

# Rainwater chemistry observation in a karst city: variations, influence factors, sources and potential environmental effects

Jie Zeng and Guilin Han

Institute of Earth Sciences, China University of Geosciences (Beijing), Beijing, China

## ABSTRACT

The rainwater chemistry and related air contaminants are used to investigate the rainwater ions sources, variations, and influence factors from 2012 to 2014 in Guiyang city (the typical karst urban area of Southwest China). According to temporal rainwater ion concentrations, the obvious variations were presented in the study period, such as  $\text{Ca}^{2+}$  ( $125\sim 6,652 \mu\text{eq L}^{-1}$ ) and  $\text{SO}_4^{2-}$  ( $11\sim 4,127 \mu\text{eq L}^{-1}$ ). Consequently,  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ ,  $\text{SO}_4^{2-}$  and  $\text{Cl}^-$  are considered as the leading ions. Three critical influencing factors of rainwater ions concentrations, including sources variations, rainfall amount and long-distance migration (rainfall amount > 100 mm) are identified. Based on the typical ionic ratios, source identification suggested that anthropogenic inputs mainly contributed to  $\text{F}^-$ ,  $\text{NO}_3^-$  and  $\text{SO}_4^{2-}$ , while the dusts (crustal sources) are the primary sources of  $\text{Mg}^{2+}$ ,  $\text{Ca}^{2+}$  and  $\text{K}^+$ .  $\text{Cl}^-$  Enrichment in long-distance transport is the main contributor of  $\text{Cl}^-$ . According to the observation of high level of total wet acid deposition, the more detailed spatio-temporal monitoring of rainfall-related acid deposition (particularly sulfur deposition) is required to understand its potential environmental effects in the aquatic ecosystem of the earth surface.

## INTRODUCTION

Wet deposition (rainwater) is a significant sink of atmospheric contaminants, such as sulfur/nitrogen oxides and aerosol (*Benedict et al., 2018; Martins et al., 2019; Wei et al., 2019; Wu et al., 2012; Yang et al., 2019*). Two processes including in- and below-cloud procedures are the keys to the elimination of atmospheric pollutants during the entire precipitation process (*Gonçalves et al., 2002; Xiao et al., 2013*), and the chemical components and pH are varied concomitantly (*Facchini Cerqueira et al., 2014; Larssen et al., 2006*). The chemistry-varied rainwater in different environments can further influence the chemical elemental redistribution and biogeochemical cycles on the earth-surface ecosystem, particularly, aquatic ecosystems (*Bhattarai et al., 2019; Martins et al., 2019*). Furthermore, exploring the rainwater chemistry is beneficial for estimating the local atmospheric quality, which could be applied to identify the sources of atmospheric pollutants based on various physical-chemical procedures of different

pollutants (Cereceda-Balic *et al.*, 2020; Rouvalis *et al.*, 2009; Wei *et al.*, 2020). The previous work has categorized three types of major ions (chemical species) origins in rainwater, including crust sources (terrestrial dust), marine sources (sea-salt input), and anthropogenic sources (human emission) (Jain, Madhavan & Ratnam, 2019; Liu *et al.*, 2013; Xu *et al.*, 2015). All of the source variations, local meteorology, geomorphology, and environmental protect guidelines affect the rainwater chemical species (Cable & Deng, 2018; Szép *et al.*, 2018).

A large number of studies in developed regions (e.g., Europe and the United States) have shown that the rainwater chemical components are relatively homogenous on the large temporal-spatial scale due to the common environmental precautions and unified economic development model (Keresztesi *et al.*, 2019; Keresztesi *et al.*, 2020b; Mullaugh *et al.*, 2015). However, the regional economic development is extremely uneven in rapidly developing China (Wang *et al.*, 2017b). During the different stages of social-economic development, air contaminants types vary greatly (Cable & Deng, 2018; Cong *et al.*, 2015), further changing rainwater chemical species in the environmental system (Jin *et al.*, 2019; Xu *et al.*, 2015). This kind of heterogeneity of rainwater chemistry particularly occurs in the less developed regions of Southwest China (e.g., Guizhou Province), where is the typical continuous distribution area of karst landform over the world (Liu, Han & Zhang, 2020). The rainwater-related studies involved in various karst environmental types (urban, forest and agriculture) (Wu *et al.*, 2012; Xiao *et al.*, 2013). In addition, under the unique geological background of karst landform (such as karst depression and sinkholes), rainfall dominates the migration of surficial material, which makes biogeochemical cycling more sensitive to rainfall event (Qin *et al.*, 2020; Wang *et al.*, 2020; Xu *et al.*, 2020; Yue *et al.*, 2019).

