Background: The COVID-19 pandemic has led to a spike in deleterious mental health. This dual-center retrospective cross-sectional study assessed the prevalence of depression in young adults during this pandemic and explored its association with various physical fitness measures. **Methods:** This study enrolled 12,889 (80% female) young adults (mean age 20 ± 1) who performed a National Student Physical Fitness battery from December 1st, 2019, to January 20th, 2020, and completed a questionnaire including Beck's Depression Inventory in May 2020. Independent associations between prior physical fitness and depression during the pandemic were assessed using multivariable linear and binary logistic regressions accordingly, covariates including age, dwelling location, economic level, smoking, alcohol, living status, weight change, and exercise volume during the pandemic. Sex- and baseline stress-stratified analyses were performed. **Results:** Of the study population 13.9% of men and 15.0% of women sampled qualified for a diagnosis of depression. After multivariable adjustment, anaerobic (mean change [95% CI], -3.3 [-4.8 to 1.8]) aerobic (-1.5 [-2.64 to -0.5]), explosive (-1.64 [-2.7 to -0.6]) and muscular (-1.7 [-3.0 to -0.5]) fitness were independently and inversely associated with depression for the overall population. These remained consistent after sex- and baseline stress-stratification. In binary logistic regression, the combined participants with moderate, high or excellent fitness also showed a much lower risk compared to those least fit in anaerobic (odd ratio (OR) [95% CI], 0.68 [0.55 to 0.82]), aerobic (0.80 [0.68 to 0.91]), explosive (0.72 [0.61 to 0.82]), and muscular (0.66 [0.57 to 0.75]) fitness. **Conclusions:** These findings suggest that prior physical fitness may be inversely associated with depression in young adults

during a pandemic.

64   **ABSTRACT**

65   **Background:** The COVID-19 pandemic has led to a spike in deleterious mental health. This

66   dual-center retrospective cross-sectional study assessed the prevalence of depression in young

67   adults during this pandemic and explored its association with various physical fitness measures.

68   **Methods:** This study enrolled 12,889 (80% female) young adults (mean age 20 ± 1) who

69   performed a National Student Physical Fitness battery from December 1st, 2019, to January 20th,

70   2020, and completed a questionnaire including Beck's Depression Inventory in May 2020.

71   Independent associations between prior physical fitness and depression during the pandemic

72   were assessed using multivariable linear and binary logistic regressions accordingly, covariates

73   including age, dwelling location, economic level, smoking, alcohol, living status, weight change,

74   and exercise volume during the pandemic. Sex- and baseline stress-stratified analyses were

75   performed.

76   **Results:** Of the study population 13.9% of men and 15.0% of women sampled qualified for a

77   diagnosis of depression. After multivariable adjustment, anaerobic (mean change [95% CI], -3.3

78   [-4.8 to 1.8]) aerobic (-1.5 [-2.64 to -0.5]), explosive (-1.64 [-2.7 to -0.6]) and muscular (-1.7 [-

79   3.0 to -0.5]) fitness were independently and inversely associated with depression for the overall

80   population. These remained consistent after sex- and baseline stress-stratification. In binary

81   logistic regression, the combined participants with moderate, high or excellent fitness also

82   showed a much lower risk compared to those least fit in anaerobic (odd ratio (OR) [95% CI],

83   0.68 [0.55 to 0.82]), aerobic (0.80 [0.68 to 0.91]), explosive (0.72 [0.61 to 0.82]), and muscular

84   (0.66 [0.57 to 0.75]) fitness.

85   **Conclusions:** These findings suggest that prior physical fitness may be inversely associated with

86   depression in young adults during a pandemic.

87   **Keywords:** Depression; Physical fitness; COVID-19.

88   **INTRODUCTION**

89   Since its onset, coronavirus-2019 (COVID-19) has personified overwhelming stresses, stemming

90   from - infections, loss of work, loss of freedoms, isolation, and death, leaving behind an aura of

91   uncertainty amongst the world's citizens. COVID-19 has led to a spike in deleterious mental

92   health issues (Wang et al. 2020), particularly in depression (Brooks et al. 2020). There's concern

93   that such a surge may lead to an increased rate of suicides,(Reger et al. 2020) domestic abuse,

94   economic, and somatic health issues. (Moulton et al. 2015) Hence, evidence-based research is

95   needed to address the rise in depression across multiple populations as a result of COVID-19.

