**Aim:** The global increase in the cultivation of native wild plants has raised concerns regarding potential risks associated with translocating genetic lineages beyond their natural range. This study aimed to investigate whether agricultural cultivation of neo-crops a) accounts for the levels of genetic diversity present in wild populations, and whether b) cultivated populations are genetically divergent from wild populations and thus pose a potential threat to wild genetic diversity.

**Location:** The Cape Floristic Region (CFR), located along the southern Cape of South Africa.

**Methods:** High Resolution Melt analysis (HRM) coupled with Sanger sequencing was used to screen three non-coding chloroplast DNA loci in *Cyclopia* Vent. (Fabaceae), a CFR endemic neo-crop cultivated for the production of a herbal infusion referred to as Honeybush tea. Wild and cultivated populations for three of three widely cultivated Honeybush species (*C. intermedia*, *C. longifolia*, and *C. subternata*) were screened. Genetic diversity and differentiation were measured and compared between wild and cultivated groups.

**Results:** Across all asseccions, a total of 17 haplotypes were detected, four of which were shared between wild and cultivated populations, while the remaining 13 were only detected in wild populations. Genetic diversity and differentiation was significantly higher in wild populations than in cultivated populations.

**Conclusions:** If no guidelines exist to facilitate the introduction of native wild plant taxa to a cultivated setting, wild genetic diversity patterns are likely to be compromised by cultivated populations. In the case presented here, cultivation represents a genetic bottleneck, failing to account for rare haplotypes, and may have disrupted species boundaries by initiating interspecific hybridization. More empirical work is required to evaluate the extent to which neo-crop cultivation poses a risk to wild genetic resources in the CFR and globally.

# **The transition to agricultural cultivation of neo-crops may fail to account for wild genetic diversity patterns: insights from the Cape Floristic Region.**

## **Introduction**

Commercial trade of wild crop and medicinal plants relies predominantly on material sourced from wild populations. However, consumer demand for 'natural products' and products manufactured from renewable resources has promoted an increase in the domestication and cultivation of wild crop species (Lubbe and Verpoorte 2011), referred to here as neo-crops. If managed effectively, cultivation could facilitate the preservation of these economically important species by safeguarding genetic diversity *ex-situ*. Alternatively, widespread cultivation may reduce incentives to protect natural populations, with natural populations being replaced by cultivated ones. Additionally, the cultivation of commercial strains adjacent to natural populations may increase the risk of exposing wild plants to non-local genetic lineages that may result in hybridization, and thus, genetic erosion (Hammer and Teklu 2008; Laikre et al. 2010).

Gene flow from cultivated to wild populations is particularly common in traditional crop systems (Ellstrand et al. 1999) and can negatively impact wild populations by disrupting local genetic diversity and adaptation (Laikre et al. 2010). Neutral and selective pressures result in the divergence of ecological and genetic traits among geographically separate populations (Hufford and Mazer 2003). When this geographic separation is overcome due to anthropocentric translocation of genetic material, the fate of non-local genes that escape into wild populations is challenging to predict. There have, however, been cases where non-local lineages have invaded native populations, resulting in a loss of local genetic diversity (e.g. *Carex caryophyllea* Latourr (Cyperaceae), Whitlock et al. 2010; and *Phragmites australis* (Cav.) Steud,

Chambers et al. 1999). A precautionary approach that limits the distance that genetic material is translocated should, therefore, be adopted during anthropogenic redistribution of genetic material (Byrne and Stone 2011; Galuszynski and Potts 2020a). This is rarely the case, and the evolutionary history of the taxa involved is often not considered. Rather, in many cases, seed is sourced from distant populations or seed lots and have already undergone some form of screening for individuals with commercially favorable traits (Hyten et al. 2006; Schipmann et al. 2005; Tembrock et al. 2017; Yuan et al. 2010), that may be detrimental when introduced to natural populations.