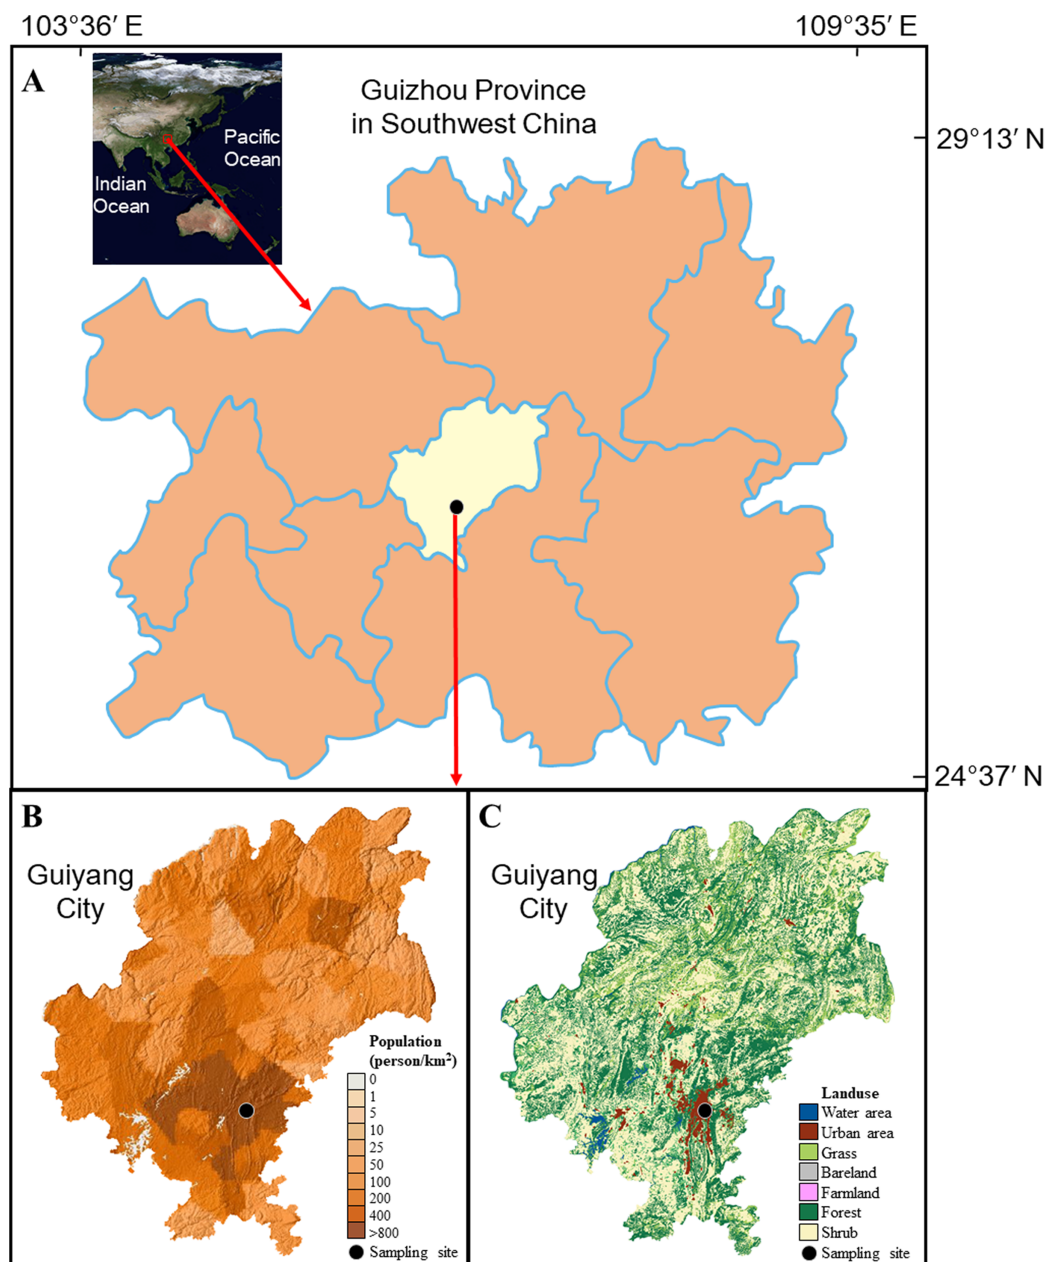

In view of the importance of rainfall processes in karst regions, the in-depth investigation of rainwater chemical compositions in the region is necessary, which significantly benefits the better environmental management and improves the knowledge of karst ecological geochemistry. However, the discussions on acid wet deposition (in the form of rainwater) and its potential environmental effect in karst area in related-studies are relatively rare, so there have been few results for comparison across China.

To advance further knowledge of rainwater chemicals in karst urban area, this study took Guiyang, the most typical karst city in SW China, as a case to conduct a systematic investigation based on the 26 monthly mixed rainwater samples collected in May 2012 to June 2014. The aims are to: (1) investigate the rainwater chemical components in the study period, (2) clarify the seasonal variations of rainwater ions and their influencing factors, (3) identify the potential sources of rainwater ions, and (4) explore the possible impacts of rain-associated acid deposition on environment.

## MATERIALS & METHODS

### Background of study area and sample collection

Guiyang City is the capital of Guizhou Province with a landmass of 8,034 km<sup>2</sup>, located in Southwest China (Fig. 1A), which is one of the continuous largest karst regions over world

**Figure 1** Background of sampling site. (A) the position of Guiyang city; (B) the population density of Guiyang city; (C) the land use of Guiyang city, more details of the surrounding of sampling site can be found in Fig. S1. The data was from Computer Network Information Center of the Chinese Academy of Sciences. [Full-size !\[\]\(ba1b80118482ccef74a5d718ca4d7242\_img.jpg\) DOI: 10.7717/peerj.11167/fig-1](https://doi.org/10.7717/peerj.11167/fig-1)

(Zeng & Han, 2020). This city is encircled by hills (elevation ~1,000 m). The karst geomorphology is widespread developed in Guiyang city and carbonate and clastic rocks control the lithology. Subtropical monsoon climate is the characteristic of this city (air temperature ranges from  $-7.3$  to  $35.1$  °C, with a yearly average of  $15.3$  °C; average relative humidity is 77%) (Xiao et al., 2013). Generally, the seasons can be divided into spring (March to May), summer (June to August), autumn (September to November), and

winter (December to February). Rainfall events mainly happened in wet season (May to October). The annual rainfall amount is 900–1,500 mm.

As a heavily contaminated karst city in southwest China (Liu *et al.*, 2017; Xiao *et al.*, 2013), more than 4.5 million inhabitants are living here, presenting a high population density (550 people per km<sup>2</sup> in 2013). Most of the population is concentrated in the urban area, making the population density up to 800 people per km<sup>2</sup> and the high degree of urbanization (Figs. 1B and 1C, Fig. S1). The large population results in the emission of atmospheric pollutants, e.g., NO<sub>x</sub> derived from high level of traffic (more than 680,000 vehicles in Guiyang city). Since 2003, the air SO<sub>2</sub> concentration in Guiyang has shown a significant decreasing trend, while the air NO<sub>2</sub> concentration increased gradually (Fig. S2A) (Zhang & Ma, 2016). The annual mean concentrations of air SO<sub>2</sub> and NO<sub>2</sub> were 0.031 and 0.033 mg m<sup>-3</sup> in 2013, and 0.024 and 0.031 mg m<sup>-3</sup> in 2014 (Yang, Ge & Wu, 2018; Zhang & Ma, 2016). The annual total SO<sub>2</sub> emission and total NO<sub>x</sub> emission were about 10.6 × 10<sup>4</sup> t and 5.7 × 10<sup>4</sup> t in the study period. The land cover mainly includes water area, urban area, grass land, bare land, farmland, forest, and shrub in the study region (Fig. 1C).

The rainwater samples were collected at the Institute of Geochemistry, CAS, on the central urban built-up area of Guiyang city (26.34 N, 106.43 E, Fig. 1C). This site could well reflect the anthropogenic influence on rainwater in Guiyang city because it is located in the center of the urban built-up area with the highest population density. The polyethylene sampler (set at the place of 15 m over surface) was applied manually to collect rainwater. The polyethylene lid was applied to escape the deposition of atmospheric dust in without-rain days. The sampler was completely cleaned via the deionized-water after each sampling event. The filtration was concluded for each sample by Millipore membrane filters (0.22 μm). The samples after filtration were saved in pre-cleaned polyethylene bottles and kept refrigerated (4 °C). The rainwater samples obtained in each month were proportionally mixed according to the precipitation amount of each precipitation event, and therefore formed a monthly mixed sample. The measured results of mixed sample can denote the monthly weighted-mean values (Jia & Chen, 2010). Ultimately, 26 monthly mixed samples were obtained from May 2012 to June 2014. It is noteworthy that the relatively low rainfall amount was observed in 2013 for Guiyang city with almost no rainfall in July (the dotted box in Fig. S2B). That is, the total rainfall amount in 2013 was 888 mm (only ~70% of the previous annual rainfall), which was also far lower than that in 2012 (1,226 mm) and 2014 (1,562 mm). More details about the daily distribution of rainfall amount can be found in Fig. S3.

### Measurement of rainwater chemicals

Twenty-six samples were divided into two parts and stored in pre-cleaned polyethylene bottles to measure anion and cation concentrations (HNO<sub>3</sub> acidified, pH < 2). The ion chromatography (IC, DX-120; Dionex Corporation, Sunnyvale, CA, USA) was used to determine the concentrations of major anions, such as NO<sub>3</sub><sup>-</sup>, SO<sub>4</sub><sup>2-</sup>, Cl<sup>-</sup>, and F<sup>-</sup> with the limit of detection (LOD) of 0.06, 0.10, 0.04 and 0.03 mg L<sup>-1</sup>. The ICP-AES (IRIS Intrepid-II; Thermo Scientific, Waltham, MA, USA) was applied for detecting the cations

concentrations ( $\text{Na}^+$ ,  $\text{Ca}^{2+}$ ,  $\text{K}^+$ , and  $\text{Mg}^{2+}$ ) with the LOD of 0.03, 0.04, 0.01 and 0.01  $\text{mg L}^{-1}$ .

