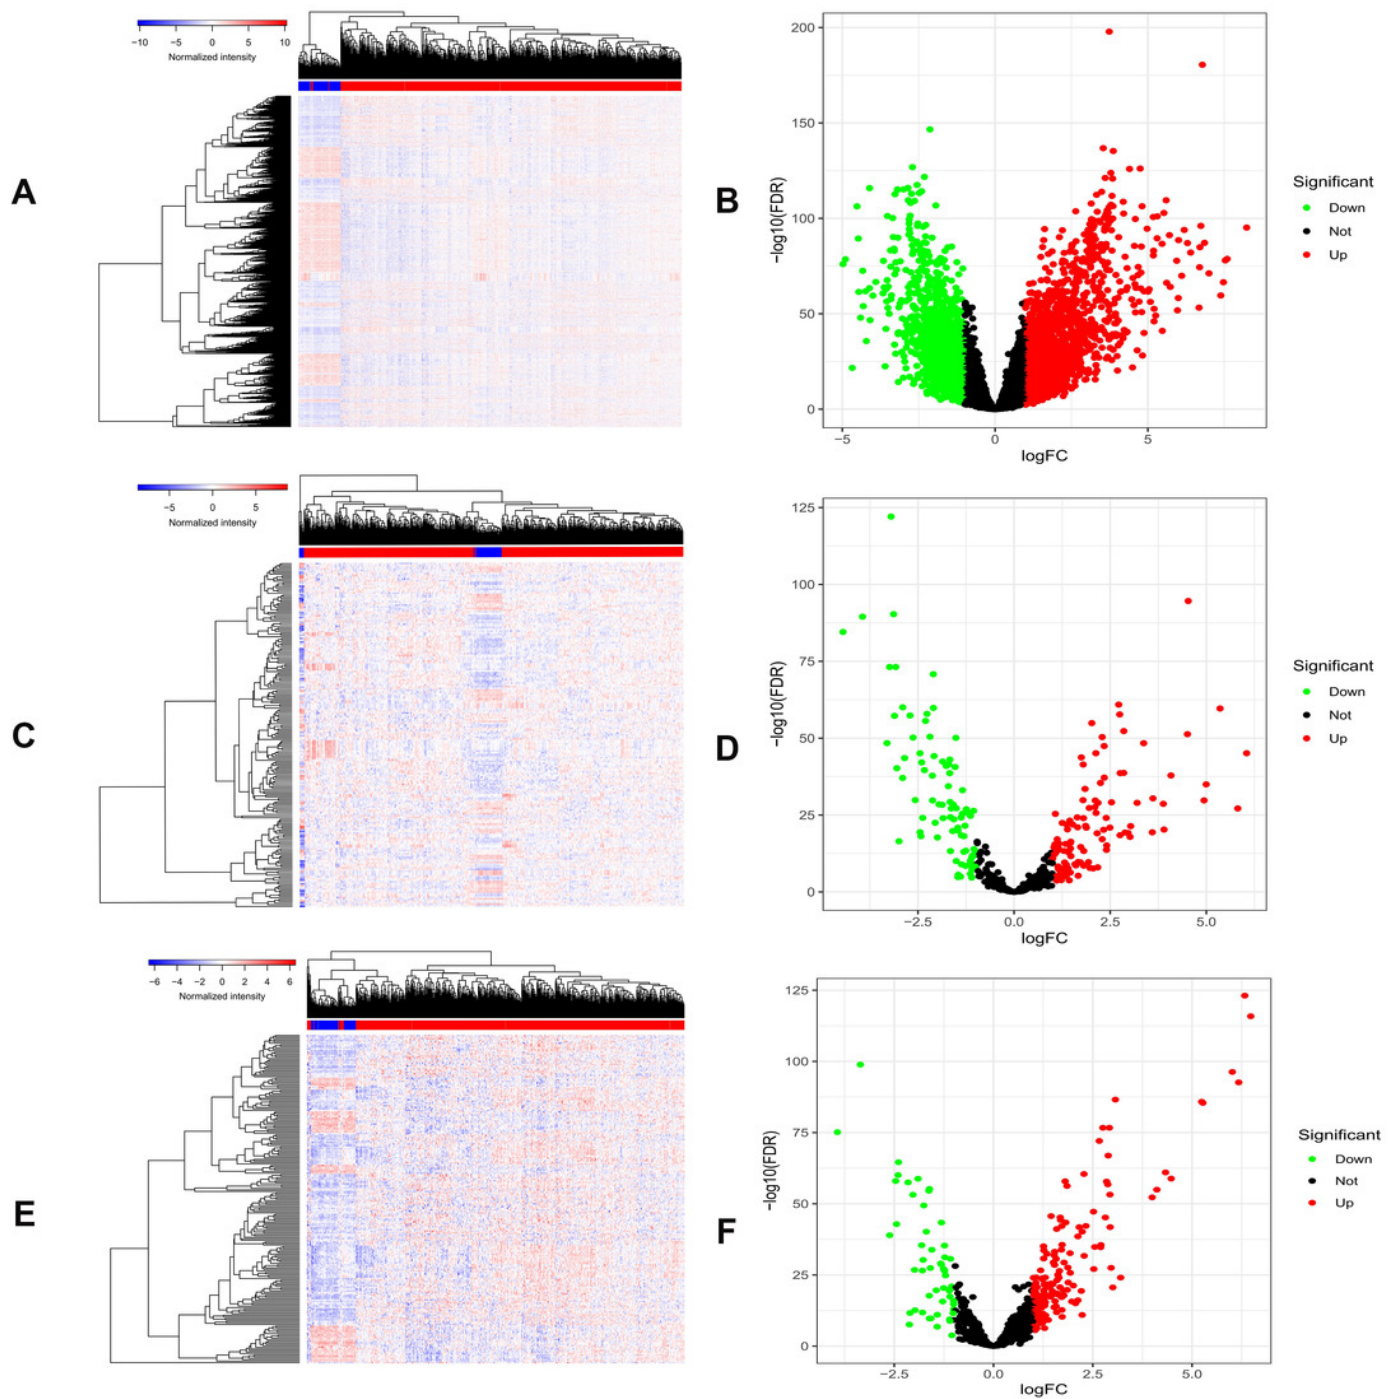

Figure 3

Figure 3 Construction of ceRNA network in LUAD.LUAD, lung adenocarcinoma. ceRNA, competing endogenous RNA.

