

Motor neurons in the escape response circuit of white shrimp (*Litopenaeus setiferus*)

Zen Faulkes

Many decapod crustaceans perform escape tailflips involving giant interneurons, which includes a specialized fast flexor motor giant (MoG) neuron, and populations of larger, less specialized fast flexor motor neurons and fast extensor motor neurons. These escape-related neurons are well described in crayfish (Reptantia), but not in more basal decapod groups. To clarify the evolution of the escape circuit, I examined the fast flexor and extensor motor neurons of white shrimp (*Litopenaeus setiferus*; Dendrobranchiata) using backfilling. In crayfish, the MoGs in each abdominal ganglion are a bilateral pair of separate neurons. In *L. setiferus*, the MoGs have massive, possibly syncytial, cell bodies and fused axons. The non-MoG fast flexor motor neurons and fast extensor motor neurons are generally found in similar locations to where they are found in crayfish, but the number of motor neurons in both the flexor and extensor pools is smaller than crayfish. The loss of fusion in the MoGs and increased number of fast motor neurons in reptantian decapods may be correlated with an increased reliance on non-giant mediated tailflipping.

13 **ABSTRACT**

14 Many decapod crustaceans perform escape tailflips involving giant interneurons, which
15 includes a specialized fast flexor motor giant (MoG) neuron, and populations of larger,
16 less specialized fast flexor motor neurons and fast extensor motor neurons. These
17 escape-related neurons are well described in crayfish (Reptantia), but not in more basal
18 decapod groups. To clarify the evolution of the escape circuit, I examined the fast flexor
19 and extensor motor neurons of white shrimp (*Litopenaeus setiferus*; Dendrobranchiata)
20 using backfilling. In crayfish, the MoGs in each abdominal ganglion are a bilateral pair of
21 separate neurons. In *L. setiferus*, the MoGs have massive, possibly syncytial, cell
22 bodies and fused axons. The non-MoG fast flexor motor neurons and fast extensor
23 motor neurons are generally found in similar locations to where they are found in
24 crayfish, but the number of motor neurons in both the flexor and extensor pools is
25 smaller than crayfish. The loss of fusion in the MoGs and increased number of fast
26 motor neurons in reptantian decapods may be correlated with an increased reliance on
27 non-giant mediated tailflipping.

Decapod crustaceans escape from predators and other sudden stimuli by tailflipping. The neural basis of escape tailflips has been well-studied (Wine & Krasne 1972; Wine & Krasne 1982; Edwards, Heitler & Krasne 1999; Krasne & Edwards 2002; Faulkes 2008), particularly in Louisiana red swamp crayfish (*Procambarus clarkii*). The core of the escape circuit consists of medial giant interneurons (MGs) and lateral giant interneurons (LGs) that drive fast flexor motor neurons, including a specialized fast flexor motor giant (MoG) neuron. Some of these neurons are found in non-decapod crustaceans (Silvey & Wilson 1979), indicating that having this escape circuit is an ancestral condition for the decapods.

Crustacean escape behaviour is an excellent model for studying the evolution of neural circuits. First, the behaviour has an obvious survival value (Herberholz, Sen & Edwards 2004). Second, many of the responsible neurons have no function other than escape. Third, the core neurons responsible for escape should be found in thousands of species. There are over 14,000 decapod crustacean species (De Grave et al. 2009), and perhaps 50% may have both MGs and LGs (Faulkes 2008). Indeed, many curious features of the neural circuit cannot be understood without thinking about the evolutionary history of the circuit (Edwards, Heitler & Krasne 1999; Krasne & Edwards 2002), leading Krasne and Edwards (2002) to write, “it may follow that reasonable understanding of the nervous system may be impossible without evolutionary analysis, a most sobering possibility.”