The procedural blanks, standard reference materials (SRM, GBW08606, National Research Center for Certified Reference Materials, China), and replicates were measured together with all samples to ensure quality control. In brief, the satisfactory repeatability and accuracy for all ions (<5%) were observed in replicate samples and SRM. Moreover, all the measured ions in procedural blank were under the LOD or smaller than 5% of corresponding ions in rainwater samples, implying a trustworthy detected procedure.

### Calculation and correlation analysis

To calculate the volume-weighted mean (VWM) concentrations of rainwater ions in the whole study period (May 2012 to June 2014), the equation below is applied (Zhou *et al.*, 2019):

$$C = \frac{\sum C_i P_i}{\sum P_i} \quad (1)$$

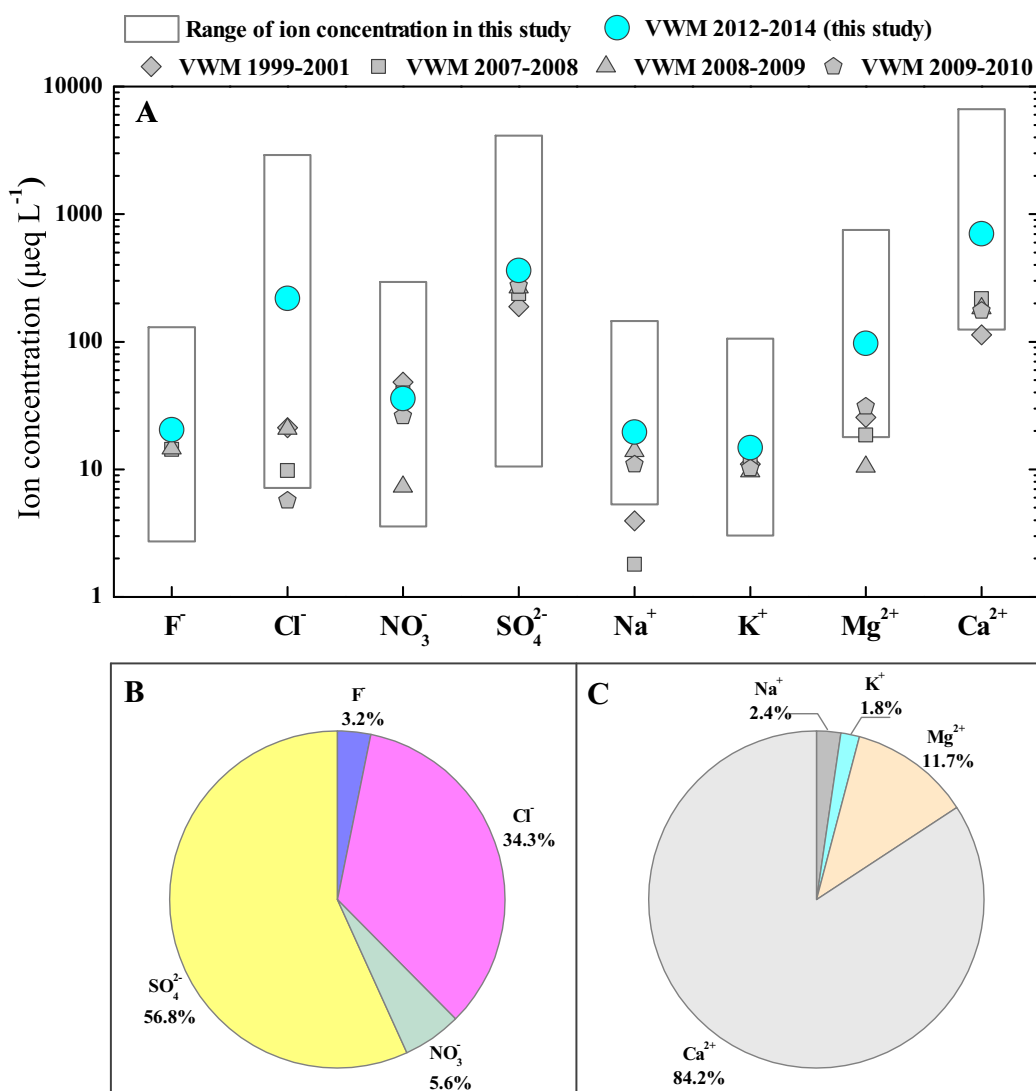

where C,  $C_i$ , and  $P_i$  are the VWM concentration of rainwater ions in the whole study period, the ion concentration of each monthly mixed sample, and the monthly rainfall amount, respectively.

For the statistical analyses of rainwater chemical data, the normal distribution of these data is concluded by the Kolmogorov–Smirnov test (K–S test, a non-parametric test usually used to analyze sample data set in environmental research), and Pearson's correlation analyses is therefore applied for potential ion source identification. The Pearson's correlation coefficient is performed using SPSS 21.0 (IBM, Armonk, NY, USA). Furthermore, the representative air contaminants ( $\text{PM}_{10}$ ,  $\text{NO}_2$  and  $\text{SO}_2$ ) are also involved in correlation analysis to clarify the relationship between these species and rainwater ions.

## RESULTS

The statistical results of rainwater ion concentrations (monthly ranges and annual VWM values) are summarized and plotted in Fig. 2A. The significant variations in each ion concentration are observed in Guiyang city. That is, all the concentrations of rainwater ions presented a large range, e.g. the  $\text{Ca}^{2+}$  concentration ranged from 125 to 6,652  $\mu\text{eq L}^{-1}$  and the concentration of  $\text{SO}_4^{2-}$  fluctuated from 11 to 4,127  $\mu\text{eq L}^{-1}$  (Fig. 2A). Thus, the annual VWM concentrations of each ion are more suitable for comparison. The rainwater ion concentrations in this study followed the sequences based on VWM values:  $\text{Ca}^{2+}$  (700.1  $\mu\text{eq L}^{-1}$ ) >  $\text{Mg}^{2+}$  (97.0  $\mu\text{eq L}^{-1}$ ) >  $\text{Na}^+$  (19.6  $\mu\text{eq L}^{-1}$ ) >  $\text{K}^+$  (14.8  $\mu\text{eq L}^{-1}$ ) and  $\text{SO}_4^{2-}$  (361.4  $\mu\text{eq L}^{-1}$ ) >  $\text{Cl}^-$  (218.3  $\mu\text{eq L}^{-1}$ ) >  $\text{NO}_3^-$  (35.9  $\mu\text{eq L}^{-1}$ ) >  $\text{F}^-$  (20.4  $\mu\text{eq L}^{-1}$ ) (Fig. 2A).