Cultivated populations are likely to be poor representatives of local genetic diversity. In the case of the stimulant plant qat (*Catha edulis* [Vahl] Forssk. ex Endl., Celastraceae), genotypes sourced from wild populations in Ethiopia were used to establish cultivated populations in Yemen and Kenya, yet both regions support genetically distinct natural qat populations that could have formed the basis for local cultivation (Tembrock et al. 2017). In contrast, cultivated populations of the Chinese skullcap (*Scutellaria baicalensis* Georgi, Lamiaceae) contained a combination of haplotypes sourced from multiple, geographically separate, wild populations, lacking the phylogeographic structuring present in wild populations (Yuan et al. 2010). Despite representing different approaches to collecting genetic material for cultivation, if gene flow were to occur from cultivated to wild populations in either of these cases, the genetic integrity of wild populations would be compromised.

The Cape Floristic Region (CFR; Goldblatt 1978), located on the southern coast of South Africa is well known for its species richness, supporting over 9000 species in an area of approximately 90 000 km<sup>2</sup> (Goldblatt and Manning 2002), and home to various economically important plant species (Reinten et al. 2011; Scott and Hewett 2008; Turpie et al. 2003). The high floristic diversity of this region has resulted from low extinction rates in a topographically and edaphically heterogeneous landscape, which produces steep ecological gradients and isolate populations over relatively short distances (Barracough 2006; Cowling et al. 2009; Cowling et al. 2017). Genetic divergence (within and among species) in the CFR is therefore possible over relatively short distances, producing plant populations that exhibit spatially structured genetic diversity (phylogeographic structuring) (Galuszynski & Potts, 2020b; Tolley et al., 2014). The CFR

is thus, an ideal system for testing the representation of wild genetic variation in cultivated neo-crop plants.

The commercial trade in South African plant products relies predominantly on raw material sourced from wild populations (van Wyk and Prinsloo 2018). However, species used for the production of products with high export value are becoming widely cultivated (Reinten et al. 2011; Turpie et al. 2003). This transition to cultivation may pose a threat to the genetic integrity of wild populations of the target species, as the underlying levels and distribution of genetic diversity are not considered during the selection and translocation of commercially important CFR plants (van Wyk 2008). The consequences of this have already led to interspecific hybridization among *Protea* L. species (Proteaceae) (Macqueen and Potts 2018) and possible genetic erosion of wild Rooibos (*Aspalathus linearis* (Burm.f.) R.Dahlgren, Fabaceae) (Malgas et al. 2010). As a result, concerns regarding potential genetic risk associated with a shift to widespread cultivation of Honeybush tea — a herbal infusion produced from members of the CFR endemic genus *Cyclopia* Vent (Fabaceae) — have been raised (Potts 2017).

The global increase in demand for Honeybush tea, coupled with local declines in wild populations, prompted interest in cultivation (Joubert et al. 2011). Initial breeding trials included 12 of the 23 *Cyclopia* species and involved the selection of individuals with commercially favorable traits (e.g. bushy and vigorous growth forms), and cross pollination experiments (Joubert et al. 2011). Seed produced from these trials formed the foundation of early Honeybush cultivation, which was promoted in areas that supported natural *Cyclopia* populations (Jacobs 2008; Joubert et al. 2011). This history of domestication trials and translocation is not unique to Honeybush, with a similar approach applied to neo-crops elsewhere in Southern Africa (Akininifesi et al. 2006), Australia (Ahmed and Johnson 2000), and South Korea (Pemberton and Lee 1996), and may be typical of neo-crop development.

This study is the first to describe the levels of genetic diversity among wild and cultivated populations of an endemic crop plant originating from the CFR, focusing specifically on three widely cultivated *Cyclopia* species. High Resolution Melt analysis (HRM, Wittwer et al. 2003) coupled with sequence confirmation is applied to screen variation across two non-coding

chloroplast DNA (cpDNA) regions (the *atpI* - *atpH* intergenic spacer and *ndhA* intron). This study explores the prediction that cultivated *Cyclopia* populations will fail to reflect the spatial distribution and diversity of chloroplast lineages present in the wild. Thus, the current state of honeybush cultivation, and likely neo-crop cultivation in general, may represent a genetic risk to the integrity of wild populations occurring in close proximity to cultivated populations.