Most escape circuit research has been done on crayfish, which belong to Reptantia, a more derived taxon of decapod crustaceans. The more basal decapod taxa, Dendrobranchiata, Caridea, and Stenopodidea (Dixon, Ahyong & Schram 2003;

Porter, Perez-Losada & Crandall 2005) are less well studied, but it is already known that these shrimps and prawns differ in several ways from crayfish. First, crayfish neurons are unmyelinated, but giant interneurons are myelinated in all three non-reptantian taxa (Holmes, Pumphrey & Young 1941; Heuser & Doggenweiler 1966; Xu & Terakawa 1999). Because of the combination of giant interneurons and myelin, shrimp giant axons have the fastest conduction velocity known (Xu & Terakawa 1999). Second, the left and right fast flexor motor giant neurons (MoGs) are separate in crayfish (Mittenthal & Wine 1978), but the MoG axons fuse in caridean shrimp and prawns (Johnson 1924; Holmes 1942; Friedlander & Levinthal 1982). Axonal fusion may promote greater synchrony in muscle activation, which should in turn lead to more powerful tailflips. This should reduce response latency, leading to greater chance of escape. It is surprising that this has been lost in crayfish. Third, at the behavioural level, crayfish giant mediated tailflips are stereotyped and propel the animal in a single plane (Reichert & Wine 1983), but some shrimp can perform a lateral roll during an escape tailflip (Arnott, Neil & Ansell 1998). It is not known how shrimp achieve this, particularly given the bilateral fusion of the MoG axons.

Dendrobranchiate shrimp are the most basal decapod crustacean taxa (Dixon, Ahyong & Schram 2003; Porter, Perez-Losada & Crandall 2005), and thus are in an interesting position for evolutionary studies of the escape response, but little is known about the motor neurons involved in that group. Here, I examine the fast flexor and fast extensor motor systems of white shrimp, *Litopenaeus setiferus*. Some of this work has been presented in abstract (Faulkes 2007).

METHODS

Live white shrimp, *Litopenaeus setiferus* (Linnaeus, 1767), fished from waters around South Padre Island, Texas, were purchased from commercial seafood stores in Port Isabel, Texas and housed in aquaria. Individuals were anaesthetized by chilling on ice and dissected in physiological saline. The abdominal nerve cord was removed.

Neurons were backfilled (Pitman, Tweedle & Cohen 1972; Quicke & Brace 1979; Altman & Tyrer 1980; Jones & Page 1983). The nerve containing the neurons of interest was placed in a well of petroleum jelly containing 0.3 M solution of either nickel chloride or cobalt chloride, while the remaining tissue was bathed in physiological saline (mM: 410 NaCl, 12.7 KCl, 10.3 CaCl₂, 10 MgCl₂, and 14 Na₂SO₄, 10 tris[hydroxymethyl]aminomethane (Trizma Base); pH adjusted to pH 7.4). The tissue was incubated in a refrigerator for 7-18 hours, precipitated with ammonium sulfide or dithiooxamide (a.k.a. rubeanic acid; this term is used hereafter), fixed in 4% formalin in saline, dehydrated with a progressive ethanol series (70% for 10 minutes, 90% for 10 minutes, 100% for 10 minutes, and 100% again for 5 minutes), and cleared in methyl salicylate. When precipitated with ammonium sulfide, neurons containing cobalt or nickel ions turn black or gray. When precipitated with dithiooxamide, neurons containing cobalt ions turn yellow, and those containing nickel ions turn blue (Quicke & Brace 1979; Jones & Page 1983). Neurons containing some mixture of the two ions turn an intermediate colour, ranging from dark orange to purplish-red (Quicke & Brace 1979; Jones & Page 1983).

The third nerve (N3) was filled 42 times in 30 abdominal ganglia of 14 individuals. The second nerve (N2) was filled 98 times in 61 ganglia of 23 individuals.

Abdominal ganglia 1 through 5 were filled, although most fills were of the anterior four ganglia. Because backfills are often incomplete, the number of cells reported is the maximum number of cells seen across multiple individuals.

Cleared backfills were viewed on an Olympus CX41 microscope, and photographed using an attached Olympus C-5050Zoom digital camera. Images were assembled into final figures using Corel Photo-Paint 12. Some large images were stitched together from multiple photographs.