96

97   Physical fitness, particularly cardiorespiratory fitness, and exercise training have repeatedly been

98   shown to be negatively associated with future CVD and diabetes risk (Dun et al. 2019a; Dun et

99   al. 2019b; Myers et al. 2015; Pedersen et al. 2019) as well as having a positive relationship with

100   mental health in multiple populations. (Baumeister et al. 2017; Cho et al. 2019; Kerling et al.

101   2015) Studies have been published on COVID-19 and previous outbreaks and their adverse

102   effects on mental health.(Brooks et al. 2020; Torales et al. 2020) Furthermore, recent studies

103   have alluded to an association between current physical activity and mental health during the

104   pandemic (Lopez-Bueno et al. 2020; Stanton et al. 2020), with a commonality that decreased

105   physical activity appears with lockdowns. However, these studies are largely limited to current

106   physical activity and mental health. To our knowledge, none have explored the possible

107   association between prior multiple physical fitness and pandemic-related depression.

108   From the existing evidence, it may be hypothesized that physical fitness factors are inversely

109   correlated with depression during COVID-19. Therefore, this retrospective cross-sectional

110   study's aims are two-fold: to assess the prevalence of depression in young adults during the

111   pandemic and to investigate the associations between a variety of different measures of physical

112   fitness, including prior anaerobic, aerobic, explosive, muscular, flexibility, and pulmonary fitness

113   on the prevalence of depression during the COVID-19 pandemic.

114

115   **METHODS**

116   **Study design and participants**

117   This retrospective cross-sectional study enrolled two universities (Hunan Traditional Chinese

118   Medical College, Hunan, China, and Medical College of Jinhua Polytechnic, Zhejiang, China)

119   selected by convenience sampling, that performed the Chinese National Student Physical Fitness

120   Standard (CNSPFS) battery between December 1st, 2019 to January 20th, 2020 when

121   government-issued sanctioned lockdowns and social distancing. A total of 14,059 university

122   students who were free of chronic diseases and had completed a CNSPFS were screened. Of

123   these, 13,013 participants (response rate of 93.2%) completed a follow-up questionnaire from

124   May 1st to 23rd, 2020. Participants who provided poor quality questionnaires were excluded (n =

125   124). The criteria of poor quality were: (1) If the ID information in the CNSPFS system did not

126   match that of the follow-up questionnaire; or (2) If the 81-question survey was completed in less

127   than three minutes. A total of 12,889 participants were included in the study. All baseline data

128   were extracted from the CNSPFS system; the data during the COVID-19 pandemic were

129   collected from the survey platform (https://www.wjx.cn). Data from the two time-points were

130   linked by identifying each participant's university student ID number and matching them

131   accordingly. This study was evaluated and approved by the Review Board of Xiangya Hospital

132   Central South University (approval No. 202005126). Written informed consent was documented

133   during the baseline, and digital informed consent was given upon initiating the survey. All

134   participants were codified and anonymized to protect the confidentiality of individual

135   participants.

136

137   **Physical fitness**

138   Fitness measures were obtained from the completion of the CNSPFS battery, and scores were

139   attained through the standardized scoring system that weighted each fitness indicator score by

140   age- and sex-specific percentage. The CNSPFS battery included a 50-m sprint,(Duffield et al.

141   2004) an 800-m (women) and 1,000-m (men),(Margaria et al. 1975) a standing long

142   jump,(Robertson & Fleming 1987) timed sit-ups (women) and pull-ups (men), (Rutherford &

143   Corbin 1994) sit and reach test and vital lung capacity respectively. (Ranu et al. 2011) Anaerobic,

144   aerobic, explosive, muscular fitness, flexibility, and pulmonary fitness were assessed through

145   these tests. The scores were classified as follows: low fitness (<60), moderate fitness (60 - 79),

146   high fitness (80 - 89), and excellent fitness (>90). All tests were administered by trained physical

147   education teachers following the CNSPFS standard operating procedures. The test-retest

148   reliability across all assessments employed as an intraclass correlation coefficient (ICC) > 0.90.