Figures 2B and C presented the percentages of each ion, which indicates that  $\text{SO}_4^{2-}$ ,  $\text{Cl}^-$ ,  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$  are the dominant chemical compositions of rainwater in Guiyang city.  $\text{SO}_4^{2-}$  and  $\text{Cl}^-$  account for 56.8% and 34.3% of total measured anions, which are the most and second richest anion (Fig. 2B). The  $\text{SO}_4^{2-}$  showed the highest percentage, suggesting

**Figure 2** Ion compositions of rainwater in Guiyang city. (A) Overview of rainwater ion contents ( $\mu\text{eq L}^{-1}$ ) of in Guiyang city, data from previous studies was also included (Han & Liu, 2006; Han et al., 2019; Han, Wu & Tang, 2011; Xiao et al., 2013); (B) Rainwater anion composition percentages; (C) Rainwater cation composition percentages. [Full-size !\[\]\(1679558f37f6db0dd8360a2a7e913e90\_img.jpg\) DOI: 10.7717/peerj.11167/fig-2](https://doi.org/10.7717/peerj.11167/fig-2)

the potential effect of strong anthropogenic activities (Keresztesi et al., 2019; Zhou et al., 2019). In Fig. 2C,  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ ,  $\text{Na}^{+}$  and  $\text{K}^{+}$  account for 84.2%, 11.7%, 2.4% and 1.8% of the total detected cations. Thus,  $\text{Ca}^{2+}$  is the absolute leading cation and  $\text{Mg}^{2+}$  is also a more important contributor to cations relative to  $\text{Na}^{+}$  and  $\text{K}^{+}$ . Both geology and urbanization are responsible for the cation compositions. The wide-distributed carbonate in karst region is an important potential source of Ca-enriched dust, which can be washed down by rainfall and further be the significant source of rainwater  $\text{Ca}^{2+}$  (Han et al., 2019). Additionally, vast Ca-contained pollutants were continually discharge into the atmosphere due the accelerated development of urbanization (construction industry and other human activities). The aqueous calcium hydroxide was generally applied to remove

the sulfur dioxide emitted from coal-fired industries (wet desulfurization) (Garea et al., 1996; Wang et al., 2017a), which is another potential source of atmospheric Ca, in particular, since the effective implementation of environmental protection policies, such as National Acid Rain and SO<sub>2</sub> Pollution Prevention Plan (Wen et al., 2020; Yu et al., 2019). In summary, Ca<sup>2+</sup> and Mg<sup>2+</sup> concentrations make up 95.9% of cations, and SO<sub>4</sub><sup>2-</sup> and Cl<sup>-</sup> make up 91.1% of anions.

## DISCUSSION

### Comparison between different zones

We listed the rainwater ion concentration in Guiyang city, together with historical data in Guiyang city, and those published data in various eco-environmental systems (Table 1). In historical comparison, all ion concentrations in the study period (May 2012 to June 2014) were higher than those historical data, with the exception of NO<sub>3</sub><sup>-</sup> that slightly lower than 2007 (Fig. 2A and Table 1) (Han & Liu, 2006; Han et al., 2019; Han, Wu & Tang, 2011; Xiao et al., 2013). In particular, the Cl<sup>-</sup> concentration of this study showed a level comparable to that of oceanic rainwater (Table 1) (Xiao et al., 2016), which reflects that the Cl<sup>-</sup> was underwent the very strong process of enrichment and concentration (indicates potential anthropogenic input) during the transportation of atmospheric clouds (Jain, Madhavan & Ratnam, 2019), while the HCl-released reaction caused Cl<sup>-</sup> depletion was negligible. Overall, rainwater ion concentrations in Guiyang city were on the rise. For the horizontal comparison, the concentrations of most ions (Cl<sup>-</sup>, F<sup>-</sup>, SO<sub>4</sub><sup>2-</sup>, Na<sup>+</sup>, Ca<sup>2+</sup> and Mg<sup>2+</sup>) of rainwater in this study is higher than that in other karst areas (Table 1), including karst agricultural area (Puding), karst forest area (Maolan), Bohemian karst area