RESULTS

Fast flexor motor neurons

The non-MoG fast flexor cell bodies are found in three clusters (Figure 1), as in other decapods (Mittenthal & Wine 1978). The flexor medial contralateral (FMC) cluster is contralateral and anterior of the filled N3 (in the terminology of Mittenthal and Wine, “posterior” refers to the position of the axon relative to the cell body). The flexor posterior ipsilateral (FPI) cluster is ipsilateral and anterior of the filled N3. The flexor anterior contralateral (FAC) cluster of cell bodies is contralateral and posterior to the filled N3. As in other species (Mittenthal & Wine 1978), there is segmental variation in the number of cell bodies in each ganglion, with the more posterior showing the greatest deviation (Table 1). White shrimp have one or two fewer cell bodies in each cluster than most other decapods examined to date (Table 2). The FMC cell bodies are more widely separated in *L. setiferus* than crayfish, with one anterior of the MoG cell body and near the midline, and the other more posterior and lateral of the MoG cell body. Although this separation means these two cells would not normally be described

as being in a “cluster,” the FMC in other species is rarely a tight grouping of cell bodies. Fast flexor cell bodies are often pairs or singletons, depending on the number, somewhat separated from other cells in the cluster; e.g., Figure 3a, b in Espinoza et al. (2006); see also Mittenthal & Wine (1978).

The MoG cell bodies in *L. setiferus* have a variegated appearance, irregular shape, and press closely together so that they look like one large mass covering much of the ventral surface of the abdominal ganglion (Figure 2, Supplemental Video 1). They are not two widely separate, bilateral, spherical cell bodies reported in caridean prawns (Holmes 1942). In *L. setiferus*, each MoG is ~300 μm across the ventral surface of the ganglion, and about 100 μm when viewed in the sagittal plane. Other fast flexor motor neurons in *L. setiferus* are ~50-100 μm in diameter.

Two lines of evidence show the MoG axons are fused bilaterally. First, when the N3 of one side is filled with cobalt chloride and the other N3 is filled with nickel chloride and precipitated with rubeanic acid, the MoG cell bodies are dark red, clearly distinct from the blue and yellow of the other cells filled by a single nerve (Figure 1, Figure 2A, B), indicating they are filled with a mixture of both chemicals. Second, a single medial axon is visible in the cord between ganglia, which bifurcates and leaves both the left and right N3 (Figure 3). Although the MoG cell bodies are pressed so close together to be sometimes indistinguishable as two cell bodies (e.g., Figure 2B), two axons emerge from the MoG cell bodies (Figure 2A), project dorsally a short distance within the ganglion before fusing as previously reported (Johnson 1924; Holmes 1942), continuing into the nerve cord as one axon until slightly anterior of the point where N3 exits the body, when it bifurcates and sends a branch both left and right (Figure 3B, C).

The fast flexor motor axons appear slightly “haloed” (Figure 3C) compared to the smooth axons seen filled through N2 (Figure 4).

Fast extensor motor neurons and other N2 neurons

In crayfish, the second nerve (N2) of abdominal ganglia is a mixed nerve that splits some distance from the ganglion. The anterior branch (N2a) contains tactile afferents (Leise, Hall & Mulloney 1987). The posterior branch (N2p) contains fast extensor motor neurons (Treistman & Remler 1975; Drummond & Macmillan 1998), slow extensor motor neurons (Drummond & Macmillan 1998), and neurons associated with muscle receptor organs (MROs) (Leise, Hall & Mulloney 1987).

In *L. setiferus*, N2 splits into two branches very near the ganglion, with the anterior branch slightly thicker than the posterior. Fills from N2a revealed many fine processes projecting to the middle of the ganglion and no cell bodies (Figure 4A). This is a probably a purely sensory branch containing only tactile afferents, as in *Pacifastacus leniusculus* (Leise, Hall & Mulloney 1987).

Many cell bodies fill through N2p (Figure 4B). Reasonable hypotheses about the identity of cell bodies can be based on their sizes and putative homology with other species (Table 3). Fast extensor motor neurons are usually double or more the diameter of slow extensor motor neurons (Otsuka, Kravitz & Potter 1967; Wine & Hagiwara 1977), although the largest slow extensor motor neurons approach the size of the smallest fast extensor neuron (Wine & Hagiwara 1977; Drummond & Macmillan 1998). Fills of N2p revealed four large cell bodies located along the posterior margin of the ganglion, one contralateral and three ipsilateral, which are putative fast extensor motor neurons. All abdominal ganglia showed this pattern and no segmental variation

was evident. In other decapods, the contralateral cell body is an inhibitory motor neuron and the ipsilateral cell bodies are excitatory motor neurons (Otsuka, Kravitz & Potter 1967; Treistman & Remler 1975; Wine & Hagiwara 1977); the same is likely true in *L. setiferus*.

