Understanding the factors underpinning species abundance patterns in space and time is essential to implement effective cave conservation actions. Yet, the methods employed to monitor cave biodiversity still lack standardization, and no quantitative assessment has yet tried to optimize the amount and type of information required to efficiently identify disturbances in cave ecosystems. Using a comprehensive monitoring dataset for tropical iron caves, comprising abundance measurements for 33 target taxa surveyed across 95 caves along four years, here we provide first evidence-based recommendations to optimize monitoring programs seeking to follow target species abundance through time. We found that seasonality did not influence the ability to detect temporal abundance trends. However, in most species, abundance estimates assessed during the dry season resulted in a more accurate detection of temporal abundance trends, and at least three surveys were required to identify global temporal abundance trends. Finally, we identified a subset of species that could potentially serve as short-term disturbance indicators. Results suggest that iron cave monitoring programs implemented in our study region could focus sampling efforts in the dry season, where detectability of target species is higher, while assuring data collection for at least three years. More generally, our study reveals the importance of long-term cave monitoring programs for detecting possible disturbances in subterranean ecosystems, and for using the generated information to optimize future monitoring efforts.

## 14 Abstract

15

16 Understanding the factors underpinning species abundance patterns in space and time is essential  
17 to implement effective cave conservation actions. Yet, the methods employed to monitor cave  
18 biodiversity still lack standardization, and no quantitative assessment has yet tried to optimize the  
19 amount and type of information required to efficiently identify disturbances in cave ecosystems.  
20 Using a comprehensive monitoring dataset for tropical iron caves, comprising abundance  
21 measurements for 33 target taxa surveyed across 95 caves along four years, here we provide first  
22 evidence-based recommendations to optimize monitoring programs seeking to follow target  
23 species abundance through time. We found that seasonality did not influence the ability to detect  
24 temporal abundance trends. However, in most species, abundance estimates assessed during the  
25 dry season resulted in a more accurate detection of temporal abundance trends, and at least three  
26 surveys were required to identify global temporal abundance trends. Finally, we identified a  
27 subset of species that could potentially serve as short-term disturbance indicators. Results suggest  
28 that iron cave monitoring programs implemented in our study region could focus sampling efforts  
29 in the dry season, where detectability of target species is higher, while assuring data collection for  
30 at least three years. More generally, our study reveals the importance of long-term cave  
31 monitoring programs for detecting possible disturbances in subterranean ecosystems, and for  
32 using the generated information to optimize future monitoring efforts.

## 39 Introduction

40

41 Quantifying long-term changes in abundance of cave-dwelling organisms and identifying  
42 indicator species, reflecting the health status of subterranean ecosystems, are among the  
43 fundamental research goals of modern subterranean conservation biology (Mammola et al.,  
44 2020). For instance, the lack of knowledge about the factors underpinning abundance patterns in  
45 space and time are among the main impediments to the effective protection of cave fauna  
46 (Cardoso et al., 2011). Long-term studies in caves are scarce (Di Russo et al., 1997; Salvidio et  
47 al., 2019), and most previous efforts assessing community-level responses have evaluated  
48 population dynamics (Bichuette & Trajano, 2003; Ferreira et al., 2005; Lunghi, 2018), ecological  
49 niches (Mammola & Isaia, 2016; Mammola, Piano & Isaia, 2016), or temporal and spatial  
50 variation (Tobin, Hutchins & Schwartz, 2013; Ferreira et al., 2015; Owen et al., 2016; Paixão,  
51 Emanuelle Arantes Ferreira & Paixão, 2017; Mammola & Isaia, 2018; Ferreira & Pellegrini,  
52 2019; Pellegrini, Faria & Ferreira, 2020). Few studies have evaluated the influence of  
53 anthropogenic disturbance on cave biodiversity (Bernardi, Souza-Silva & Ferreira, 2010;  
54 Pellegrini & Lopes Ferreira, 2012; Faille, Bourdeau & Deharveng, 2015; Cajaiba, Cabral &  
55 Santos, 2016; Pellegrini et al., 2016; Jaffé et al., 2018).

56 Due to the unique characteristics of subterranean environments, an important fraction of  
57 cave fauna exhibits adaptations for life in these extreme environments (Pipan & Culver, 2013).  
58 Some of these species are obligate subterranean dwellers and often comprise narrow-range  
59 endemic and threatened species (Harvey, 2002), so stringent legislation has been put in place in  
60 some countries to protect them (Harvey et al., 2011; Culver & Pipan, 2014). In Brazil, companies  
61 executing projects that could potentially impact cave ecosystems are required by law to assess the  
62 extent of impacts and implement control, monitoring and/or compensation measures (CONAMA,  
63 1986; Decree, 2008; MMA/ICMBio, 2019). After environmental licenses are granted, some caves  
64 are included in long-term monitoring programs, ultimately seeking to detect possible disturbances  
65 on subterranean fauna. These studies generate comprehensive biological databases containing  
66 valuable information for numerous caves sampled over long periods of time (Jaffé et al., 2016,  
67 2018; Trevelin et al., 2019). However, although many recommendations have been made to  
68 monitor cave biodiversity (Eberhard, 2001; NPS, 2015; Culver & Sket, 2016), methods still lack  
69 standardization, and no quantitative assessment has yet tried to optimize the amount and type of  
70 information required to efficiently identify disturbances in cave ecosystems. This is nevertheless  
71 essential to design systematic, repeatable, and intensive surveys of cave-dwelling organisms,  
72 allowing the formulation of evidence-based management decisions (Wynne et al., 2018, 2019).