## Methods and materials

### Target taxa and sampling

The species selected for evaluation (*C. intermedia* E.Mey, *C. subternata* Vogel., and *C. longifolia* Vogel.) represent the most widely cultivated Honeybush taxa, cultivated in the Western Cape and Eastern Cape provinces of South Africa (Joubert et al., 2011; McGregor 2017). Consequently, these three species have likely experienced the greatest extent of redistribution outside of their natural range through cultivation (Fig 1; Fig 3 in Joubert et al., 2011) — placing them at high risk of genetic pollution. Additionally, these species represent three distinct distribution and life history patterns (Schutte 1997): a widespread obligate resprouter occurring at altitudes between 500 - 1700 m (*C. intermedia*), a widespread coastal lowland obligate seeder (*C. subternata*) and a critically endangered Eastern Cape endemic, riparian specialist with a mixed post fire response of facultative seeding and sprouting (*C. longifolia*). Since life history traits and range size impact a species' demographic history (Ellegren and Galtier 2016), these three taxa are likely to exhibit different genetic diversity patterns that need to be accounted for during translocation and cultivation.

Two of these species (*C. Intermedia* and *C. Subternata*) were subject of recent phylogeographic studies (Galuszynski and Potts 2020a; 2020c) and these previously published data sets were bolstered with additional samples to ensure that 24 individuals were available from each populations for analysis. Samples were collected from four geographically separated wild populations across the natural range of each species. The intention was to a) maximise the genetic variation detected among populations, and b) provide a representative reference of

haplotypes to describe the origins of material under cultivation. Cultivated material was sampled from Honeybush farms identified remotely from internet searches rather than relying on existing farmer networks, and were located in different mountain ranges (details of the locations are provided in Fig 1 and Table 1). This approach was employed to avoid potentially redundant sampling of cultivated material originating from seed exchange between farmers located in close proximity to one another, however, the true origin of the commercial seed remains uncertain (see discussion). The cultivators included in the study are situated near to three of the four major Honeybush nurseries reported by Joubert et al. (2011) (Fig 1). Three cultivated populations of each species were sampled. From all populations (wild and cultivated), a total of 24 plants were sampled with a minimum of 5m distance between sampled individuals. The final data set consisted of 504 samples collected across 21 (12 wild, 9 cultivated) populations of three commercially important *Cyclopia* species, population locations are mapped in Fig. 1. Fresh leaf material was collected from a healthy growing tip of each individual and placed into silica desiccating medium for a minimum of two weeks prior to DNA extraction. All sampling was approved by the relevant landowners involved and permitting agencies, Cape Nature (Permit number: CN35-28-4367), the Eastern Cape Department of Economic Development, Environmental Affairs and Tourism (Permit numbers: CRO 84/ 16CR, CRO 85/ 16CR), and the Eastern Cape Parks and Tourism Agency (Permit number: RA\_0185)

## DNA extraction and haplotype detection

The DNA extraction and haplotype detection protocol followed the approach previously described in Galuszynski and Potts (2020c) and a brief overview of the approach is provided here. Whole genomic DNA was extracted using a modified CTAB DNA extraction approach, adapted from Doyle & Doyle (1987). Extracted DNA was quantified using a NanoDrop 2000c Spectrophotometer (Thermo Fisher Scientific, Wilmington, DE19810r Scientific, USA) and diluted to 5 ng/μL for PCR amplification and subsequent HRM analysis.

High Resolution Melt analysis involves the gradual heating of PCR products amplified in the presence of a DNA saturating dye. As the double stranded DNA is heated it dissociates at a rate

based on the binding strength of the nucleotide sequence under analysis. As such, different nucleotide sequences should produce a distinct melt curve when plotting sample differences in measured fluorescence against change in temperature.