The other small cell bodies filling through N2p are located in several places. One is found contralateral and posterior, near the putative fast extensor inhibitor; about 3-5 small cell bodies sit along the posterior lateral margin; two are lateral, sitting in the notch between the exit paths of N1 and N2; one small cell body is located anterior of the exit point of N1 (seen in abdominal ganglia 1 and 2; presence in other ganglia unknown); one small cell body is near the exact center of the ganglion.

Two axons from N2p bifurcate near the midline, and send processes both anterior and posterior for unknown distances (Figure 4C). These are almost certainly axons of the stretch receptors of MROs, which have been described in many species, and are almost always present as a pair of bifurcating axons (Sillar & Heitler 1985a; Leise, Hall & Mulloney 1987; Wallis et al. 1995).

At least three small axons turn posterior and run along the lateral margin of the nerve cord (ganglia 1-3); one exceptionally clear fill in ganglion 1 revealed five such axons. I was unable to fill any cell bodies associated with these axons; fills rarely extended past the exit point of N3. Despite this incomplete picture of their anatomy, these neurons are probably accessory neurons related to the MROs (Wine & Hagiwara 1977; Leise, Hall & Mulloney 1987). There are 4 accessory neurons in abdominal ganglion 2 of *Procambarus clarkii* (Wine & Hagiwara 1977)

The backfilled axons of fast extensor motor neurons do not have the “haloed” appearance of fast flexor motor neurons.

DISCUSSION

The fast flexor motor giant neurons (MoGs) in *Litopenaeus setiferus* have a structure unlike that reported for any other decapod crustacean. Two aspects of the structure of the MoGs suggest that they may be syncytial cells formed by the fusion of many small neurons. First, they are larger than any other fast flexor motor neurons in this or other species, which are usually ~100 µm in diameter (Otsuka, Kravitz & Potter 1967; Mittenthal & Wine 1978; Sillar & Heitler 1985a; Wilson & Paul 1987; Espinoza et al. 2006). Second, they are not spherical as most other neuron cell bodies are. Third, their variegated appearance suggests they have a different internal structure than other neurons. The hypothesized syncytial structure is reminiscent of the third-order giant neurons in squid stellate ganglia, which are also syncytial cells formed from many cell bodies, and also involved in an escape response (Young 1936; Young 1939). Annelid worms also have syncytial giant neurons (Nicol 1948; Günther 1975) that are involved in escape responses (Nicol 1948; Günther 1975; O’Gara, Vining & Drewes 1982).

Although the size and hypothesized fusion in the MoG cell body fusion is unexpected, it is consistent with the long-known fusion of the MoG axons in other caridean shrimp species (Johnson 1924; Holmes 1942; Friedlander & Levinthal 1982). Given that there are genetic mechanisms to fuse the MoG axons during development (Friedlander & Levinthal 1982), the same mechanisms could be used to fuse cell bodies. Reduction of fusion appears to be an evolutionary trend in the decapods, starting with hypothesized fusion of MoG cell bodies (this study) and axons in

dendrobranchiates (this study; Xu & Terakawa 1999), to fusion of the MoG axons only in carideans (Holmes 1942), to no MoG fusion in reptantians (Mittenthal & Wine 1978).

The remaining fast flexor and fast extensor motor neurons appear to be found in homologous positions to the better studied reptantian species. In almost every case, there are fewer cell bodies in *L. setiferus* than in the homologous groups of neurons in most reptantian decapods. If other non-reptantian species have similarly small numbers of motor neurons, it would suggest that duplication of fast abdominal motor neurons occurred during decapod evolution. The loss or reduction of the massive MoG cell bodies may be correlated with the increased number of fast abdominal motor neurons in reptantians: the amount of ganglionic “real estate” consumed by the MoGs may have constrained the addition of any new fast motor neurons.

The “haloed” appearance of the fast flexors, but not fast extensors, may be indicative of myelination. In *Palaemon serratus*, the MoG axons are myelinated in the periphery, and references to other axons of similar size being myelinated suggest the other fast flexor motor neurons are also myelinated (Holmes 1942).