73 In Brazil, most cave monitoring programs have focused on assessing temporal changes in  
74 relative abundance in a set of selected species (ativoambiental, 2019; BRANDT, 2019). However,  
75 the temporal frequency of field surveys, the impact of seasonal fluctuations in population size,  
76 and the sample sizes needed to detect temporal changes in population abundance, are yet to be  
77 systematically assessed. Moreover, the selection of species surveyed in these monitoring  
78 programs is not based on their usefulness as disturbance bio-indicators. Here we aim to fill these  
79 gaps, taking advantage of a comprehensive cave monitoring dataset containing abundance  
80 measurements for target target taxa surveyed across iron caves along four years.

81

## 82 Material & Methods

83

### 84 Study Area

85 The study was performed in the *Serra dos Carajás* region, southeast of the state of Pará, in the  
86 Brazilian Amazon. This region is within the limits of the *Floresta Nacional de Carajás*, a

87 protected area of 400,000 ha allowing sustainable use. The caves analyzed in this study are  
88 located in two highlands known as *Serra Norte* and *Serra Sul* (Fig. 1). These two regions harbor  
89 banded ironstone formations known as *cangas*, unique *campo rupestre* ecosystems resembling  
90 mountain savannas (Zappi et al., 2019), and one of the world's largest deposits of iron ore  
91 (Poveromo, 1999).

92

### 93 *Database*

94 We used data generated by independent environmental consulting companies, so our study did  
95 not involve any field work. Vale S.A., a mining company, began operations in the region more  
96 than two decades ago (Souza-Filho et al., 2019), and has conducted numerous caves surveys over  
97 the last years as part of a large monitoring program related to environmental licensing processes.  
98 All surveys were authorized by Instituto Brasileiro do Meio Ambiente e dos Recursos Naturais  
99 Renováveis (IBAMA), under licenses ABIO 455/2014 (Projeto Serra Carajás S11D nº  
100 02001.000711/2009-46) and ABIO 639/2015 (Projeto Ferro Serra Norte – Estudo Global das  
101 Ampliações das minas N4 e N5 nº 02001.002197/2002-15). We compiled the data generated in  
102 these surveys to collect information from 33 target taxa across 95 caves, surveyed between  
103 August 2015 and September 2019. The selection of species included in these monitoring  
104 programs was based on the following criteria, as stated in environmental assessment reports  
105 (Vale, 2015, 2017): Large body size and easy to identify in the field, abundant and showing a  
106 wide distribution range, resolved taxonomic classification (at least to the morpho-species level),  
107 and short life cycles allowing the rapid detection of changes in population dynamics (see Table 1  
108 for the full list of target taxa and their ecological classification). All the selected species were  
109 actively surveyed during each field trip, so absences represent true absences rather than missing  
110 data. In each cave, the absolute abundance of each target taxa was quantified at least once during  
111 the rainy and the dry season, and sometimes multiple times in one year. Sampling was performed  
112 through an active visual search throughout the caves, aiming to cover all available micro-habitats  
113 (spaces under rocks, small cracks, moist soil, etc.) and organic deposits (litter, logs, carcasses,  
114 guano, etc.). Animals were collected with the aid of tweezers and brushes, and all individuals  
115 found in each cave were counted to estimate abundance per species, as performed in other studies  
116 (Silva, Martins & Ferreira, 2011; Ferreira et al., 2015; Bento et al., 2016; Pellegrini & Ferreira,  
117 2016; Paixão, Emanuelle Arantes Ferreira & Paixão, 2017; Ferreira & Pellegrini, 2019; Souza-  
118 Silva, Iniesta & Ferreira, 2020).

119

### 120 *Environmental conditions and landscape metrics*

121 External and internal environmental conditions were monitored during the entire period across  
122 caves. Monitored variables included the deviation in average bimonthly rainfall in relation to the  
123 expected from a 20-years series (in mm, retrieved from small weather stations located in nearby  
124 mines S11D e N4E), and mean internal temperature (°C) on the date of the surveys (retrieved  
125 from portable data loggers placed in the most distant location from cave entrances). We also  
126 recorded the Area (meters<sup>2</sup>) of each studied cave as an additional internal condition widely known  
127 to influence biodiversity patterns in these ecosystems (Jaffé et al., 2016, 2018). Using 30m  
128 resolution land-cover maps from 2015 to 2019 (Souza et al., 2020), we then quantified a suit of  
129 landscape metrics, including the proportional amount of forest, canga and mining land covers  
130 surrounding caves, and topographic distance to the nearest mine (see details in Supplemental  
131 Table S1). These were all calculated at two different spatial scales (circular buffers with 500 and  
132 1000 m radius), using the R packages *landscapemetrics* (Hesselbarth et al., 2019) and  
133 *TopoDistance* (Wang, 2020). Two of these metrics directly captured possible disturbance of  
134 subterranean environments that could account for changes in the abundance of the studied  
135 species: Mining cover and distance to the nearest mine.