Three DNA fragments from two non-coding cpDNA regions (*atpI-atpH* intergenic spacer and *ndhA* intron) were amplified using *Cyclopia* specific primers and subsequently screened for nucleotide variation via HRM curve analysis. Samples were run in duplicates and HRM clustering was conducted on a single population basis following the recommendations of Dang et al. (2012). This was achieved by grouping populations using the ‘well group’ option in the CFX Manager Software (Bio-Rad Laboratories, Hercules, California, U.S.A.) and running the HRM clustering on these predefined population well groups. All reactions (PCR amplification and subsequent HRM) took place in a 96 well plate CFX Connect (Bio-Rad Laboratories, Hercules, California, U.S.A.). Haplotype melt curve grouping was achieved using the automated clustering algorithm of the High Precision Melt software (Bio-Rad Laboratories, Hercules, California, U.S.A.) ( $\Delta T_m = 0.05$ , curve shape sensitivity = 70%, temperature correction = 20). HRM cluster to haplotype confirmation was achieved by unidirectional sequencing, as described in Galuszynski and Potts (2020c). The chloroplast regions targeted by HRM were sequenced for a subset of individuals per HRM cluster from populations not previously studied by Galuszynski and Potts (2020a; 2020c). A total of 39 individuals for the *atpI-atpH* intergenic spacer and 36 individuals for the *ndhA* intron were PCR amplified using the reverse primers and following PCR protocols of (Shaw et al. 2007) and sequenced. The PCR and HRM conditions and details of the primers used in this study, are provided in S1.

Sequences were assembled using *CondonCode Aligner [v2.0.1]* (CodonCode Corp, <http://www.codoncode.com>). Each base-call was assigned a quality score using the PHRED base-calling program (Ewing et al. 1998). Sequences were then automatically aligned using ClustalW (Thompson et al. 1994) and visually inspected. All indels that were difficult to score (due to homopolymer repeats that are prone to alignment errors) were removed. The cpDNA regions under investigation are maternally inherited in tandem and not subject to recombination (Reboud & Zeyl 1994), and were therefore combined for subsequent analysis. A custom R script

(provided with a minimum working example online:  
<https://doi.org/10.6084/m9.figshare.12624620.v1>) was then used to assign each sample its  
 respective haplotype identity based on HRM clustering.

## Haplotype diversity analysis

All analyses were performed in *R* [v3.5.1] (R Core Team 2018). The genealogical relationships among haplotypes were established using a Statistical Parsimony (SP) network (Fig. 2) constructed in *TCS* [v1.2.1] (Clement et al. 2000). As *TCS* treats each base pair in an indel as an evolutionary event, all indels were reduced to a single base pair prior to analysis with default options selected for network construction. Haplotype diversity and differentiation was compared between wild and cultivated individuals grouped by species and origin. Differences in gene diversity (GD) between wild and cultivated populations were tested via Mantel tests (Mantel 1967); using *Hs.test* function implemented in the *adegenet* [v2.1.1] library, (Jombart & Ahmed 2011). Genetic differentiation between wild and cultivated populations were tested via an Analysis of Molecular Variance (AMOVA) (Excoffier et al. 1992) using the *poppr.amova* function with 999 permutations implemented in the *poppr* [v2.8.3] library (Kamvar et al. 2014). Three additional population differentiation measures were calculated: two fixation indices, pairwise  $G_{ST}$  (Nei 1973) and  $G_{ST}^{*}$  (Hedrick 2005), and a measure of genetic divergence, Jost's  $D$  (Jost 2008), using the *pairwise\_Gst\_Nei*, *pairwise\_Gst\_Hendrick*, and *pairwise\_D* functions respectively, all from the *mmod* [v1.3.3] library (Winter 2012). Population clustering was inferred from a Neighbor Joining tree constructed using Prevostis pairwise population genetic distance (Prevosti et al. 1975), calculated using the *prevosti.dist* function in the *poppr* library). This distance measure treats alignment gaps as evolutionary events and all gaps were reduced to a single base pair prior to analysis. Support for population clustering was assessed via a bootstrap analysis with 9999 replicates, implemented using the *aboot* function implemented in *poppr*.