The smaller number of fast abdominal neurons might indicate that shrimp have less fine grained control over the fast flexor motor muscles than crayfish. In many reptantian crustaceans, the fast flexor muscles are used in two distinct forms of tailflipping. The MoGs and other fast flexor neurons are used in single stereotyped escape tailflips triggered by giant interneurons. The MoGs are not involved in repetitive variable tailflipping, which is controlled by an undescribed system of non-giant interneurons (Reichert, Wine & Hagiwara 1981; Reichert & Wine 1983; Sillar & Heitler 1985b; Wilson & Paul 1987; Faulkes 2004); non-giant tailflipping would be generated by

the remaining pool of fast flexor motor neurons. A larger pool of motor neurons may allow for some of the fine control necessary for such variability. Previously, I suggested that non-giant tailflipping originated at the base of the decapod clade (Faulkes 2008), but I did not express this hypothesis as tentatively as it should have been. It is not known if non-reptantian decapods have variable, non-giant tailflipping behaviour like many reptantians do. Indeed, the myelination of the entire population of fast flexors and the axonal fusion of the MoGs point to a circuit specialized for explosive starts. It may be that tailflipping cannot occur without activity of the giant neurons in shrimp, and that a small pool of neurons is sufficient to generate shrimps' more consistently explosive tailflips. Alternately, the variation in motor neuron number may be trivial and have little functional impact, because crustacean muscles generally have sparse polyneuronal innervation. In *Munida quadrispina*, the FAC cluster of fast flexor motor neurons was lost with no visible change in tailflipping behaviour (Wilson & Paul 1987).

361 cephalopods. *Philosophical Transactions of the Royal Society of London. Series*
362 *B, Biological sciences* 229: 465-505.

1

Fast flexor motor neurons in *L. setiferus*.

Complete fill of all fast flexor neurons, showing both all clusters of motor neuron cell bodies in abdominal ganglia 2 and 3. Cluster labels (FPI, FMC, FAC) shown for cell bodies in blue, filled from nerve shown at right. Bilateral N3 fill of abdominal ganglion 2, with nickel chloride used on N3 shown at right (blue), and cobalt chloride used on N3 shown at left (yellow), precipitated using rubeanic acid. Anterior towards top; ventral view.

2

Motor giant (MoG) cell bodies in *L. setiferus*.

(A) Fast flexor neurons in varying focal planes of abdominal ganglion 2. Same individual in Figure 1; ganglion is anterior to filled nerve. (i) Unlabeled image showing MoG detail. (ii-iv) MoG cell body (outlined in ii) and axons, FMC cell bodies, and FPI cell bodies not visible in a single focal plane. Letters identify yellow cell bodies of neurons filled with cobalt chloride from left nerve; numbers identify blue cell bodies of neurons filled with nickel chloride from nerve shown at right. (B) MoG structure in abdominal ganglion 1. (C) MoG structure in abdominal ganglion 3. Bilateral fills using cobalt chloride and nickel chloride precipitated with rubeanic acid in A-B; fills using cobalt chloride precipitated with ammonium sulphide in C. Anterior toward top; ventral view.

3

Motor giant (MoG) axons in *L. setiferus*.

(A) Lateral view of MoG in abdominal ganglion 3, showing axons projecting from ventral cell bodies. (B) Bilateral fill of N3 in abdominal ganglion 3, showing central position of fused MoG axons compared to other fast flexor motor neuron axons. (C) Unilateral fill of abdominal ganglion 1, showing that fill from one side (top of image) results in axon filling that projects out the other, unfilled nerve (bottom). Fills using cobalt chloride precipitated with ammonium sulphide. Anterior towards left of page. Lateral view with dorsal towards top of page in A, ventral view in B, C.

4

Extensor-related neurons in *L. setiferus*.

(A, B) Bilateral fill of nerve 2 in abdominal ganglion 1. (A) Putative sensory neurons (blue) filled by anterior branch of nerve 2. (B) Motor neurons (yellow) filled by posterior branch of nerve 2. (C) Muscle receptor organ (MRO) axons (blue) filled through posterior branch of nerve 2 in abdominal ganglion 1. Fills made using cobalt chloride and nickel chloride precipitated with rubeanic acid. Anterior towards top.