136

137 *Assessing drivers of community composition across caves*

138 Aiming to quantify how environment, cave, and landscape variables influenced overall  
139 community composition, we ran a partial redundancy analysis (RDA) controlling for differences  
140 between both highlands (Serra Norte and Serra Sul), using the *vegan* package (Oksanen et al.,  
141 2019). The community composition matrix containing relative abundances for each taxa was used  
142 as response variable and predictor variables included year, season, microclimate and landscape  
143 metrics (Legendre & Legendre, 1998). The highland where caves were located was specified as a  
144 conditional variable on the model to control for the effect of cave's geographical location.  
145 Microclimate and landscape variables were standardized, community composition was Hellinger-  
146 transformed, and permutation tests were used to assess significance of marginal effects (Legendre  
147 & Legendre, 1998).

148

149 *Assessing the influence of seasonality on the detection of temporal abundance trends*

150 One of the main goals of cave monitoring programs was to assess changes in species abundance  
151 over time, and thereby identify species with declining or increasing populations in a particular  
152 cave. To understand how seasonality influenced the detection of abundance trends over time, we  
153 ran linear models containing the total number of observed individuals as the response variable  
154 and the interaction between sampling date and season. If seasonality influences temporal  
155 abundance trends, we would expect to find significant interaction terms. No significant  
156 interactions, on the other hand, would indicate that the trends can be detected regardless of the  
157 season when the surveys were performed. To prevent overfitting, linear models were ran for taxa  
158 and caves represented by at least five surveys in each season (final sample size was 16 taxa and  
159 50 caves). Given the large number of models we used the Benjamini & Hochberg approach to  
160 adjust *p*-values, employing the *p.adjust* function from the stats R package (R, 2020).

161

162 *Assessing the influence of sampling effort on the detection of temporal abundance trends*

163 Given the extensive field exposure of people and elevated costs associated with cave monitoring  
164 programs, it is important to quantify how the sampling effort influences the detection of temporal  
165 abundance trends. To do so we compared linear model coefficients of models fitted with the full  
166 dataset with those of models fitted with reduced datasets. We first split the data by season and ran  
167 linear models containing the total number of observed individuals as the response variable and  
168 sampling date as predictor. In these full models we included observations for all sampling dates,  
169 and excluded taxa and caves represented by less than three surveys per season. We then ran linear  
170 models on data subsets containing a reduced number of observations (ranging between two and  
171 the maximum number of sampling dates found in each cave and taxa). For each data subset  
172 containing a given number of observations (surveys) we performed ten random samplings  
173 without replacement, to ensure the sampling of different sampling dates. Finally, we compared  
174 coefficients from full models with those of subset models using root mean squared error (rmse),  
175 implemented through the *rmse* function from the Metrics R package (Hamner & Frasco, 2018).  
176 Lower values of rmse indicate more similar model coefficients.

177

178 *Identifying disturbance indicator species*

179 Given the life history variation between species and their different susceptibility to habitat  
180 disturbance, it is essential to identify indicator species that show a rapid response to disturbance  
181 in order to optimize monitoring programs. By focusing on these indicator species, monitoring  
182 programs could survey caves more efficiently, thereby making resources available to study more  
183 caves or other aspects of cave biodiversity requiring attention. Here we tried to identify  
184 disturbance indicator species by assessing the relationship between disturbance metrics and

185 species abundance patterns. We first modeled patterns of relative abundance across all caves,  
186 using the function *manyglm* from the R package *mvabund* (Wang et al., 2012). It uses a  
187 multivariate generalized linear model (GLM) to make inferences by fitting separate GLMs to a  
188 common set of explanatory variables, and testing significance through resampling-based  
189 hypothesis testing. We ran negative binomial GLMs containing abundance as the response  
190 variable and sampling season nested in year, distance to mine and mining cover as predictor  
191 variables. Significance *p*-values were calculated using 999 resampling iterations via PIT trap  
192 resampling, adjusted for multiple testing using a step-down resampling procedure (Wang et al.,  
193 2012). We then used univariate coefficient estimates and significance for individual species, to  
194 identify specific responses to disturbance metrics (distance to mine and mining cover).

195 We then assessed the relationship between disturbance metrics and temporal trends in  
196 species abundance within each cave. To do so we ran linear models containing the total number  
197 of observed individuals as the response variable and sampling date as predictor, excluding taxa  
198 and caves represented by surveys spanning less than three years (some caves where surveyed  
199 multiple times in a single year but these were only included in this analysis if surveys spanned at  
200 least three different years). We then used the model coefficients for each species at each cave,  
201 representing temporal abundance trends (positive coefficients showing an increase and negative  
202 coefficients a decrease in abundance through time), to run a second set of linear models  
203 regressing temporal abundance trends on disturbance metrics. These second set of models thus  
204 contained as response variable the model coefficients representing temporal abundance trends for  
205 each species at each cave, and distance to mine and mining cover (at different spatial and  
206 temporal scales) as predictors. To prevent overfitting we excluded species represented by less  
207 than ten coefficients (caves), and only constructed models containing a single predictor. We then  
208 ran likelihood-ratio tests, where we compared each model with a null model containing no  
209 predictors, and selected those predictor variables resulting in a significant decrease in the model's  
210 log-likelihood. Finally, we retrieved and plotted coefficients and *p*-values for these best-fitting  
211 models. All data and R scripts are available in GitHub  
212 ([https://github.com/rojaff/cave\\_monitoring](https://github.com/rojaff/cave_monitoring)).