## Results

# Haplotype detection

Of the 504 samples screened for haplotype variation, seven (six wild and one cultivated) failed to PCR amplify despite repeated efforts and the final dataset consisted of 497 samples. High Resolution Melt analysis with haplotype confirmation by sequencing revealed 17 cpDNA haplotypes with 100% specificity for all three loci (i.e. no cases of different haplotypes being grouped into the same HRM cluster were detected). The final concatenated dataset consisted of 794 bp (457 bp from the *atpI-atpH* intergenic spacer and 339 bp from the *ndhA* intron) with an overall GC content of 28.1%. The alignment contained 22 polymorphic sites including nine transitions, ten transversions, and three indels (two of 7 bp and one of 71 bp). Haplotype frequency within populations and nucleotide variation among haplotypes are summarized in Tables 1 and 2, respectively.

# Genetic diversity analysis

The SP network (Fig 2) revealed relatively low divergence among haplotypes, with all haplotypes diverging from a central variant. Of the 17 haplotypes detected, only four were present in cultivated populations. These four haplotypes (in addition to a fifth haplotype, detected only in wild *C. subternata* and *C. intermedia* populations from Garcia's Pass, GAR Fig 1) were shared among species. Two of these haplotypes were detected in *C. intermedia* populations (wild and cultivated) and cultivated *C. subternata* populations, but were not present in any wild *C. subternata* populations screened.

Clustering of *Cyclopia* populations, based on pairwise population genetic distance resulted in weak grouping of species. Cultivated populations, however, exhibited little differentiation and generally clustered together based on species (Fig 3). Similarly, wild *C. longifolia* populations exhibited little genetic differentiation and all wild and cultivated populations of this species formed a single group (Fig 3). Wild *C. intermedia* and *C. subternata* populations tended to exhibit higher levels of genetic divergence. All cultivated *C. subternata* populations were clustered with two wild populations originating from the Tsitsikamma mountains (Kareedouw Pass KAR, and Bloukrans Bridge BKB). The remaining wild *C. subternata* populations were more

divergent and did not cluster with other *C. subternata* populations. The *C. intermedia* and *C. subternata* populations sampled from Garcia's pass (GAR) exhibited no genetic differentiation (both fixed for haplotype F). In general, wild *C. intermedia* populations tended to be genetically distinct, supporting unique haplotypes and formed no clear clusters in the Neighbor Joining population tree (Fig 3). Cultivated *C. intermedia* populations did not exhibit this variability. Rather, all cultivated *C. intermedia* populations form a single cluster with the wild *C. intermedia* population sampled from the Langkloof (LK).

In the cases of *C. subternata* and *C. intermedia*, genetic structuring was detected in wild populations, with 60.1% and 83.3% of genetic variation detected among populations for the two species, respectively (associated  $F_{st}$  values significant,  $p < 0.005$ ,  $F_{st} = 0.093$  and  $0.023$ , respectively). In contrast, no structuring was detected in cultivated populations of these species, with 4.3% and 1.7% of variation structured within cultivated populations for *C. intermedia* and *C. subternata*, respectively ( $p < 0.005$ ,  $F_{st} = 0.0001$  for both species). No genetic structuring was found for wild or cultivated *C. longifolia* populations, as all populations shared the same common haplotype and only two rare haplotypes (N and M, Fig 2) were detected in wild populations. Gene diversity and genetic differentiation followed a similar pattern, with wild *C. intermedia* and *C. subternata* populations having higher mean diversity than cultivated populations ( $p < 0.01$ ), but no differences in gene diversity was detected between wild and cultivated *C. longifolia* populations. Mean genetic differentiation ( $G_{st}$ ,  $G'_{st}$  and Jost's  $D$ ) was higher in all wild populations than in cultivated populations. All population differentiation and diversity measures are summarized in Table 3.