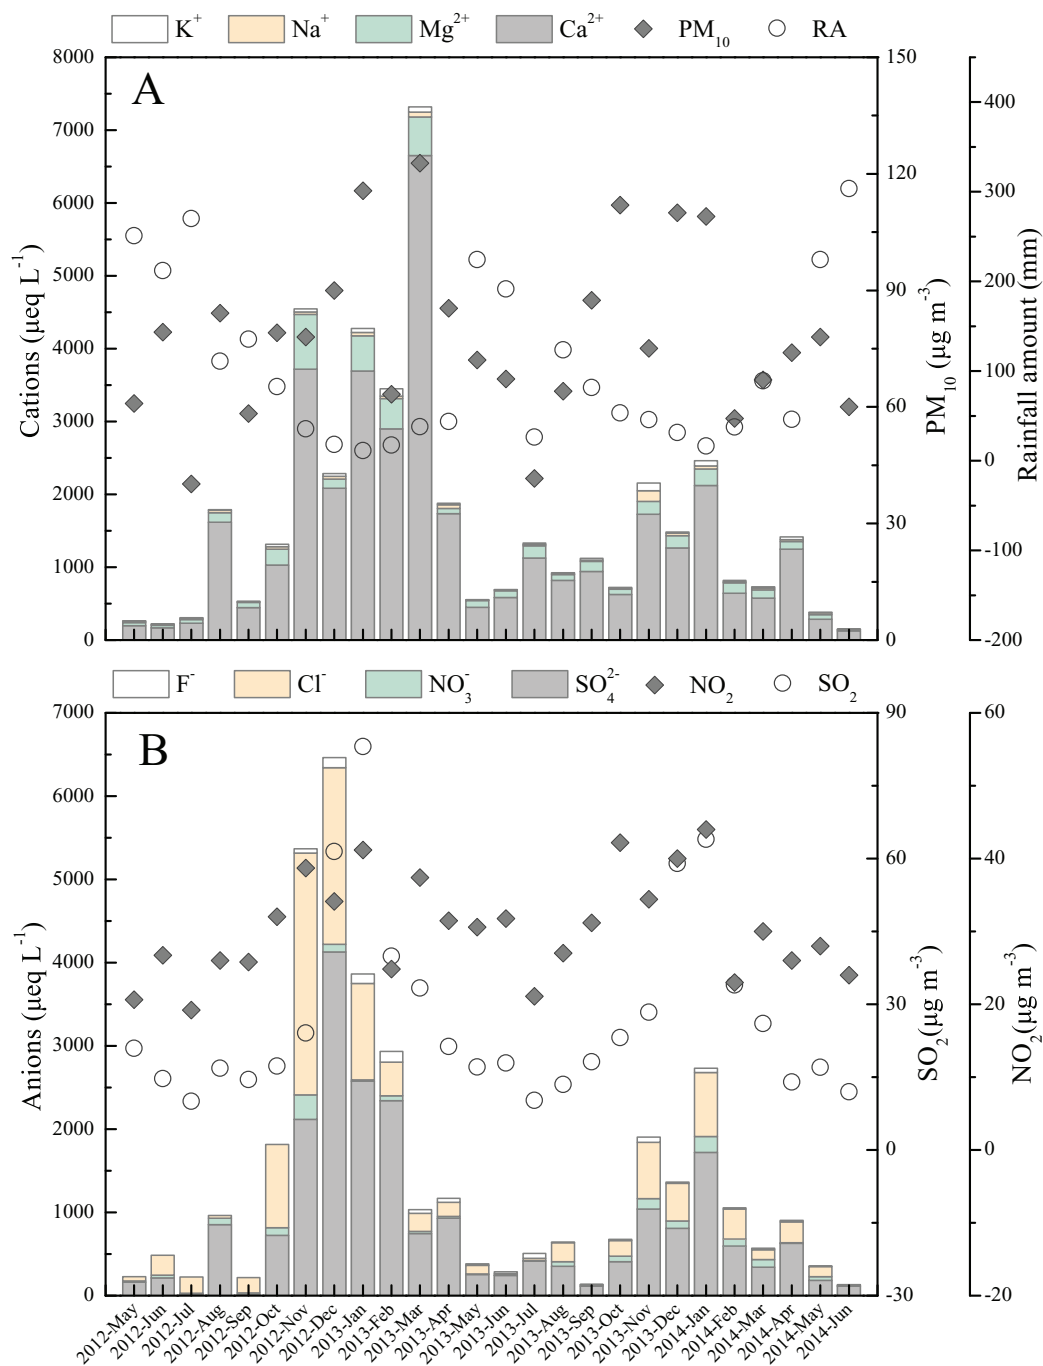

(Prague) (*Špičková et al., 2008; Zeng et al., 2020*). Only the  $K^+$  and  $NO_3^-$  concentrations of rainwater in Guiyang city are lower than those of rainwater in Bohemian karst area (*Špičková et al., 2008*). This reveals the impact of the different intensity of local human emission (e.g., transportation emissions, fossil fuel burning, agricultural production) on rainwater ionic species under various karst environmental types. Moreover, it is noteworthy that the concentrations of  $SO_4^{2-}$  and  $NO_3^-$  (typical human-derived ions) in Guiyang city are close to that in inland megacity (Beijing) (*Xu et al., 2015*), and the concentrations of  $Ca^{2+}$  is even higher than that of desert environment (Alxa) (*Rao et al., 2017*).

### Temporal variation, influencing causes and neutralization coefficients of ion compositions

The highest total ion concentrations were found in cooler months (October to March), while the warmer months (April to September) were accompanied by the lowest concentrations (*Fig. 3*). All ions displayed the parallel temporal change trends, which can be interpreted by two factors. First, the temporal change of potential substance origin is the significant factor of rainwater ions concentrations variation, such as the change of air particulate matter (high content of  $Ca^{2+}$ ) and gaseous air pollutants (*Jain, Madhavan & Ratnam, 2019*). This can be further supported by the observed monthly variations in air  $PM_{10}$ ,  $SO_2$ , and  $NO_2$  content, that is, the high/low concentrations of rainwater  $Ca^{2+}$  was accompanied by high/low air  $PM_{10}$ ,  $SO_2$  and  $NO_2$  content (*Figs. 3A and 3B*). These related parameters show significant positive correlation. The correlation coefficients ( $p < 0.05$ ) are 0.58, 0.74 and 0.51 between  $Ca^{2+}$  and air  $PM_{10}$ ,  $SO_4^{2-}$  and air  $SO_2$ , and  $NO_3^-$  and air  $NO_2$ , respectively. Second, the relative frequent rainfall event in wet season (warmer months) can effectively wash down the various atmospheric components, and further result in the air contaminants could not have a long retention time compared to dry season (warmer months) (*Xiao & Liu, 2002*), while more air components are scoured by rainwater in dry season with little rainfall (*Szép et al., 2019*).

Overall, the ions concentrations presented a converse temporal trend to the precipitation amount from the monthly scale (*Fig. 3*). This revealed that precipitation amount is the important factor impacting rainwater ionic species, which is in agreement to the previous findings (*Keresztesi et al., 2020b; Szép et al., 2018*). The more clear relationship between rainfall amount and ions concentrations were illuminated in *Figs. 4A–4H*. The further correlation analysis of ions concentrations and precipitation amount after logarithmic computation (*Figs. 4I–4P*) revealed that ions concentrations in Guiyang city are observably impacted by the dilution effect (or scouring effect) under large rainfall amount (e.g.,  $r = -0.84$  for  $Ca^{2+}$  and  $r = -0.77$  for  $SO_4^{2-}$ ,  $p < 0.05$ ), which is commonly found in other areas (*Silva, Gonçalves & Freitas, 2009; Szép et al., 2018*). In this scouring process, the air components, such as sulfur/nitrogen oxides, Mg and Ca-mineral, and particulate nitrate (e.g., nitrated phenols (*Li et al., 2020b*)) are powerfully scoured down (below-cloud processes) during the early rain-stage, causing the high ionic concentration observed under the low precipitation amount condition (*Jia & Chen, 2010*). In contrast, without the continuous supplements of gaseous air contaminants or suspended matters,