213

## 214 Results

215

216 Overall community composition was weakly influenced by seasonality, cave size, environmental  
217 conditions, and the composition and configuration of landscapes surrounding caves, as more than  
218 87% of variance in community composition remained unexplained by these factors (Table 2).

219 Seasonality did not influence the ability to detect species abundance trends over time, since  
220 the interaction effect between sampling date and season was not significant in any taxa nor cave  
221 (Fig. 2). Increasing the number of samples resulted in more similar model coefficients between  
222 full and subset models, and root mean squared errors usually stabilized after three surveys (Fig.  
223 3). However, in most species the dry season datasets allowed a more accurate detection of  
224 temporal abundance trends, as revealed by lower root mean squared errors (Fig. 3).

225 Whereas relative abundance was associated to at least one disturbance metric in 22 species  
226 (Fig. 4), temporal trends in abundance were found associated with disturbance metrics in only  
227 five species (Fig. 5). Overall, two taxa displayed consistent responses across effects, which  
228 makes them potential indicator species for cave monitoring programs: The troglobiont *Charinus*  
229 *ferreus*, which appeared negatively affected by disturbance, and a species belonging the  
230 Theraphosidae family, which seem to be favored by disturbance (Table 3).

231

## 232 Discussion

233

234 By analyzing abundance measurements for 33 target taxa surveyed across 95 caves along four  
235 years, we found that overall community composition was weakly influenced by seasonality, cave  
236 size, environmental conditions, and the composition and configuration of landscapes surrounding  
237 caves. Furthermore, our results show that seasonality did not influence the ability to detect  
238 abundance trends over time. However, in most species, abundance estimates assessed during the  
239 dry season resulted in a more accurate detection of temporal abundance trends, and at least three  
240 surveys were required to identify global temporal abundance trends. Finally, we identified a  
241 subset of species that could potentially serve as short-term disturbance indicators, some showing  
242 consistent responses in different analyses.

243 Subterranean communities have been shown to be affected by seasonality, environmental  
244 conditions, cave characteristics, and the structure of surrounding landscapes (Simões, Souza-  
245 Silva & Ferreira, 2015; Pellegrini et al., 2016; Bento et al., 2016; Mammola & Isaia, 2018;  
246 Salvidio et al., 2019; Pellegrini, Faria & Ferreira, 2020; Rabelo, Souza-Silva & Ferreira, 2020).  
247 However, our results reveal that overall community composition was only weakly influenced by  
248 these factors, as our model explained merely 13% of total variation in community composition  
249 (Table 2). In contrast, previous work have found that cave morphology, microclimate, cave depth,  
250 and sampling date explain up to 50% of the variation in community structure in limestone and  
251 marble caves (Tobin, Hutchins & Schwartz, 2013; Lunghi, Manenti & Ficetola, 2014). Our  
252 results thus suggest that other factors, not considered in our analyses, play an important role  
253 structuring subterranean communities of iron caves. Inter-specific interactions, for instance, are  
254 known to have a profound influences on community structure (Ferreira & Martins, 1999;  
255 Mammola, Piano & Isaia, 2016). Alternatively, biological samples collected in iron caves may  
256 not capture the dynamics of the entire subterranean habitat, comprised by a network of fissures  
257 and voids and traditionally referred to as *Milieu Souterrain Superficiel* (MSS) (Culver & Pipan,  
258 2014; Mammola et al., 2016; Mammola, 2018). For instance, most of the surveyed caves were  
259 larger than 5x5 m (Fig. S1), so they did not represent suitable sampling sites for the MSS  
260 (Mammola et al., 2016).

261 Even though seasonality affected overall community composition, it did not influence the  
262 ability to detect species abundance trends over time. External climatic conditions are increasingly  
263 attenuated at higher cave depths (Tobin, Hutchins & Schwartz, 2013), so species occurring in the  
264 inner portions of caves appear to have life cycles decoupled from external seasons, whereas  
265 species inhabiting the outermost portions of caves seem to be more strongly affected by  
266 seasonality (Di Russo et al., 1997; Gunn, Hardwick & Wood, 2000; Bichuette & Trajano, 2003;  
267 Ferreira et al., 2015; Mammola, Piano & Isaia, 2016; Lunghi, 2018). Recognizing the impact of  
268 seasonality on species detection, the current Brazilian legislation stipulates that cave biodiversity  
269 surveys need to comprise at least two sampling events, one during the dry and one during the  
270 rainy season (MMA, 2017). It is worth emphasizing that these sampling requirements targeted a  
271 more accurate estimation of species richness, but not the continuous monitoring of focus species  
272 in time. Two sampling events are likely insufficient to obtain reliable species richness estimates  
273 for highly diverse caves (Auler & Piló, 2015; Wynne et al., 2018), so some authors have argued  
274 for the estimation of optimal sample sizes based on species accumulation curves (Trajano &  
275 Bichuette, 2010; Trajano, 2013). Our results provide the first evidence-based recommendations to  
276 optimize sampling efforts of monitoring programs seeking to assess target species abundance  
277 through time. Specifically, our findings suggest that monitoring efforts aiming to detect changes  
278 in abundance through time do not need to sample during two different seasons each year (Fig. 2).  
279 Sampling efforts of such monitoring programs could thus be optimized by performing more  
280 focused surveys and by surveying a larger number of caves during the same period each year.