## Discussion

This study set out to explore haplotype diversity patterns in wild and cultivated populations of Honeybush, an endemic neo-crop from the Cape Floristic Region (CFR) of South Africa. Cultivated populations appear to have originated from a small number of founding populations and/or individuals and represent a genetic bottleneck. Thus, cultivated populations tend to lack

the genetic diversity and phylogeographic structuring present in wild populations and may represent a genetic threat to wild populations if gene-flow occurs.

# **Origin of cultivated genetic diversity**

Despite initial *Cyclopia* breeding material originating from multiple wild populations (Joubert et al. 2011, Fig 1), screening for individuals with commercially desirable traits has likely removed much of the haplotype richness from commercial breeding stock. The transition to Honeybush cultivation therefore represents a genetic bottleneck — under representing rare haplotypes and homogenizing the cultivated genepool.

Based on the NJ clustering of populations (Fig 3), cultivated *C. intermedia* have likely originated from populations located in the Langkloof (LK); *C. subternata* populations from the Tsitsikamma and/or Outeniqua mountains (these wild populations share the same common haplotype found in cultivated populations); while *C. longifolia* originates from its only known wild source, the Van Stadens River system. These findings are consistent with those from recent microsatellite analysis of *C. subternata* (Niemandt et al. 2018). They compared wild populations from the Tsitsikamma and Outeniqua mountains to the Agricultural Resource Council's (ARC) commercial genebank (an important source of commercially traded Honeybush seed), revealing no genetic differentiation between the two wild populations sampled and the genebank accessions. The lack of haplotype diversity detected in cultivated populations is therefore unlikely to be a byproduct of failing to detect variation in the slow evolving chloroplast genome (Schaal et al. 1998), as greater divergence was detected among populations originating from the Tsitsikamma or Outeniqua mountains using cpDNA screening via HRM than in the microsatellite based study.

The history of the movement of cultivated seed remains speculative and conversations with cultivators during sampling revealed that seed is largely sourced from existing farmer networks in their respective areas (with the initial origin of seed unknown). However, *C. subternata* cultivated in Harkerville (H) was confirmed to have been established from commercial seed and did not differ in dominant haplotypes from other cultivated populations. Furthermore,

Harkerville shared a rare haplotype with cultivated material from Uniondale (U) — where putative hybrids were detected (N.C. Galuszynski personal observations, 2018, leaf material from these individuals was collected and is stored at the Nelson Mandela University in Port Elizabeth, South Africa). This rare haplotype was only detected in wild *C. intermedia* populations located in the Swartberg Mountains (SWB) and may be evidence of possible chloroplast capture (Hansen et al. 2003) resulting from interspecific crosses taking place during the initial breeding trials (Joubert et al. 2011) or under field cultivation. The reasoning behind this argument is two fold. First, the chloroplast regions screened exhibit phylogeographic structuring in both species (Galuszynski and Potts 2020a, 2020c) and it is therefore unlikely that a wild *C. subternata* population will support this rare haplotype outside of the Swartberg mountains (where *C. subternata* does not naturally occur). Secondly, *C. intermedia* and *C. subternata* have been found to successfully produce hybrid offspring with other members of the genus under experimental conditions, and *C. intermedia* material from the Swartberg was included in the initial Honeybush cultivation trials (Joubert et al. 2011, Fig 1). However, interspecific hybridization should be investigated through additional molecular work targeting the nuclear genome, which is subject to recombination and provides more insight into introgression history.