Table 1 (on next page)

Number of fast flexor motor neurons in each abdominal ganglion of *L. setiferus*.

FMC = flexor medial contralateral; MoG = motor giant fast flexor motor neuron; FPI = flexor posterior ipsilateral; FAC = flexor anterior contralateral

| Abdominal ganglia(on) | FMC (Non-MoG) | MoG | FPI | FAC |
|-----------------------|---------------|-----|-----|-----|
| A1-4 | 3 | 1 | 3 | 1 |
| A5 | 3 | 1 | 2 | 0 |
| A6 | ? | ? | ? | 0 |

2

Table 2 (on next page)

Number of fast flexor motor neurons in abdominal ganglion 2 of different species.

FMC = flexor medial contralateral; MoG = motor giant fast flexor motor neuron; FPI = flexor posterior ipsilateral; FAC = flexor anterior contralateral. ¹ Espinoza et al., 2006, ² Mittenthal and Wine, 1978, ³ Sillar and Heitler, 1985a, ⁴ Wilson and Paul, 1987, ⁵ Otsuka et al., 1967, ⁶ See discussion in Mittenthal and Wine, 1978

| Species | FMC (non MoG) | MoG | FPI | FAC |
|--|---------------|----------------|-----|-----|
| White shrimp (<i>Litopenaeus setiferus</i>) | 2 | 1 | 3 | 1 |
| Spiny lobster (<i>Panulirus argus</i>) ¹ | 3 | 0 | 4 | 3 |
| Crayfish (<i>Procambarus clarkii</i>) ² | 3 | 1 | 4 | 3 |
| American clawed lobster (<i>Homarus americanus</i>) ⁵ | 3 | 1 ⁶ | 4 | 3 |
| Squat lobster (<i>Galathea strigosa</i>) ³ | 4 | 0 | 4 | 2 |
| Squat lobster (<i>Munida quadrispina</i>) ⁴ | 3 | 0 | 4 | 0 |

2

3

Table 3(on next page)

Extensor motor neurons and MRO related neurons of different species.

FEMNs = fast extensor motor neurons; SEMNs = slow extensor motor neurons; EE = extensor excitors; I = inhibitor. ¹ Treistman and Remler, 1975; Wine and Hagiwara, 1977 (but see Leise et al., 1987, which notes that Wine & Hagiwara misidentified some extensor neurons), ² Leise et al., 1987, ³ Drummond and Macmillan, 1998a; Drummond and Macmillan, 1998b, ⁴ FEMNs: Otsuka et al., 1967, SEMNs: Jones and Page, 1986, ⁵ Sillar and Heitler, 1985a; accessory neurons are shown in Figure 9, but the exact number is not mentioned in the text, ⁶ Wallis et al., 1995; assignment of fast and slow based on examination of Figure 5.

| Species | Ganglia | Ipsilateral FEMNs | Contralateral FEMNs | Ipsilateral SEMNs | Contralateral SEMNs | Accessory neurons |
|---|---------|----------------------|------------------------|----------------------|------------------------|----------------------|
| White shrimp (<i>Litopenaeus setiferus</i>) | A1-4 | 3 | 1 | 5? | 1 | 3 |
| Louisiana red swamp crayfish (<i>Procambarus clarkii</i>) ¹ | A1-4 | 5 | 1 (I) | 5 | 1 | 4 |
| Signal crayfish (<i>Pacifastacus leniusculus</i>) ² | A2-5 | 5 | 3 | 4 | 1 | 4 |
| Australian yabby (<i>Cherax destructor</i>) ³ | A3 | 5 | 1 (I) | 5 | 1 | 4 |
| American clawed lobster (<i>Homarus americanus</i>) ⁴ | A1-4 | 3 (EE) | 1 (I) | 4 | 1 | ? |
| Squat lobster (<i>Galathea strigosa</i>) ⁵ | A2 | 4-5 (EE) | 1 (I) | 4 | 1 | 3? |
| Squat lobster (<i>Munida quadrispina</i>) ⁶ | A2-3 | 4 | 1 | 3 | 1 | 3 |