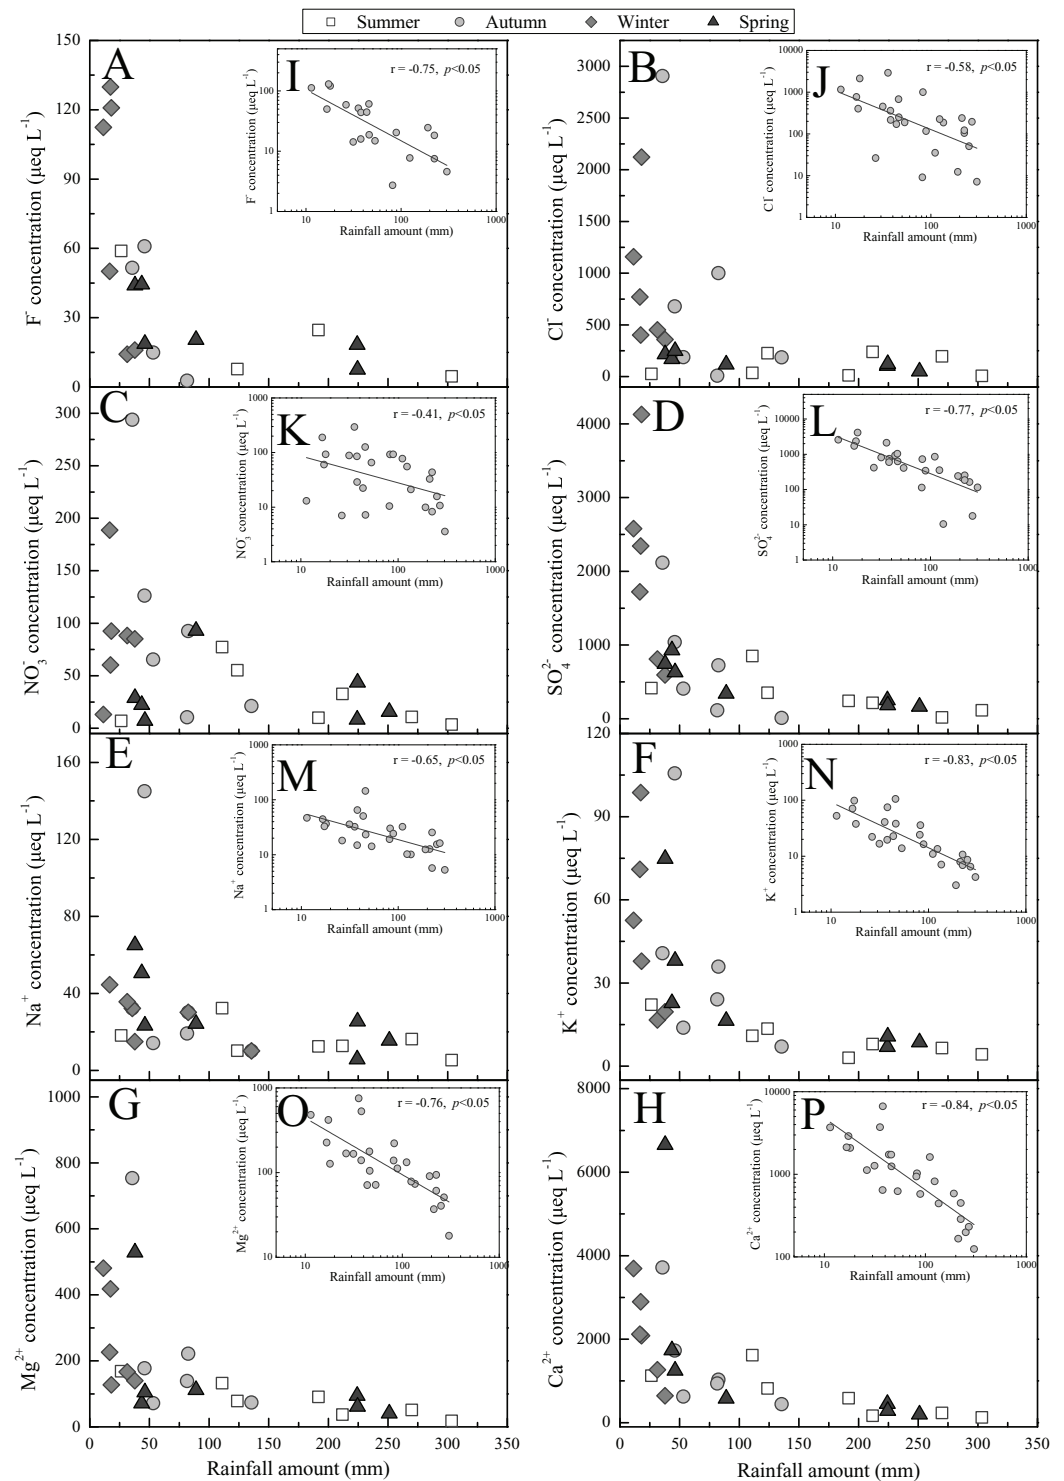

**Figure 3** Monthly variations in ion concentrations and other parameters. (A) Cations concentration, PM<sub>10</sub>, rainfall amount (RA); (B) anions concentration and atmospheric SO<sub>2</sub> and NO<sub>2</sub> content. The PM<sub>10</sub> and air SO<sub>2</sub> and NO<sub>2</sub> data are from literature (Yang, Ge & Wu, 2018; Zhang & Ma, 2016)

Full-size DOI: 10.7717/peerj.11167/fig-3

the ionic concentration of the late rain-stage (prolonged precipitation event) is decreased progressively and stayed at a low content level (Figs. 4A–4H) (Gonçalves et al., 2002). It is noteworthy that the critical point to distinguish between early and late rain-stage is ~100 mm for all ions from Figs. 4A–4H. This indicates that the various species in the

**Figure 4** Relationships between ions concentrations and rainfall amount in Guiyang city from 2012-Summer to 2014-Spring. A–H represent the relationships between rainfall amount and F<sup>-</sup>, Cl<sup>-</sup>, NO<sub>3</sub><sup>-</sup>, SO<sub>4</sub><sup>2-</sup>, Na<sup>+</sup>, K<sup>+</sup>, Mg<sup>2+</sup>, and Ca<sup>2+</sup>; I–P are the corresponding logarithmic ion content vs. logarithmic rainfall amount. Full-size DOI: 10.7717/peerj.11167/fig-4

atmosphere are almost washed down completely within the precipitation of 100 mm, and the similar critical points (different rainfall values) were observed in previous studies (Silva, Gonçalves & Freitas, 2009; Xiao et al., 2013; Zeng et al., 2020). Conversely, if the precipitation amount exceeds 100 mm, the rainwater ion concentrations decreased insignificantly with the increase of rainfall amount and even stayed at a basically constant and very low concentration level (Figs. 4A–4H). At this time, the rainwater ionic contents primarily reveal in-cloud processes, that is, the ionic concentration of rainwater is similar to the cloud-water (gas/aerosols-dissolved cloud drops) (Rao et al., 2017; Silva, Gonçalves & Freitas, 2009). Under such condition (precipitation >100 mm), the scouring effect is negligible, while the long-range transportation is regarded as the most critical reason influencing rainwater ionic compositions (Gonçalves et al., 2002).

To gain more information regarding to the neutralization coefficients of different alkaline ions in rainwater, the VWM concentrations-based neutralization factors (NFs) were calculated according to the equation:  $NF \text{ of } X = [X]/[NO_3^- + SO_4^{2-}]$ , where  $X = Na^+, K^+, Mg^{2+}, Ca^{2+}$  (Xiao et al., 2013). The NF values of  $Na^+, K^+, Mg^{2+}$  and  $Ca^{2+}$  in rainwater at Guiyang city were 0.05, 0.04, 0.24 and 1.76, respectively. These results suggest that  $Ca^{2+}$  is the dominant neutralization alkaline ion in the rainwater, following by the ions of  $Mg^{2+}, Na^+$ , and  $K^+$ , which also indicate the significant potential influence of Ca-enriched substances derived from the construction industry and windblown dust. Furthermore, the enrichment factors (EF) of ions in rainwater relative to the corresponding ions in seawater/crust were calculated as:  $EF_{seawater} = [X/Na^+]_{rainwater} / [X/Na^+]_{seawater}$ ;  $EF_{crust} = [X/Ca^{2+}]_{rainwater} / [X/Ca^{2+}]_{crust}$ , where the ion equivalent ratios of  $[X/Na^+]_{seawater}$  and  $[X/Ca^{2+}]_{crust}$  were followed the previous work (Berner & Berner, 1987; Rudnick & Gao, 2004). The  $EF_{seawater}$  of  $K^+, Mg^{2+}, SO_4^{2-}$  and  $Ca^{2+}$  was calculated as 35, 22, 152 and 814, while the  $EF_{crust}$  of  $K^+, Mg^{2+}$  and  $Na^+$  were 0.05, 0.14 and 0.03. These results significantly suggest that most of the rainwater ions were concentrated relative to the seawater, but depleted relative to the earth's crust.