149   The details about performing CNSPFS have been described previously. (Yi et al. 2019; Zhu et al.

150   2017)

151

152   **Baseline stress and depression during the COVID-19 pandemic**

153   Baseline stress was assessed concurrently with the CNSPFS test through a modified question as

154   described previously. (Frazier et al. 2014) Beck's Depression Inventory, second edition (BDI-II)

155   was also administered during the follow-up questionnaire performed in May. (Yang & Stewart

156   2020) The BDI-II is a 21-item self-report questionnaire validated in young Chinese adults (Yang

157   & Stewart 2020; Zhu et al. 2018) and well correlated with a clinical diagnosis of

158   depression,(Moullec et al. 2015) with four response options for each item. The added total scores

159   of the BDI-II can vary from 0 to 63 and are classified as: 0–13 no depression, 14–19 mild

160   depression, 20–28 moderate depression, and 29–63 severe depression. (Beck et al. 1996; Zhu et

161   al. 2018)

162

163   **Covariates**

164   Exercise and physical activity habits were collected through a modified version with added items

165   of the International Physical Activity Questionnaire-Long form-Chinese (IPAQ-LC) which had

166   shown adequate reliability and reasonable validity for use in Chinese students(Macfarlane et al.

167   2011). Questions regarded exercise pre-and during the lockdown, including frequency, duration,

168   and intensity of aerobic exercise and strength exercise. Smoking status and alcohol intake were

169   assessed as daily and weekly consumption, respectively. Socioeconomic status and dwelling

170   location were retrieved from the university databases. Pre-pandemic body weight was assessed at

171   the time of the CNSPFS test, while body weight during the COVID-19 pandemic was obtained

172   via a self-reported questionnaire throughout May 2020. (Ross et al. 2019)

173

174   **Characteristics of Lockdown**

175   The first lockdown order in China was delivered on January 23rd, 2020 by the government of

176   Wuhan, Hubei province, followed by the other provinces across China. The main requirements

177   were: (1) all individuals were ordered to stay home or at their place of residence, except for

178   permitted work, local shopping, or other permitted errands, or as otherwise authorized. (2) all

179   schools, sports facilities, entertainment, and recreational venues, personal care and beauty

180   services, and the majority of factories and markets were closed.

181

182   **Statistical methods**

183   For data of participants' demographics and characteristics, independent t-test and Chi-square test

184   were used for assessment in mean difference between sexes of continuous and categorical

185   variables, respectively.

186

187   The primary outcomes of the present study were the change in BDI-II depression scores

188   (continuous variable) and the presence of depression (categorical variable), defined as a BDI-II

189   score $\geq$ 14, (Beck et al. 1996; Zhu et al. 2018) during the COVID-19 pandemic. The

190   independent variables included prior fitness factors, stress, socioeconomic status, dwelling

191   location, and smoking, alcohol, living status, changes in body weight, and exercise volume per

192   week during the pandemic. The associations between each independent variable and BDI-II

193   depression score change were assessed by univariate analyses. The independent relationships of

194   prior physical fitness factors and BDI-II depression score change were assessed using

195   multivariable linear regression. The associations between prior physical fitness factors and the

196   presence of depression, defined as a BDI-II depression score $\geq$ 14, were evaluated via binary

197   logistic regression in which the lowest level was set as the reference. The variables included in

198   the regression models were demographics, the independent variables mentioned above and

199   potentially associated with depression or those with a *p* value < 0.20 in the univariate analyses

200   were included in the multivariable linear and binary logistic regression analyses. To minimize

201   confounding from baseline psychological status, baseline stress-stratified multivariable linear

202   regression was performed. Analyses were carried out using SAS software, version 9.4 (SAS

203   Institute), a two-tailed alpha level of 0.05 was considered to be statistically significant.

204

205   **RESULTS**

206   **Demographic**

207 Demographics of 12,889 participants are presented in Table 1. Male participants were

208 proportionally a smaller percentage of the population. In the overall population, there were

209 12.2%, 60.6%, and 27.3% of participants that came from lower-income, middle-income, and

210 upper-income families, respectively, and 35.4%, 42.4%, and 22.2% of participants lived in a

211 rural, urban-rural junction, and urban areas, respectively. During the COVID-19 pandemic, 41%

212 and 59% of participants lived alone or with family/friends, respectively.

213

214 **Characteristics of prior physical fitness and prevalence of depression during the COVID-**

215 **19 pandemic**

216 Each of five physical fitness parameters was scored and graded as low fitness (not pass),

217 moderate fitness, good, or excellent according to CNSPFS that was established referring to

218 national physical fitness test data while taking age and sex into account. Across multiple physical

219 fitness tests, the mean score ranged from 53 to 78 in men and 67 to 78 in women, there were

220 significant differences in physical fitness score between sexes ($P<0.001$ for each comparison

221 except pulmonary fitness score). The grade distributions were evaluated by the histogram and

222 conformed to a normal distribution; the majority of participants were graded between moderate

223 and high fitness. Less than 25% of participants were graded as low fitness or excellent. The

224 median BDI-II depression during the pandemic scores were 2 for men and 1 for women

225 ($P<0.001$). Men and women who presented depression made up 13.9% and 15.0% of their

226 respective populations, no significance was found between sexes ($P=0.14$) (More in Table 1).