281 Importantly, restricting sampling to a single season could substantially attenuate the negative  
282 impact of cave visitation by researchers on subterranean communities (Pellegrini & Ferreira  
283 2016, Pellegrini & Lopes Ferreira 2012, Bernardi et al. 2010).

284 Although the composition and spatial distribution of subterranean communities can  
285 remain constant over periods of several years (Salvidio et al., 2019), our results suggest that  
286 sampling during at least three years is necessary to detect temporal changes in abundance patterns  
287 in most of our focus species (Fig. 3). We note that our dataset only spans a period of four years  
288 (although some caves were sampled multiple times during the same season/year), so it cannot  
289 capture longer temporal changes in abundance. We also caution that these results cannot be  
290 generalized to all subterranean fauna, as different life histories and generation times will  
291 ultimately determine how fast these organisms respond to disturbances (Ferreira, 2005;  
292 Mammola et al., 2016; Culver & Pipan, 2019). Sampling in different seasons did not influence  
293 the ability to detect general abundance trends over time, but the dry season datasets allowed a  
294 more accurate detection of temporal abundance trends in most species. These results suggest  
295 higher detection probabilities in the dry season for the subset of species where RMSE curves  
296 show a steeper decrease during the dry season (Fig. 3). Interestingly, this was the case for the  
297 troglobitic amblypygid *Charinus ferreus*, a species that is difficult to detect like other  
298 troglobionts (Wynne et al., 2018; Lunghi, 2018). Our results thus suggest that monitoring  
299 programs focusing on terrestrial subterranean fauna from our study region could concentrate  
300 sampling activity in the dry season, where most species seem to be easier to detect. Likewise, our  
301 findings highlight the importance of implementing long-term monitoring efforts spanning at least  
302 three years.

303 The concept of indicator species in ecosystem management relies on the idea of  
304 identifying taxa responsive to environmental change, that could inform policies, protocols, and  
305 best practices (Carignan & Villard, 2002). Such environmental indicators (McGeoch, 1998) seek  
306 to provide cost and time effective guidelines to address pressing conservation issues, such as  
307 those faced by large-scale mining projects (Sonter, Ali & Watson, 2018). Assessing the response  
308 of subterranean fauna to anthropogenic disturbance nevertheless requires access to long-term  
309 cave monitoring datasets, which are remarkably rare for tropical caves (McGeoch, 1998;  
310 Carignan & Villard, 2002; Mammola et al., 2020). Here we identified 20 taxa where overall  
311 abundance responded to cave disturbance, and five where temporal abundance trends were  
312 associated with disturbance. Only two taxa displayed consistent responses across effects, which  
313 makes them candidate indicator species for cave monitoring programs: *Charinus ferreus* and a  
314 species belonging the Theraphosidae family (Table 2). Both are arachnids, a group that was  
315 recently identified as biodiversity indicator for iron caves (Trevelin et al., 2019). Being a top  
316 predator restricted to cave ecosystems, the first species is a well-known troglobitic Amblypygi  
317 (Giupponi & de Miranda, 2016). Its strong and consistent response to disturbances (Figs. 4 and 5)  
318 suggest the species is associated with pristine and undisturbed ecosystems, which makes it an  
319 ideal disturbance indicator. Theraphosidae spiders, on the other hand, are sedentary sit-and-wait  
320 predators from the epigea, rarely occupying subterranean environments for reproduction or  
321 shelter (Fonseca-Ferreira, Zampaulo & Guadanucci, 2017). Our results suggest that they  
322 apparently benefit from disturbance to opportunistically colonize caves, or alternatively, that  
323 disturbances in the surrounding external habitats are forcing them to look for shelter inside the  
324 caves. The species nevertheless awaits formal taxonomic description, which currently limits its  
325 usefulness as an indicator species.

326 Effect sizes of disturbance on overall abundance and temporal abundance trends were  
327 generally small, suggesting that some effects could have remained undetected because they  
328 would require sampling over longer time periods (Di Stefano, 2001; Legg & Nagy, 2006). For  
329 instance, the ability to detect trends in tropical bat population abundance was shown to be

330 dependent on the duration of the monitoring efforts, and only long programs (> 20 years) showed  
331 sufficient statistical power to reliably detect abundance trends (Meyer et al., 2010). This could  
332 explain why some of our focus species did not exhibit coherent responses across analyses, like  
333 the troglobionts *Pyrgodesmidae* sp. and *Escadabiidae* sp., or opportunistic colonizers like the  
334 anuran *Leptodactylus pentadactylus* or *Pristimantis fenestratus*. Although empirical evidence  
335 from long-term cave monitoring efforts focusing on invertebrates is scarce (Faille, Bourdeau &  
336 Deharveng, 2015; Cajaiba, Cabral & Santos, 2016; Owen et al., 2016), our results thus suggest  
337 that longer monitoring efforts are needed to detect disturbance responses in most cave-dwelling  
338 species.