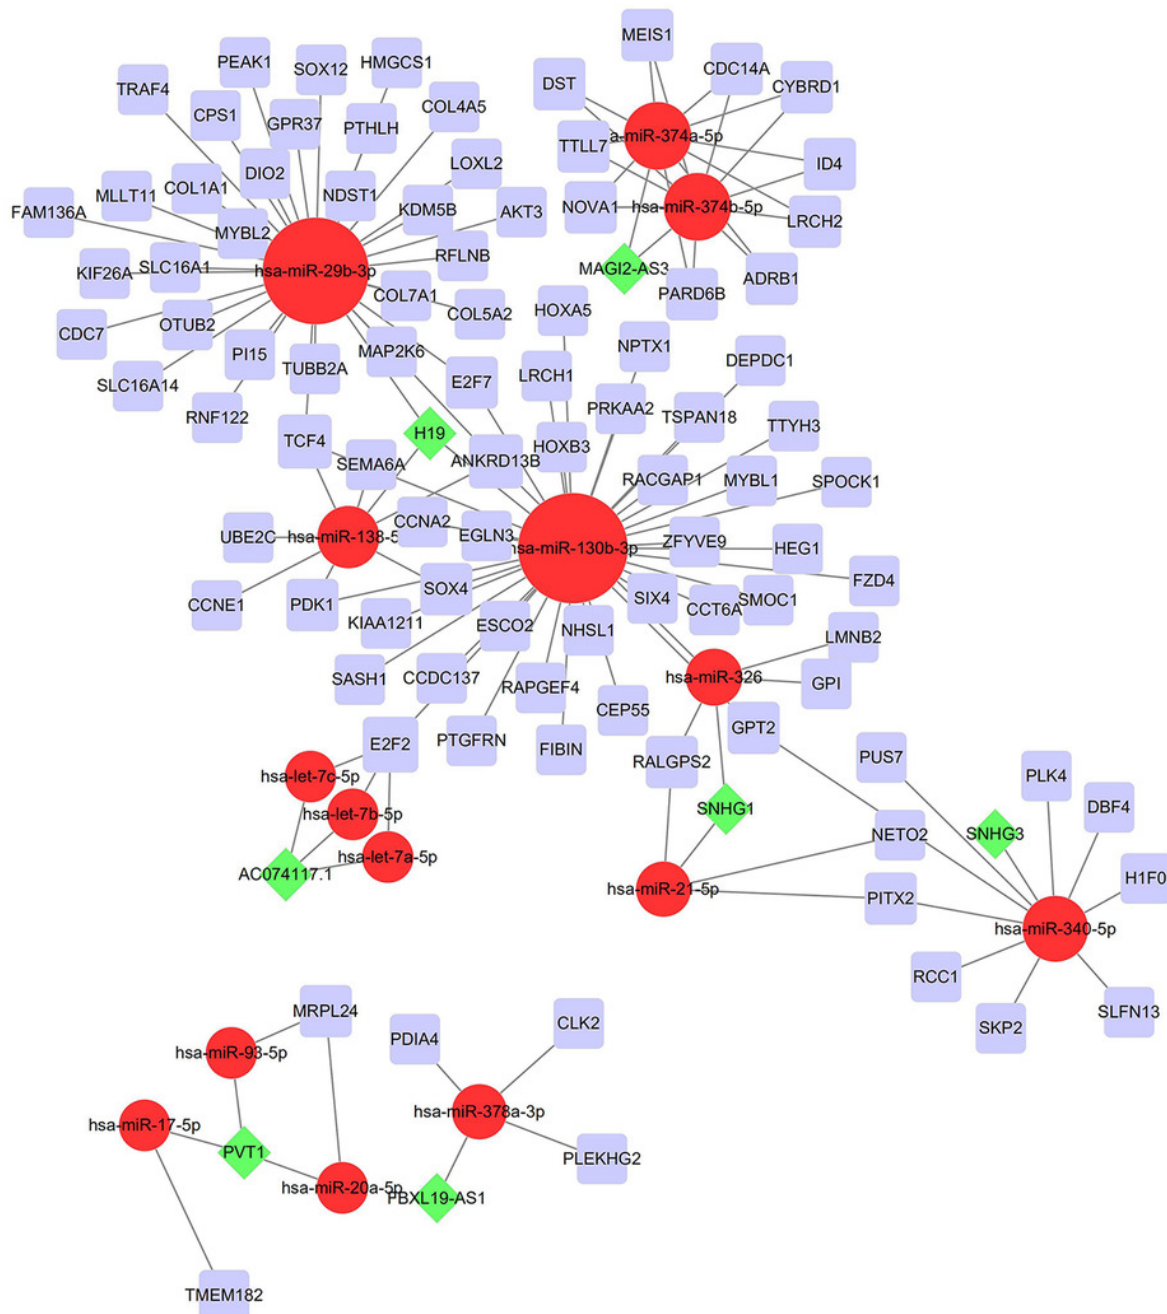

Figure 4

Figure 4 Construction of prognostic model involving the key RNAs of ceRNA network in the LUAD.

(**A**), multivariate Cox regression. (**B**), (**C**) lasso regression. (**D**) the Kaplan–Meier survival curve. (**E**) the ROC curve. ROC, the Receiver Operating Characteristic. LUAD, lung adenocarcinoma.