227

228 **Association between anaerobic fitness and depression during the pandemic**

229 After multivariable adjustment, anaerobic fitness was independently and negatively associated

230 with the BDI-II score. Across four grades, participants with excellent anaerobic fitness had an

231 average BDI-II score that was -3.300 (95% CI, -4.761 to -1.838) points lower BDI-II score than

232 those with low fitness (Table 2 and 3). This finding showed consistency in subjects with and

233 without baseline stress (-2.689 [-4.199 to -1.178]) (Table 4). In binary (participants with

234 depression versus without depression) logistic regression, compared to low fitness participants,

235 participants with an excellent anaerobic fitness had less than half the risk of the presence of

236 depression during the pandemic (OR [95% CI], 0.58 [0.37 to 0.90]), and combined participants

237 with moderate, high or excellent anaerobic fitness also showed a much lower risk 0.68 [0.55 to

238 0.82]) (Figure 1).

239

240 **Association between aerobic fitness and depression during the pandemic**

241 Aerobic fitness showed a similar association with BDI-II score. Across four grades of aerobic

242 fitness, participants categorized as excellent had an average BDI-II score on average -1.521

243 (95% CI, -2.586 to -0.455) lower than those with low fitness (Table 3). This finding was

244 consistent in participants with and without baseline stress (-1.772 [-2.846 to -0.699]) (Table 4).

245 In binary logistic regression, compared to those who had low fitness scores, combined

246   participants with moderate, high, or excellent aerobic fitness grades showed a lower risk of the

247   presence of depression (OR [95% CI], 0.80 [0.68 to 0.91]) (Figure 1).

248

249   **Association between explosive fitness and depression during the pandemic**

250   Explosive fitness was inversely correlated with depression during the COVID-19 pandemic.

251   Participants with excellent explosive fitness had an average of -1.643 (95% CI, -2.673 to -0.613)

252   lower BDI-II score than participants with low fitness (Table 2 and 3). This finding was in

253   participants with and without baseline stress across sex (-1.849 [-2.884 to -0.815]) (Table 4). In

254   binary logistic regression, compared to those with low fitness scores, participants with excellent

255   explosive fitness had a 36% lower risk of the presence of depression (OR [95% CI], 0.62 [0.46 to

256   0.85]), and combined participants with moderate, high or excellent explosive fitness scores also

257   showed a lower risk (0.72 [0.61 to 0.82]) (Figure 1).

258

259   **Association between muscular fitness and depression during the pandemic**

260   Muscular fitness was also independently and negatively correlated with depression. Participants

261   with excellent muscular fitness had an average of -1.713 (95% CI, -2.956 to -0.470) lower BDI-

262   II score than participants with low fitness (Table 3). This finding was consistent in those with

263   and without baseline stress (-2.136 [-3.383 to -0.889]) (Table 4). In binary logistic regression,

264   compared to those who were categorized as low fitness, participants with excellent muscular

265   fitness had less than half risk of the presence of depression during the pandemic (OR [95% CI],

266   0.47 [0.31 to 0.72]), and combined participants with moderate, high or excellent muscular fitness

267   also showed a much lower risk 0.66 [0.57 to 0.75]) (Figure 1).

268

269   **DISCUSSION**

270   This study is the first to examine the relationship between physical fitness across multiple

271   domains and the presence of depressive symptoms during the COVID-19 pandemic. Our data

272   showed that 13.9% of young men and 15.0% of women had BDI scores that qualified them for

273   the diagnosis of depression, which is unexpectedly similar to the level of depression reported

274   previously in older adult populations (16.5%). (Wang et al. 2020) Findings that are particularly

275   implicative as both depression and low physical fitness are risk factors for future CVD and

276   diabetes. (Moulton et al. 2015; Myers et al. 2015; Pedersen et al. 2019) This study further

277   explored the association between previous levels of explosive, anaerobic, flexibility, and

278   pulmonary domains of fitness, with depression. Our data demonstrate that apart from flexibility

279   and pulmonary fitness, all of these fitness parameters were independently inversely associated

280   with depression in young adults free from chronic diseases.