339

## 340 **Conclusions**

341

342 Our study reveals the importance of long-term cave monitoring programs for detecting possible  
343 disturbances in subterranean ecosystems, and for using the generated information to optimize  
344 future monitoring efforts. Results show that iron cave monitoring programs implemented in our  
345 study region could focus sampling efforts in the dry season, where detectability of target species  
346 is higher, while assuring data collection for at least three years. *Charinus ferreus* was identified as  
347 the most promising short-term disturbance indicator species.

348

## 349 **Acknowledgments**

350

351 We thank Ativo Ambiental and Brandt Meio Ambiente for performing the speleological surveys  
352 that generated all the data used in this study, and David Culver and Judson Wynne for helping us  
353 improve our manuscript with their constructive criticism.

**Table 3** (on next page)

Taxa displaying significant responses to disturbance metrics, considering overall abundance and temporal abundance trends.

Taxa showing consistent responses (highlighted in bold) are suggested as short-term disturbance indicators. The best sampling season (according to Fig. 3), is indicated for each taxa.

## Figure 1

Location of the study region (upper left corner) and a detail of the study area showing the spatial distribution of the caves included in our analyses (N = 95), colored by the number of surveys performed in each.

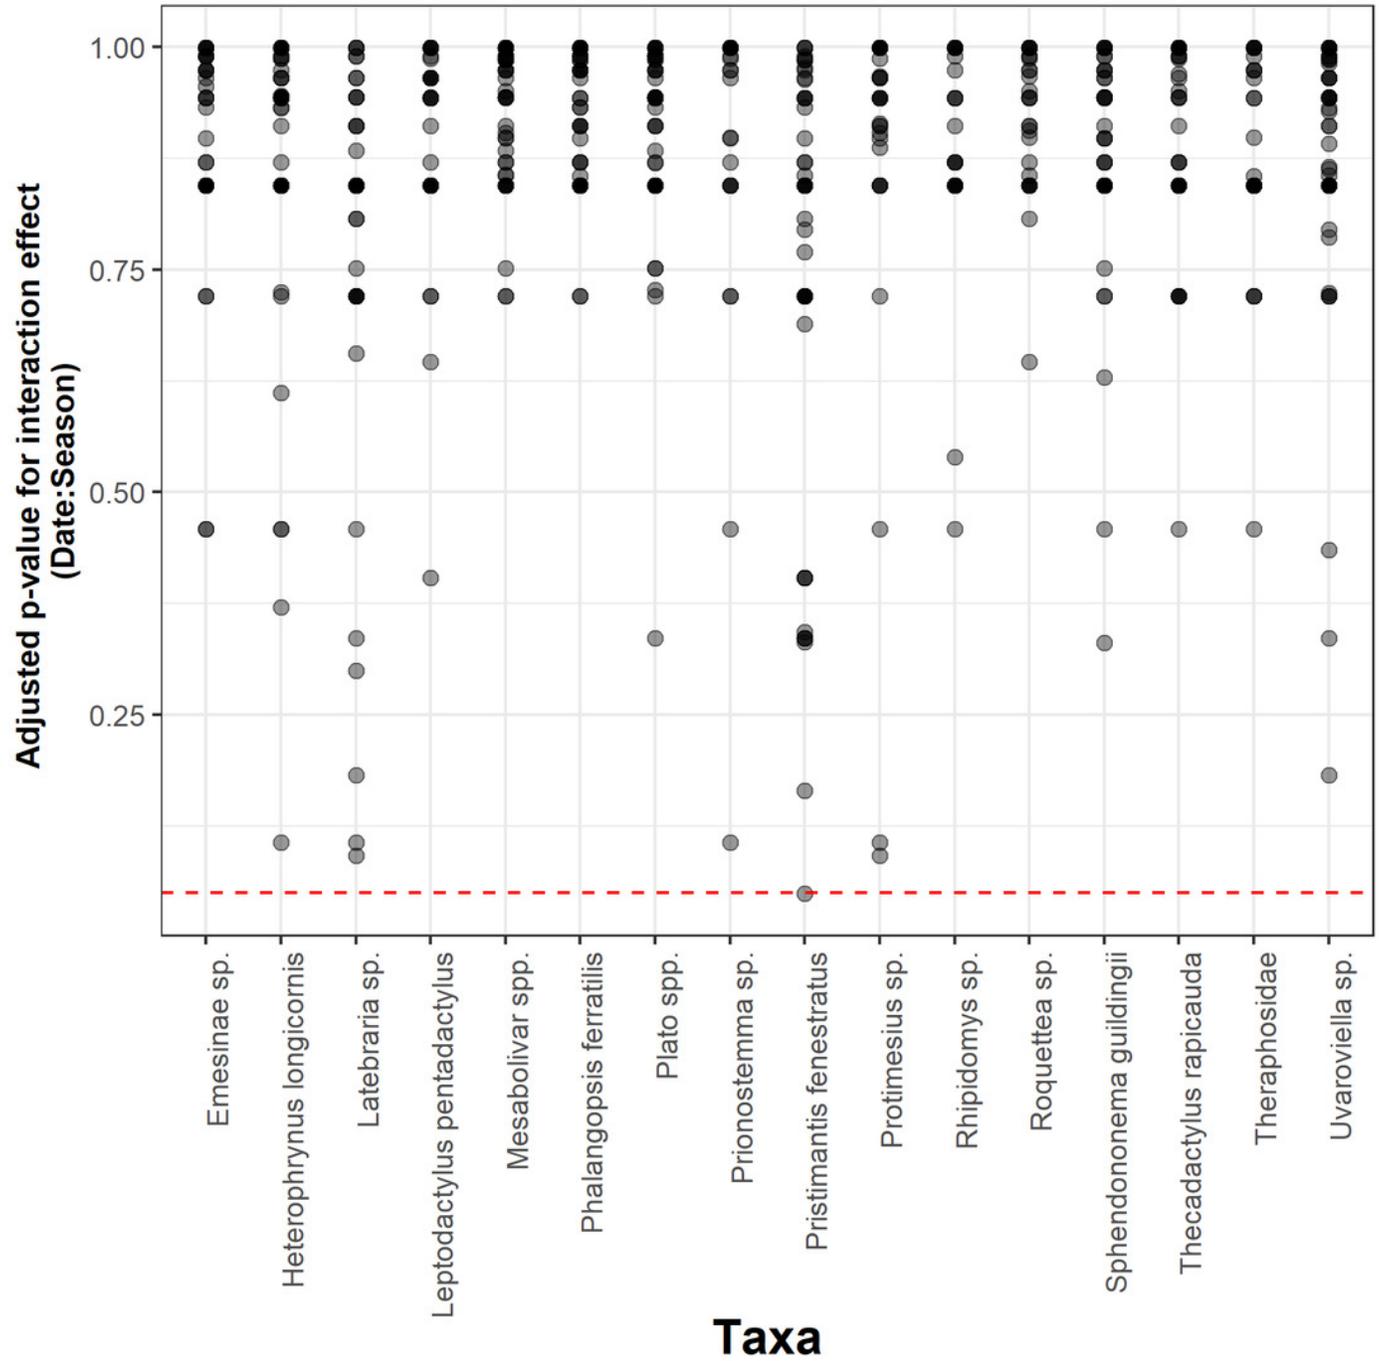

While the hillshade layer was constructed using a digital elevation model (SRTM, 1 arc-second) from USGS Earth Explorer, the land use classification shapefile was obtained from Souza-Filho et al. (2019). Coordinates are shown in decimal degrees.

## Figure 2

Adjusted  $p$ -values for the interaction between sampling date and season across 16 taxa and 50 caves.