### Source of major ions

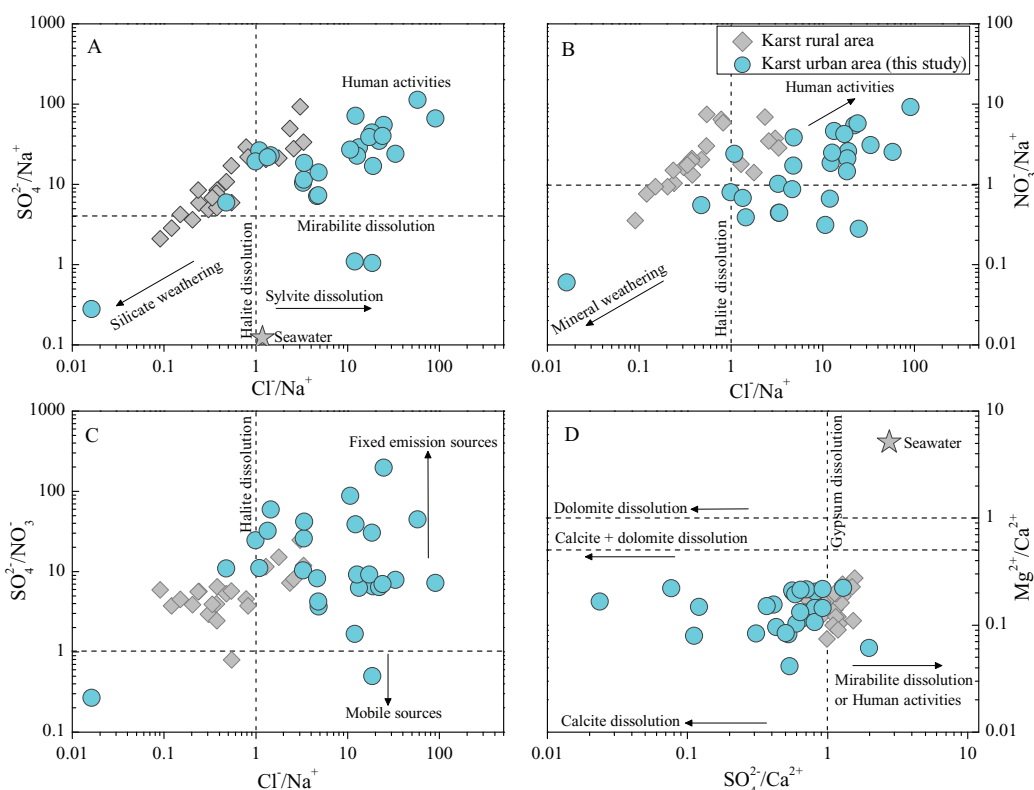

Since the alike physico-chemical natures and potential co-sources of some atmospheric components (e.g.,  $SO_x$  and  $NO_x$ ) (Vet et al., 2014), the correlation coefficient is a frequently-used tool for exploring the common origins of rainwater chemical components (Xing et al., 2019), which is applied in this study. As shown in Fig. 5, the significant negative correlations are presented between precipitation amount and all ions and air pollutants ( $p < 0.05$ ), which further confirms the important effect of precipitation amount on the variations in ionic concentrations. However, obvious positive correlations are observed between most of ion components, such as  $r = 0.85$  for  $Ca^{2+}$  and  $Mg^{2+}$ ,  $r = 0.87$  for  $SO_4^{2-}$  and  $F^-$ ,  $r = 0.77$  for  $SO_4^{2-}$  and  $Cl^-$ , and  $r = 0.45$  for  $SO_4^{2-}$  and  $NO_3^-$  (Fig. 5), it is thereby difficult to obtain further origin information of rainwater ion by correlation analysis.

To identify further the associations of various ions of rainwater and the potential origins, the representative ionic ratios (in equivalent concentration, e.g.,  $Cl^-/Na^+, SO_4^{2-}/NO_3^-$  and  $Mg^{2+}/Ca^{2+}$ ) are presented in Fig. 6A. The low  $Cl^-/Na^+$  ratios (compared with seawater) are only found in few samples, while most samples present a higher  $Cl^-/Na^+$

**Figure 5** Pearson correlation coefficients between major ions in rainwater and other parameters in Guiyang city. RA, rainfall amount; white cells denote statistically non-significant correlations ( $p > 0.05$ ), while other cells denote the significance level of  $p < 0.05$ . Full-size [DOI: 10.7717/peerj.11167/fig-5](https://doi.org/10.7717/peerj.11167/fig-5)

ratio relative to seawater (Berner & Berner, 1987). In total, the rainwater  $\text{Cl}^-/\text{Na}^+$  ratios in this study (karst urban area) are also much greater than that in karst agricultural regions (Zeng et al., 2020). In combined with the high  $\text{Cl}^-$  concentrations (comparable to the  $\text{Cl}^-$  in marine rainwater) and relative low  $\text{Na}^+$  concentrations (Table 1), here we conclude that the sea salt input  $\text{Cl}^-$  was intensively enriched in the transported processes of atmospheric clouds (Jain, Madhavan & Ratnam, 2019; Xiao et al., 2013), while the  $\text{Na}^+$  may be reduced in some degree due the input of other cations. That is, there are other potential sources of  $\text{Cl}^-$  besides marine sources. The relationship between  $\text{Cl}^-$  and the typical anthropogenic inputs  $\text{SO}_4^{2-}$  ( $r = 0.77$  for  $\text{SO}_4^{2-}$  and  $\text{Cl}^-$ ) further support this. Previous work has shown that the chlorinated chemical plants emissions and combustion of chlorinated organics in some coal combustion industries are the important anthropogenic sources of rainwater  $\text{Cl}^-$  (Facchini Cerqueira et al., 2014; Keresztesi et al., 2019; Wu et al., 2012). Moreover, the facilities using large amounts of disinfectants ( $\text{Cl}^-$ -contained) is also another potential source of rainwater  $\text{Cl}^-$ , such as the hospitals near the sampling site (Guizhou Electric Power Workers Hospital, and Guiyang First People's Hospital) and other place (e.g., swimming pool). Thus, here we attributed the high contents of rainwater  $\text{Cl}^-$  were caused by the potential coal combustion industries, disinfectants-used facilities and the  $\text{Cl}^-$  enrichment in long-distance transportation. Furthermore, most rainwater samples present high  $\text{SO}_4^{2-}/\text{Na}^+$  and  $\text{NO}_3^-/\text{Na}^+$  ratios

**Figure 6** The relationship between the ratios of typical ions (equivalent ratio) in karst urban and rural rainwater. (A)  $\text{SO}_4^{2-}/\text{Na}^+$  vs.  $\text{Cl}^-/\text{Na}^+$ , (B)  $\text{NO}_3^-/\text{Na}^+$  vs.  $\text{Cl}^-/\text{Na}^+$ , (C)  $\text{SO}_4^{2-}/\text{NO}_3^-$  vs.  $\text{Cl}^-/\text{Na}^+$ , and (D)  $\text{Mg}^{2+}/\text{Ca}^{2+}$  vs.  $\text{SO}_4^{2-}/\text{Ca}^{2+}$  ratio. Data sources for karst rural rainwater chemistry and other reference values are from (Berner & Berner, 1987; Zeng et al., 2020).