281

282   Depression and depressive symptom severity vary in individuals, and at different periods, at

283   times, it may impact functional capabilities, whose effects are deleterious on individuals'

284   physical and psychological wellbeing. While the etiology of depression remains largely

285   unknown, the onset of depression may come in various forms, ranging from physiological

286   factors, psychological factors, and those coming from an individual's environment. Both chronic

287   and acute stresses are believed to play an integral part in the development of depression. Chronic

288   stress, encompassing long-term negative environmental circumstances, such as financial

289   difficulties; conflictual relationships with family, friends, or romantic partners (Hammen et al.

290   2009), acute stresses coming from episodes of stress such as those environmental or from

291   personal loss. The COVID-19 pandemic and lockdowns have led to a surge in negative emotions

292   and increased depression(Choi et al. 2020; Lei et al. 2020).

293

294   Recent research has shown that anaerobic training to be inversely associated with depression

295   severity independent of aerobic activity. (Cangin et al. 2018) Our research showed for the first

296   time that anaerobic fitness was the greatest predictor of a lower BDI-II score among the fitness

297   parameters. After stratification of baseline stress, increasing levels of fitness were significantly

298   correlated with lower BDI-II scores in a near dose-response fashion, with those with the highest

299   fitness being less likely to be depressed (Table 4). Furthermore, in conjunction with previous

300   research,(Harvey et al. 2018; Kerling et al. 2015) our findings showed that aerobic fitness was

301   independently associated with lower depression scores. A number of studies have found that

302   aerobic exercise is an effective therapy for moderate forms of depression while also showing it

303   may be equally effective compared to other traditional methods of psychotherapy. The

304   association of aerobic fitness with lower levels of depression is not limited to young adults as

305   longitudinal studies have similar results in reducing depression in middle-aged and older

306   individuals and younger adults. (Jaworska et al. 2019)

307

308   Muscular fitness was measured through two strength tests to best evaluate for muscular strength

309   and endurance, given the variability of muscular fitness across sexes. Muscular fitness and its

310   inverse association with depressive symptoms have been previously investigated(Marques et al.

311   2020). This association was also shown in this study after multivariable analysis, showing that

312   participants in the highest subset of muscular fitness demonstrated a BDI-II score lower than

313   participants with low scores. These findings are consistent with those found during pre-pandemic

314   conditions, where increased handgrip strength as well as comprehensive muscular fitness appears

315   to act as a buffer against depressive symptoms and are associated with improvements in

316   depression. (Krogh et al. 2009; Suija et al. 2013) Previous large-scale observational studies

317   suggested that muscular fitness may even have greater effects than those associated with aerobic

318   fitness in the reduction of depression. (Bennie et al. 2019) Our findings extend those of others, in

319   that we found muscular fitness to be associated with lower depression scores during the COVID-

320   19 pandemic. Moreover, Explosive fitness, utilizing the phosphocreatine system (Baker et al.

321   2010), was found to be independently and inversely associated with depressive symptoms, with

322   the highest level of explosive fitness being associated with a lower BDI-II score. Furthermore,

323   individuals in the highest explosive fitness level had less than half the associated risk of

324   depression than individuals in the lowest levels. This is a particularly interesting finding as it

325 appears to suggest that different types of fitness than those reported elsewhere (Ren et al. 2020)

326 may have an effect of protection from depressive symptoms. Future prospective cohort or

327 intervention studies are required to better elucidate the relationships between explosive fitness

328 and the risk of depressive symptoms.

329

330 Physical fitness and its inverse relationship with depression could be brought about through

331 increased physical activity and exercise. Accumulating evidence suggests that exercise could be

332 associated with primary monoamines, whereby higher amounts of exercise have a positive

333 impact on neurotransmitter systems that regulate primary monoamines, dopamine, noradrenaline,

334 and serotonin. (Dishman 1997; Poulton & Muir 2005) As well as having a positive effect on

335 physiological states, regular exercise and higher fitness could impact psychological states.

336 Mental resilience may be improved through exercise and attainability of higher fitness,(Childs &

337 de Wit 2014) as persons who feel or believe themselves to be healthier may be less inclined to

338 fear the COVID-19 pandemic or at least feel more resilient against it. This has been

339 demonstrated as those with higher mental resilience were less likely to be depressed, (Kirby et al.