## Potential impacts of cultivated genetic material on wild populations

Higher levels of genetic diversity were detected in wild *Cyclopia* populations than cultivated populations, with multiple cases of near complete haplotype turnover among wild populations (Table 1) — cultivated populations exhibited nearly no differentiation (Table 3). This level of haplotype turnover and genetic structuring of cpDNA in the wild was expected and has been described in detail for *C. intermedia* (Galuszynski and Potts 2020a) and *C. subternata* (Galuszynski and Potts 2020c). This suggests that there may be a tendency for cultivated populations to fail to account for natural phylogeographic patterns in regions where genetic structuring of plant populations occurs, including regions that may play a significant role in the discovery of neo-crops (eg. Mesoamerica, Ornelas et al. 2013; South America, Turchetto-Zolet

et al. 2013; Australia, Byrne 2008; the Mediterranean basin, Feliner 2014; and the Cape of South Africa, Galuszynski and Potts 2020b, Tolley et al., 2014).

Genetic diversity differed between species (Table 3), suggesting different demographic histories among these closely related taxa (Ellegren and Galtier 2016). Notably, rare and locally endemic taxa are predicted to have low levels of genetic variation due to their restricted distributions and small population sizes (Ellstrand and Elam 1993; Gitzendanner and Soltis 2000; Segarra-Moragues et al. 2012), evident in wild *C. Longifolia* populations. The redistribution of genetic lineages via neo-crop cultivation needs to account for differences in demographic histories. Local endemics, for instance, may be at greater genetic risk from cultivated variants due to naturally low levels of genetic variation being more susceptible to genetic pollution by foreign lineages (Levin et al. 1996; Wolf et al. 2001). Commercial production of narrow endemics may therefore require periodic supplementing of cultivated stands with locally sourced seed material in order to promote the preservation of rare haplotypes.

Genetic pollution can only occur if genetic material is able to escape into the wild. Seed dispersal is limited to a few meters in *Cyclopia*, and one would expect the chances of seed escape to be low. However, unmonitored spillover of cultivated seed into adjacent natural habitat does occur (N. C. Galuszynski, pers. obs. 2017) in addition to rare cases of cultivated plants intentionally established in natural vegetation (N. C. Galuszynski pers. obs. 2017; G. McGregor pers. com. 2016; S. Nortje pers. com. 2019). The chloroplast genome is maternally inherited with no recombination in the majority of angiosperms (Mogensen, 1996) and is, therefore, subject to directional selective sweeps. Thus, the introduction of vigorous maternal lineages from commercial seed lots could disrupt local haplotypes diversity in wild crop plants. While the impacts of foreign haplotypes establishing in wild Honeybush populations is unknown, the introduction of foreign *Spartina alterniflora* (Poaceae) haplotypes from the United States to native Chinese populations resulted in a hybrid swarm that disrupted local cpDNA genome frequency and ecological processes due to vigorous growth displacing native plant species (Qiao et al., 2019).

Mass flowering of cultivated populations forms a powerful attractant to pollinators, increasing local pollinator density (Holzschuh et al. 2011; Westphal et al. 2003). This facilitates the spread of genetic material from cultivated populations into the wild via pollen flow, particularly in outcrossing species (Ellstrand et al., 1999), such as members of *Cyclopia* (Keon et al., 2020). By altering local allele frequencies through the introduction of large genetically depauperate commercial plantations, a landscape wide genetic bottleneck may result, promoting erosion of wild genetic diversity. The current state of neo-crop cultivation, relying on low genetic diversity breeding stock that is redistributed outside of its natural range (and possibly containing interspecific hybrid taxa as observed in the Honeybush populations in Uniondale, but requiring further research), represents a genetic threat that should be acknowledged and mitigated.

Until the genetic risks are better understood, formal guidelines should be developed to facilitate sustainable cultivation of neo-crops. In the case of Honeybush, an ecology-centric approach, as the one outlined by Potts (2017), may be desired due to the conservation value of many *Cyclopia* species; including the commercially important taxa: *C. longifolia* (critically endangered), *C. genistoides* (near threatened), *C. maculata* (near threatened), *C. plicata* (endangered), and *C. sessiliflora* (near threatened). However, it is unlikely that all neo-crops will exhibit the levels of phylogeographic structuring, genetic diversity and, conservation requirements of *Cyclopia*, and more work is required to define the extent to which wild genetic resources are at risk during neo-crop cultivation practices, particularly in species rich landscapes such as the Cape of South Africa.