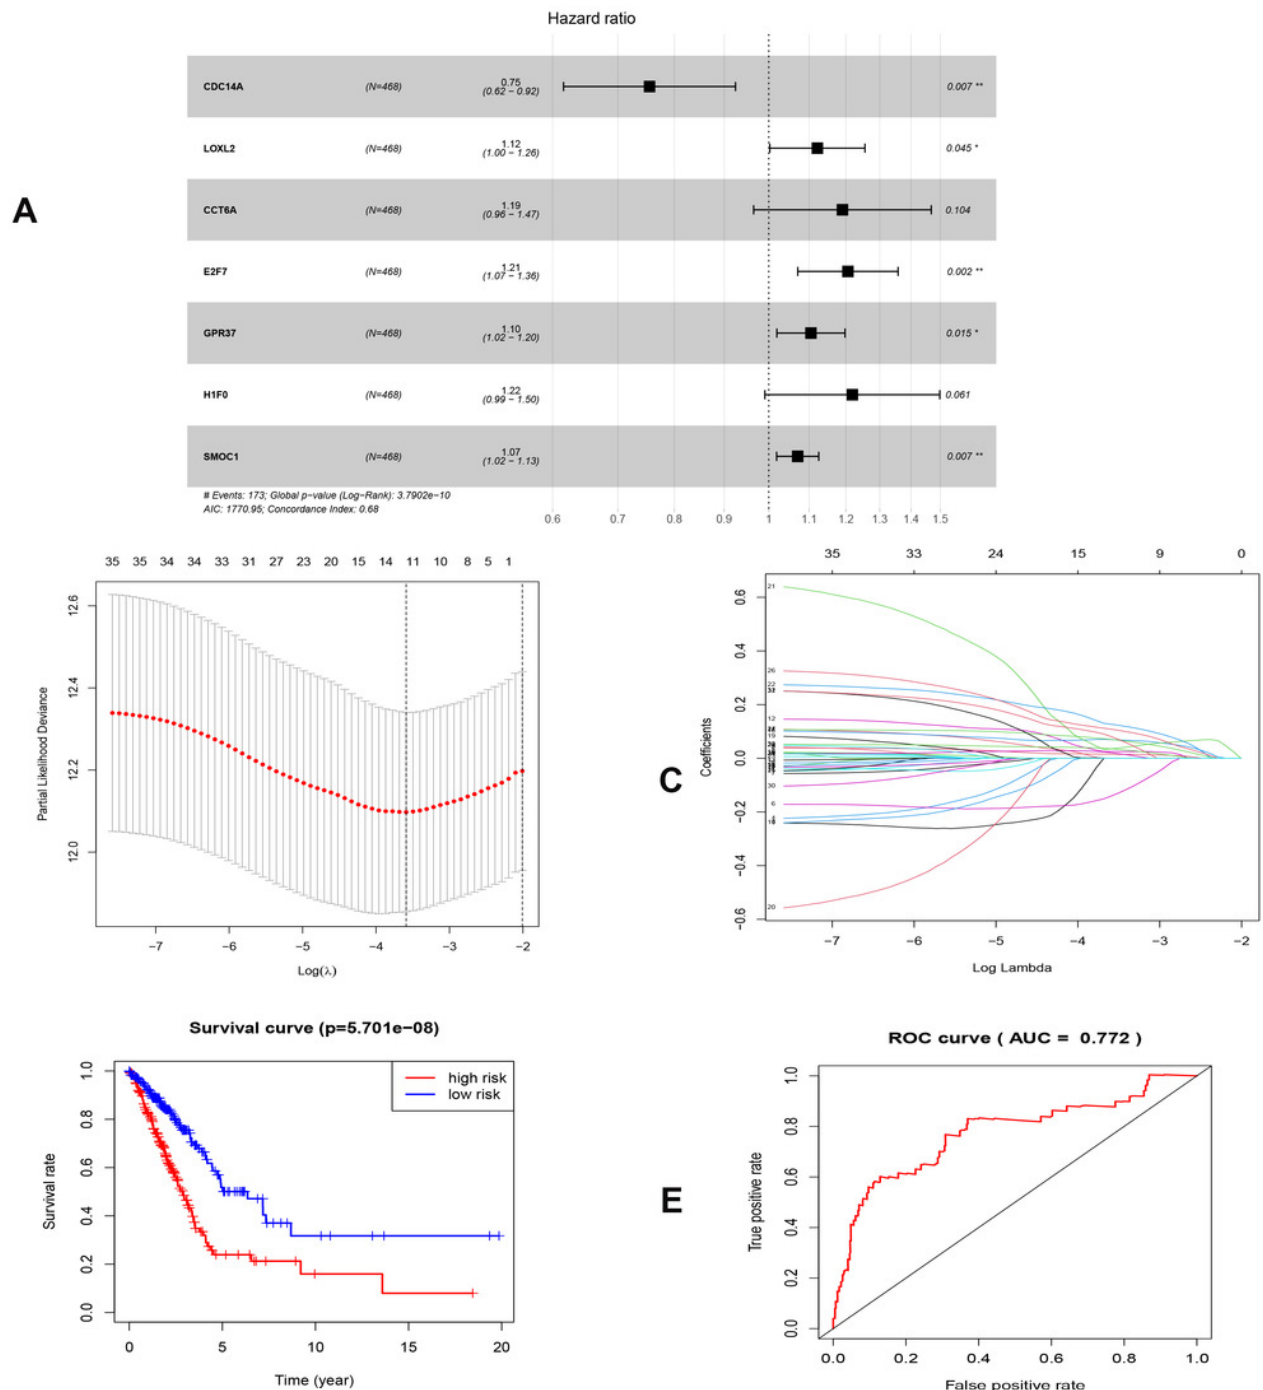

Figure 5

Figure 5 Nomograms based on key ceRNAs and immune cells.

Nomograms predicting 1-,2- and 3-year overall survival of ceRNAs signatures (**A**) and immune cells signatures (**B**).Calibration curves of the nomogram at the 3 year of ceRNAs (**C**) signatures and immune cells signatures (**D**). Differences in risk scores between >20 smoking years and ≤ 20 smoking years based on ceRNAs (**E**) and immune cells models (**F**).