Full-size DOI: 10.7717/peerj.11167/fig-6

(Figs. 6A and 6B), indicating the significant impact of anthropogenic input (human activities), that is, these anions ( $\text{SO}_4^{2-}$  and  $\text{NO}_3^-$ ) are mainly derived from anthropogenic emissions (Keresztesi et al., 2019; Xu et al., 2015). Especially,  $\text{SO}_4^{2-}/\text{NO}_3^-$  ratio exceed 1 is observed in almost all samples, even up to 198 (Fig. 6C), further reflecting the leading role of fixed contamination emission origins, e.g., transportation/diffusion of the coal-burning emissions (Li et al., 2020a; Naimabadi et al., 2018), whereas the mobile sources contribution (mainly vehicle emissions) and its long-range transport/diffusion are relative muted (Rao et al., 2017). In Fig. 6D, all the sample symbols are plotted between the lines of (calcite + dolomite dissolution) and (calcite dissolution) due to the small  $\text{Mg}^{2+}/\text{Ca}^{2+}$  ratios (0.04–0.22), implying the primarily influence of calcite dissolution of atmospheric dust derived from different carbonate weathering processes on  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$  in rainwater (Keresztesi et al., 2020a; Lü, Han & Wu, 2017). On the contrary, the sea salt contribution to the rainwater cations is very limited (based on the comparison with seawater cations ratio in Fig. 6D). In addition, although  $\text{F}^-$  and  $\text{K}^+$  related ionic ratios are not shown in Fig. 6, the previous work has indicated that the biomass burning (e.g., straw combustion) and soil dust are the main sources of  $\text{K}^+$  and the anthropogenic

emissions can be a interpretation for the higher  $F^-$  concentration in rainwater (Khare *et al.*, 2004; Zhang *et al.*, 2019). Moreover, although the rainwater  $NH_4^+$  was not measured in the present study due to the inherent difficulty of the instrument (ICP-AES) for cations measurement, the previous rainwater nitrogen isotope-based studies have concluded that the rainwater  $NH_4^+$  in Guiyang mainly from animal/human wastes (~22%), fertilizers (~22%), and agricultural biomass burning (~17%)(Liu *et al.*, 2017; Xiao *et al.*, 2012). This is highly in agreement with the characteristics (full of agricultural activities around the city and concentrated population in urban area) in such a developing city in southwest of China.

### Deposition flux and potential environmental effects

Based on the ionic concentrations and the corresponding rainfall amount in each month during study period, the rainwater ions deposition fluxes are estimated (Fig. S4). There are fairly large ion deposition fluxes in such a karst city intensively impacted by human activities, with the range of 0.5 to 3.5 keq  $ha^{-1}$ , which is also a very high level over China (0.1–2.5 keq  $ha^{-1}$ ) (Rao *et al.*, 2017; Yang *et al.*, 2012; Zhao *et al.*, 2008; Zhou *et al.*, 2019). As expected, the lowest monthly wet deposition flux is observed in July 2013 (Fig. S4) due to the extremely low rainfall amount in this month (26.4 mm) compared to the rainfall amount in other years (about 270–420 mm, Fig. S2B). These results suggest that both the sources contribution and the climatic conditions (e.g., rainfall amount) are responsible for the total ions wet deposition fluxes.

Moreover, the combination of protons in the aquatic ecosystems and nitrate and sulfate derived from wet deposition actuated water acidification in the hydrosphere have been a focus of environmental researches (Chen *et al.*, 2019; Qiao *et al.*, 2018), the wet deposition levels of sulfate and nitrate can therefore reflect the potential environmental effects of rainwater chemistry to some extent (Pan *et al.*, 2013). This phenomenon significantly impacted the carbonate weathering in karst areas further influenced the global climate change (Li *et al.*, 2008; Liu & Han, 2020; Liu & Han, 2021; Raymond *et al.*, 2013; Wang *et al.*, 2019). The previous studies on the aquatic ecosystem in Guiyang city also showed the enhanced carbonate rock weathering processes involved with exogenous sulfuric and nitric acid (Lang *et al.*, 2006; Zhong *et al.*, 2018). The monthly wet acid (nitrate and sulfate) deposition at Guiyang city ranged between 0.04 to 1.03 keq  $ha^{-1}$  (Fig. S5). The evaluated yearly wet acid deposition is 4.27 keq  $ha^{-1} year^{-1}$  via the sum of each month's fluxes in 2013. This annual deposition flux is twice as much as in karst rural areas (Zeng *et al.*, 2020). Different from the Yangtze River Delta (nitrate-dominated wet acid deposition) (Chen *et al.*, 2019), the wet acid deposition in Guiyang city is controlled by the sulfur. The sulfur contributed significantly higher than the nitrate to total acid deposition with the mean monthly contribution rate of 88% (Fig. S5). Thus, the more detailed spatio-temporal monitoring of rainwater chemistry in karst urban area is necessary for understanding the rainfall-actuated acid deposition and its potential effects on hydrosphere, especially sulfate wet deposition (as an agent of weathering).

## CONCLUSIONS

In conclusion, 26 monthly mixed rainwater samples collected in a karst city (Guiyang, 2012 to 2014) were investigated to explore the variations, influence factors and origins of ions. The rainwater ions composition varied obviously based on temporal rainwater chemistry investigation. Especially,  $\text{Ca}^{2+}$  and  $\text{SO}_4^{2-}$  concentrations range from 124.5 to 6,652.4  $\mu\text{eq L}^{-1}$  and from 10.5 to 4,127.2  $\mu\text{eq L}^{-1}$ , respectively.  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ ,  $\text{SO}_4^{2-}$  and  $\text{Cl}^-$  are the most dominant ions with obviously monthly variations. Sources variations and precipitation amount are the vital affecting factors of rainwater ions, and the long-distance transportation is also non-negligible factor when precipitation amount exceed 100 mm. Source identification indicated that  $\text{Mg}^{2+}$ ,  $\text{Ca}^{2+}$  and  $\text{K}^+$  are predominantly influenced by the crustal sources (dust), while the anthropogenic emissions are the main origins of  $\text{F}^-$ ,  $\text{NO}_3^-$  and  $\text{SO}_4^{2-}$ .  $\text{Cl}^-$  Enrichment in long-distance transport is the main contributor of  $\text{Cl}^-$ . The observed high level of total wet acid deposition implies the requirement of focus on rainfall-related acid deposition, particularly sulfur deposition as which is a potential weathering agent.

## ACKNOWLEDGEMENTS

The authors thank Dr. Yang Tang from the Institute of Geochemistry, Chinese Academy of Sciences for sampling and laboratory work.

## ADDITIONAL INFORMATION AND DECLARATIONS

### Funding

This work was supported by the National Natural Science Foundation of China (Nos. 41325010 and 41661144029). The funders had no role in study design, data collection and analysis, decision to publish, or preparation of the manuscript.

### Grant Disclosures

The following grant information was disclosed by the authors:

National Natural Science Foundation of China: 41325010 and 41661144029.

### Competing Interests

The authors declare that they have no competing interests.

### Author Contributions

- Jie Zeng analyzed the data, prepared figures and/or tables, authored or reviewed drafts of the paper, and approved the final draft.
- Guilin Han conceived and designed the experiments, performed the experiments, analyzed the data, prepared figures and/or tables, authored or reviewed drafts of the paper, and approved the final draft.

### Data Availability

The following information was supplied regarding data availability:

Raw measurements are available in the [Supplemental Files](#).

## Supplemental Information

Supplemental information for this article can be found online at <http://dx.doi.org/10.7717/peerj.11167#supplemental-information>.