# **Table 1**(on next page)

Summary of wild and cultivated Honeybush (*Cyclopia*) populations.

Population localities, including population name and abbreviation (used in Fig. 1 and 3), mountain range each population was sampled from, geographic coordinates, number of accessions screened per population (N), number of haplotypes detected per population (H) with haplotypes unique to the population given in parenthesis, and summary of haplotypes found in each population.

1

Origin	Species	Location		GPS co-ordinates		N	H	Haplotype

# **Table 3**(on next page)

Genetic diversity, fixation and differentiation measures for wild (W) and cultivated (C) Honeybush (*Cyclopia*) populations.

Significance values are indicated for comparisons of mean genetic diversity, fixation and differentiation between wild and cultivated populations for each species and all species pooled (Total).

1

Species	Source	N	Hr	GD	Gst (SD)	G'st	Jost's D	Genetic variation (%)
<i>C.intermedia</i>	W	94	6	0.202**	0.725 (0.178)***	<b>0.864 (0.111)***</b>	0.223 (0.100)***	83.3***

3

# Figure 1

Distribution of *Cyclopia* populations screened for haplotype diversity.

*Cyclopia* populations indicated by circles, with the colors for wild and cultivated populations for each species indicated. Red stars indicate the locations of Honeybush nurseries, white pentagons indicate the locations of populations initially used for cultivar development for each species respectively. The natural distribution of the three target species is indicated using the same colors used to indicate wild populations and shaded. A) Distribution of *C. intermedia*, in set indicates the study domain in relation to Africa and South Africa; B) distribution of *C. subternata*; and C) distribution of *C. longifolia*, the initial source of *C. longifolia* breeding material is the same location as the Longmore populations (LMF, LMR) and cultivated material was sourced from G, P, and U (in A and B and indicated by a light blue outline). Population naming follows the descriptions in Table 1. Cultivated populations: G = George, U = Uniondale, H = Harkerville, HAR = Harlem, P = Plettenberg Bay. Wild populations: GAR = Garcia's Pass, SWB= Swartberg Mountains, LK = Langkloof, LS = Lady Slipper, OP = Outeniqua Pass, BKB = Bloukrans Bridge, KAR= Kareedouw Pass, LMF = Longmore Forest, LMR = Longmore River, SR = Sand River, VS = Van Stadens River.

# Figure 2

The relationships among haplotypes from the merging chloroplast DNA regions screened via HRM, as inferred from the statistical parsimony algorithm.

Black circles indicate "missing" haplotypes, whilst haplotypes connected by a single line differ by a single nucleotide mutation. Areas of circles and numerical labels correspond to the haplotype frequency. Circle colour indicates the species and source of each haplotype (as denoted by the figure key, with the size of each colour segment corresponding to haplotype frequency. Note that haplotypes A and B occur at low frequencies in some species: A occurs once in cultivated and wild *C. subternata* populations, and once in wild and twice in cultivated *C. intermedia* populations, B occurs twice in cultivated *C. subternata* populations. Haplotypes marked with \* indicate possible cases of chloroplast capture, as these haplotypes were detected only in cultivated *C. Subternata* populations and wild and cultivated *C. intermedia* populations, but not in any wild *C. subternata* populations. Haplotypes frequencies for each population are given in Table 1 and nucleotide differences among haplotypes are summarized in Table 2.

# Figure 3

Unrooted Neighbour Joining clustering diagram of *Cyclopia* populations based on pairwise population genetic distance.

Branches with over 50% bootstrap support are labeled. A scale bar of pairwise population genetic distance is provided above the diagram. Branch tips are labeled by species followed by an abbreviated population name following the descriptions Table 1. Open circles indicate wild populations while closed circles indicate cultivated populations. Wild and cultivated populations that group together are indicated by bold type face.