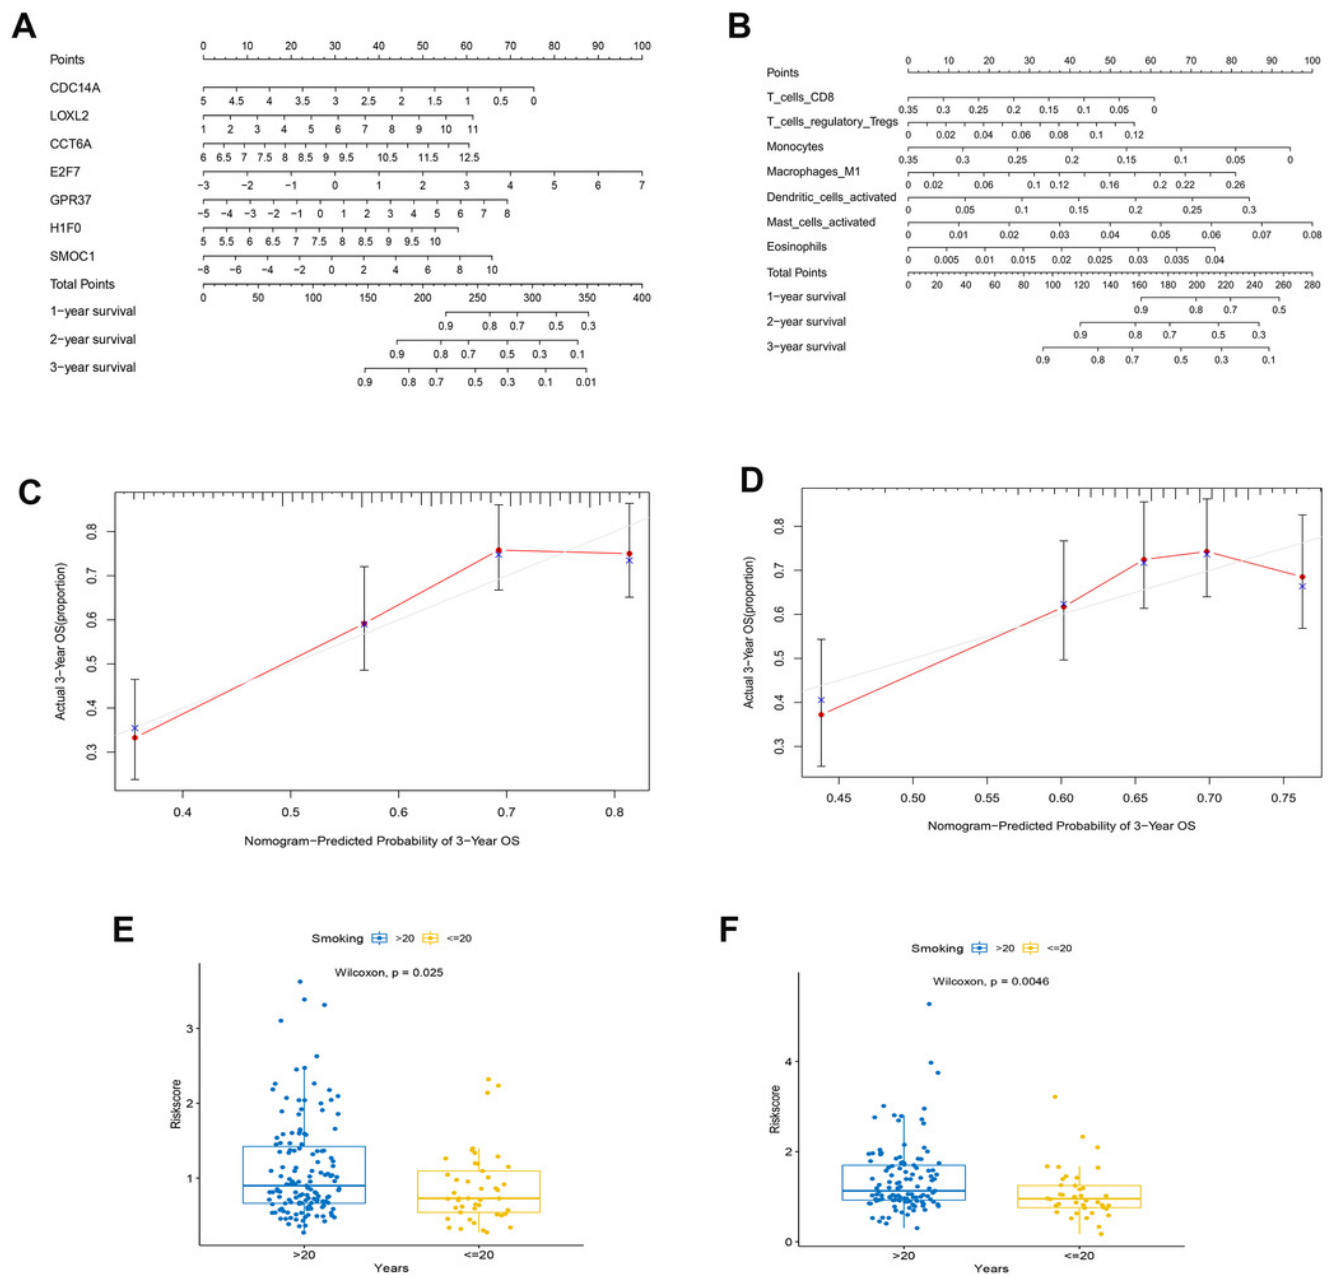

Figure 6

Figure 6 Construction of prognostic model based on key immune cells.

(**A**), multivariate Cox regression. (**B**), (**C**) lasso regression. (**D**) the Kaplan-Meier survival curve. (**E**) the ROC curve. ROC, the Receiver Operating Characteristic.