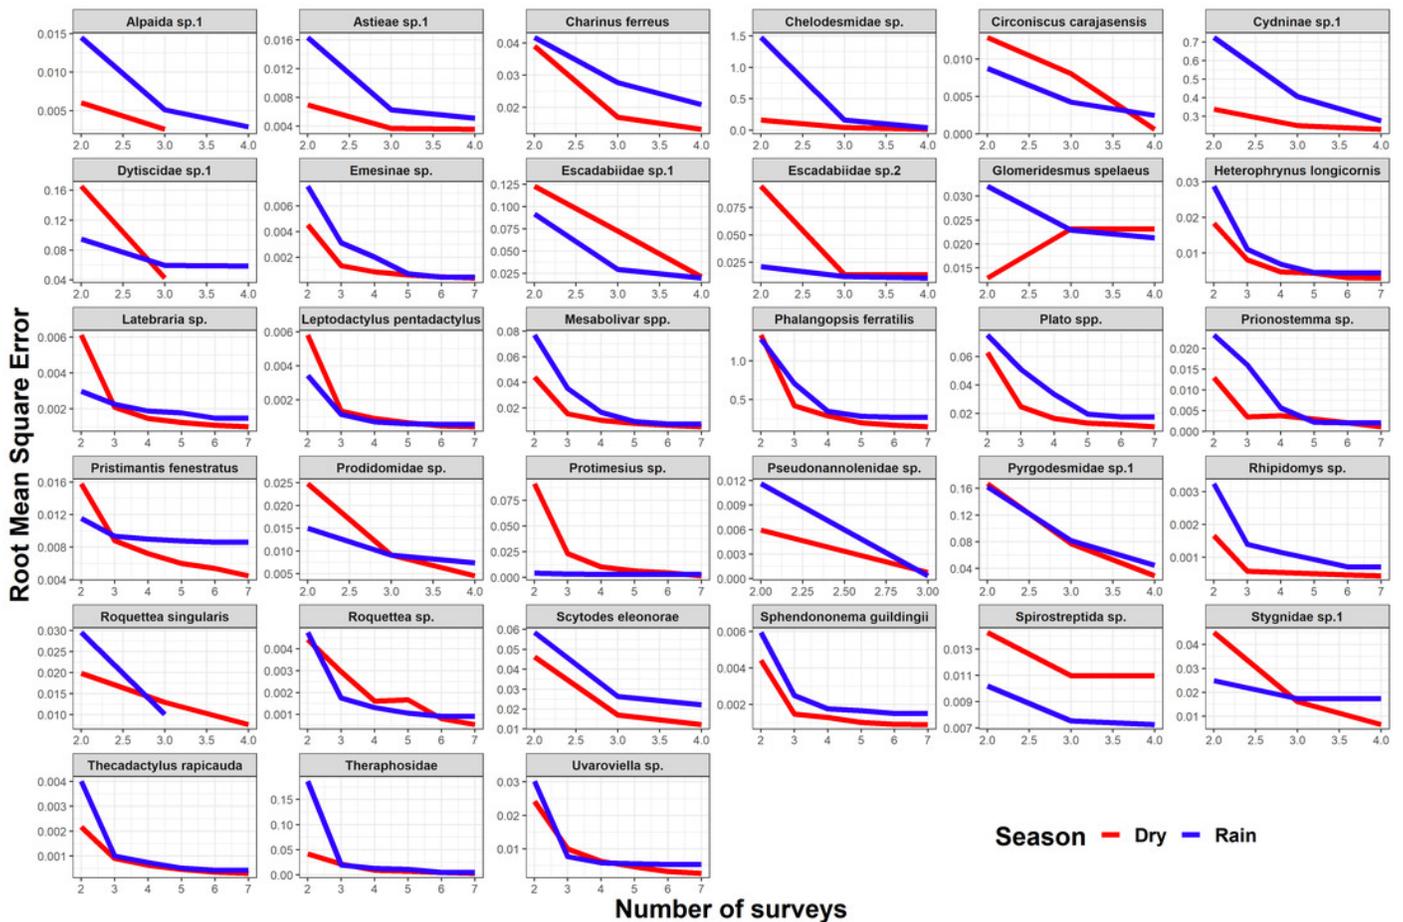

The Benjamini & Hochberg approach was used to adjust  $p$ -values and the red horizontal line shows the threshold value of 0.05 (values above this line represent cases where the interaction effect was not significant).

## Figure 3

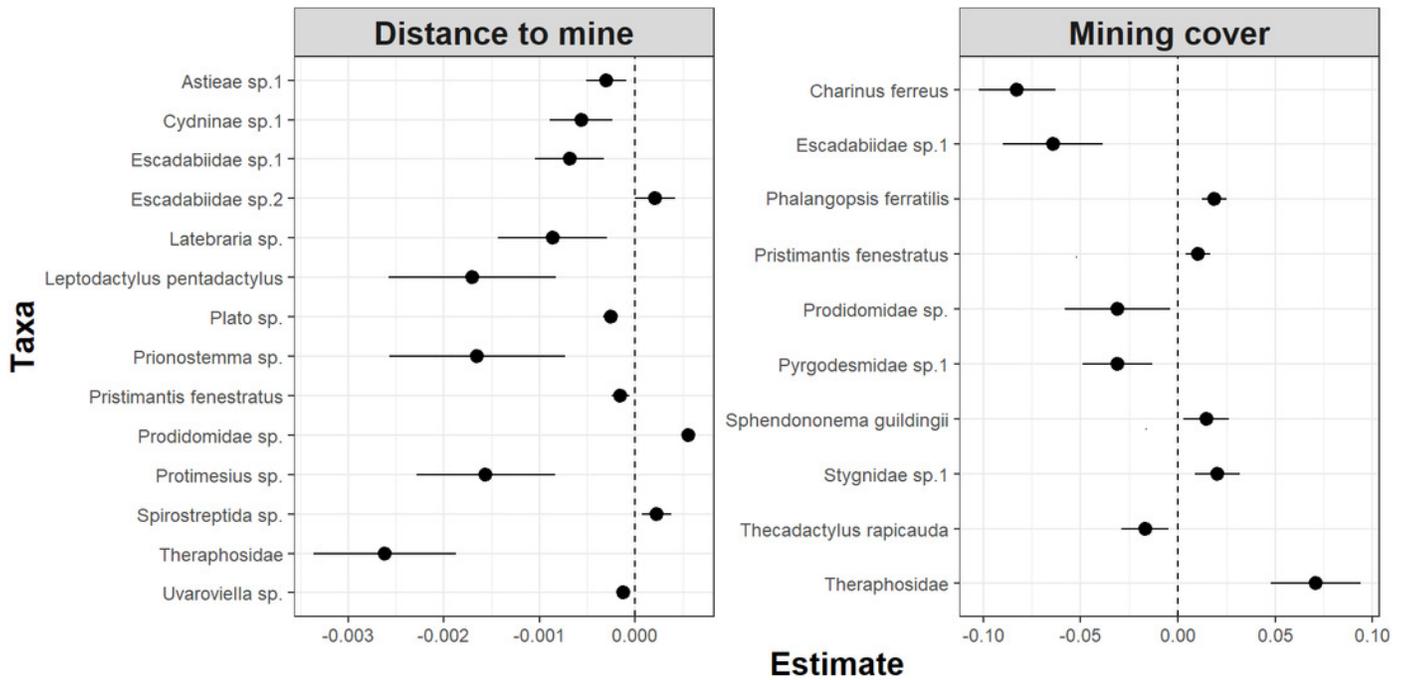

Root mean squared error (rmse) for model coefficients from full models and those of subset models containing reduced numbers of samples.

Lower values of rmse indicate more similar model coefficients (and a more reliable estimation of temporal abundance trends). For each data subset containing a given number of observations (surveys) we performed ten random samplings without replacement, to ensure the sampling of different sampling dates.

## Figure 4

Model coefficients and 95% confidence intervals for species showing significant associations between overall abundance and two disturbance metrics.

## Figure 5

Model coefficients and 95% confidence intervals for species showing significant associations between temporal abundance trends and two disturbance metrics.