340 2017) as participation in regular exercise can usually distract individuals from noxious stimuli,

341 thereby improving depression. Furthermore, since exercise is often extrinsic, increased self-

342 efficacy and self-esteem, garnered from higher muscle mass and fitness could lead to improved

343 mental health. (Blumenthal et al. 2007)

344

345   While this study provides certain insights into the associations through which higher physical

346   fitness levels in several parameters of fitness is related to a decreased risk of depressive

347   symptoms, the causation between fitness parameters and depressive symptoms could not be

348   established due to the cross-sectional study design. Associations between fitness measures and

349   depressive symptoms in young adults may be bidirectional. Studies have indicated that previous

350   depression could be a factor in the cessation of exercise, and the development of a sedentary

351   lifestyle since those with depression may have lower self-worth, and confidence, increased self-

352   criticism, and unwarranted guilt. (Faulkner et al. 2014; Ren et al. 2020) Future prospective

353   cohort or intervention studies are required to better elucidate the relationships between fitness,

354   particularly anaerobic and explosive fitness, and the risk of depressive symptoms.

355

356   Furthermore, the sample was selected through convenience sampling and therefore may be

357   subject to a degree of information bias, may not be representative of the whole population, and

358   variations within individuals exist. As is with all cross-sectional studies, our data demonstrate an

359   association between physical fitness and prevalence of rather than incidence of depression during

360   the COVID-19 pandemic, although baseline stress status was included as a covariate in all

361   multivariable analyses, and baseline stress-stratified multivariable analysis was performed, with

362   consistent findings. The present study only comprised university-educated Chinese young adults,

363   which potentially limits the generalizability of the findings. However, our findings were

364   consistent among sexes, and with multivariable adjustment of age, baseline stress, geographic

365   attribute, socio-economic level, and smoking, alcohol, living status, changes in weight, and

366   exercise volume during the pandemic. In addition, all findings were consistent in both

367   multivariable linear and binary logistic regressions. It seems plausible that the biologic effects of

368   many factors would be qualitatively similar in other populations.

369

370   **CONCLUSION**

371   Multiple physical fitness parameters are inversely associated with the prevalence of depression in

372   young adults during the COVID-19 pandemic. These associations were independent of other

373   potential confounders, such as sex, age, baseline stress, dwelling location, socio-economic level,

374   and smoking, alcohol, living status, weight changes, and exercise volume during the pandemic.

375   These findings along with previous research suggest that that techniques and lifestyle

376   management that lead to improved comprehensive fitness including a wider range of muscle

377   groups and energy systems may be considered as a possible approach to help prevent and/or

378   reverse depression during the pandemic.

392

393   **Author Contributions** SXL, YSD and JWR conceived the study. SXL and YSD were involved

394   in securing funding for the study. NJZ, WLZ, YCD, MJC, ZHH, JL and QXL coordinated the

395   study conduct and data collection. YSD did the study analyses, supervised by SXL. YSD and

396   JWR wrote the article, with assistance from RJT, TPO, QXL and SXL. All authors approved the

397   final version of the manuscript. SXL had full access to all the data in the study and had final

398   responsibility for the decision to submit for publication.

Demographics and characteristics of participants pre- and during the COVID-19 pandemic

CI, confidence interval; COVID-19, coronavirus disease-19. Data were expressed as mean ± standard deviation or number (percent) accordingly. † Socio-economic level data was obtained based on residence place of participants and 2019 Chinese Family Income data. A family earning less than ¥14,360 per year was considered a lower-income family; between ¥14,360 and ¥36,470 per year was considered a middle-income family; more than ¥36,470 per year was considered a upper-income family. * Mean difference (95% CI) and *P* value are for the comparison between men and women. ‡ Mean difference (95% CI) in percent.

3   CI, confidence interval; COVID-19, coronavirus disease-19. Data were expressed as mean ±

4   standard deviation or number (percent) accordingly.

5   † Socio-economic level data was obtained based on residence place of participants and 2019

6   Chinese Family Income data. A family earning less than ￥14,360 per year was considered a

7   lower-income family; between ￥14,360 and ￥36,470 per year was considered a middle-income

8   family; more than ￥36,470 per year was considered a upper-income family.

9   * Mean difference was calculated as women subtracted by men, and expressed as mean

10   difference (95% CI). *P* values are for the comparison between men and women.

Univariate linear regression for the relationships between prior physical fitness and depression during the COVID-19 pandemic.

CI, confidence interval; COVID-19, coronavirus disease-19; BDI-II, Becks' Depression Inventory-II. The first level of the ordered categorical variables were used as reference. Data are expressed as BDI-II score change related to each variable.
