

## **No evidence that presence of sexually transmitted infection selects for reduced mating rate in the two spot ladybird, *Adalia bipunctata*.**

Gregory D D Hurst, Sophie L Jones, Daria Pastok

Sexually transmitted infections (STIs) are common in animals and plants, and frequently impair individual fertility. Theory predicts that natural selection will favour behaviours that reduce the chance of acquiring a STI. We investigated whether an STI, *Coccipolipus hippodamiae* has selected for a reduced rate of remating by its host *Adalia bipunctata* as a mechanism to avoid exposure. We first demonstrated that rejection of mating by females did indeed reduce the chance of acquiring the mite. We then examined whether rejection rate and mating rate differed between ladybirds from mite-present and mite-absent populations when tested in a common environment. No differences in rejection intensity or remating propensity were observed between the two populations. We therefore conclude there is no evidence that STIs have driven the evolution of mating systems in this species.

1 **Abstract**

2 Sexually transmitted infections (STIs) are common in animals and plants, and frequently  
3 impair individual fertility. Theory predicts that natural selection will favour behaviours that  
4 reduce the chance of acquiring a STI. We investigated whether an STI, *Coccipolipus*  
5 *hippodamiae* has selected for a reduced rate of remating by its host *Adalia bipunctata* as a  
6 mechanism to avoid exposure. We first demonstrated that rejection of mating by females did  
7 indeed reduce the chance of acquiring the mite. We then examined whether rejection rate and  
8 mating rate differed between ladybirds from mite-present and mite-absent populations when  
9 tested in a common environment. No differences in rejection intensity or remating propensity  
10 were observed between the two populations. We therefore conclude there is no evidence that  
11 STIs have driven the evolution of mating systems in this species.

12

## 1 INTRODUCTION

2 Sexually transmitted infections (STIs) can be defined as infections that are primarily  
3 transmitted following sexual contact. Over 200 STIs have been identified to date and have  
4 been discovered in 48 families and 27 orders of hosts (Lockhart et al. 1996). Hosts vary from  
5 plants (e.g. the pollinator-transmitted anther smut *Ustilago violacea* which infects white  
6 campion, *Silene alba* (Thrall et al. 1993)), through to mammals (e.g. *Trypanosoma*  
7 *equiperdum* found in horses (Smith & Dobson 1992)). In the past, vertebrate STIs were the  
8 most heavily studied and widely understood STIs, and insect STIs were somewhat neglected  
9 (Lockhart et al. 1996; Lombardo 1998; Sheldon 1993; Smith & Dobson 1992). However in  
10 more recent years, insect STIs have received increasing attention. Knell & Webberley (2004)  
11 noted records of 73 species of STIs infecting approximately 182 species of insect. It is  
12 notable that insect STIs are most commonly multicellular ectoparasites, such as mites, worms  
13 and fungi, which contrasts with microbial STIs identified in vertebrates.

14 Most STIs have relatively small negative effects on host mortality, but tend to reduce  
15 fecundity or sterilise the host (Lockhart et al. 1996). Natural selection should therefore favour  
16 host traits that reduce the risk of infection. There are three possible behavioural routes to  
17 reducing the chance of acquiring an STI. First, if female fertility is not limited by low  
18 remating rates, exposure can be limited by mating with fewer partners. Theory predicts that  
19 STI presence should select for an increase in female refusal to mate when courted (Boots &  
20 Knell 2002; Kokko et al. 2002). Second, there is the possibility of rejection of infected  
21 partners in favour of uninfected ones. Previous studies provide no evidence for such a choice  
22 in either laboratory tests or natural populations (Abbot & Dill 2001; Nunn 2003; Webberley  
23 et al. 2002). Finally, it has been postulated that some post-copulatory grooming processes,  
24 and in cape ground squirrels, post-copulatory masturbation, may have evolved as a means of  
25 preventing STI transmission (Hart et al. 1988; Nunn 2003; Waterman 2010).

1 The interaction between the two-spot ladybird, *Adalia bipunctata*, and its ectoparasitic mite  
2 *Coccipolipus hippodamiae*, represents the best studied invertebrate-STI interaction. The mite  
3 lives under the elytra of the beetle, and larval mites move between host individuals that are  
4 copulating (Hurst et al. 1995). Mite infection in females is associated with a rapid loss of  
5 fertility, such that acquiring an infection is very costly to females. The two-spot ladybird is a  
6 promiscuous species where females mate once every 2-3 days in the wild (Haddrill et al.  
7 2008). Where the mite is present, this promiscuity leads to an epidemic of this disease during  
8 the spring/summer mating season, during which nearly all adult beetles become infected  
9 (Ryder et al. 2014; Ryder et al. 2013; Webberley et al. 2006a).

10 The STI is thus both prevalent and highly costly to female hosts, creating a selection pressure  
11 for direct avoidance of infected partners through mate choice, and indirect avoidance of mite  
12 acquisition through reduced mating rate. Previous laboratory and field studies provided no  
13 evidence that ladybirds discriminated against infected partners in mating decisions  
14 (Webberley et al. 2002). However, the hypothesis that selection has acted to increase the  
15 general tendency to reject matings has not been tested. One prediction of this hypothesis is  
16 that rejection behaviour should be more intense, and mating rate lower, in ladybirds from  
17 populations where the mite is present.

18 In this paper, we examine first whether rejection is efficient at preventing mite transfer, and  
19 then test the hypothesis that ladybirds from populations in which the STI is present have been  
20 selected for more intense rejection behaviour and lower mating rate, as a means of avoiding  
21 infection. Our measures, which are made under standardized laboratory conditions, provide  
22 no evidence that rejection behaviour or remating propensity differs between these  
23 populations.

24

1 MATERIALS AND METHOD

2

3 *Experiment 1: Is rejection of mating by a female an efficient means of preventing transmission*  
4 *of C. hippodamiae infection?*

5 Female and male ladybirds were collected from Stockholm in June/July 2011 and returned to  
6 the laboratory. They were sexed and classified as being uninfected, latent infected or  
7 infectious on the basis of absence of mites, presence of mites without infectious larval mites,  
8 and presence of larval mites ready to transmit. Pairs comprising a single infectious male with  
9 a focal uninfected female, and single infectious female with a focal uninfected male were  
10 established in clean Petri dishes in the laboratory, and behaviour observed for 30 minutes.  
11 Behaviour was scored as no interaction, rejected mating, and successful mating. Pairs that  
12 mated were allowed to mate to completion before separation of the focal partner to a new  
13 dish. The focal individual was then examined 24 hour later for the presence of larval mites.  
14 The importance of focal host sex and mating/rejection on mite transfer was analysed with a  
15 binomial GLM.

16

17 *Experiment 2: Do female beetles from populations that carry the STI show lower mating*  
18 *rates and a greater likelihood of rejecting mating?*

19 *Adalia bipunctata* were collected from two locations c. 300 km apart in Sweden during  
20 August 2012: Nässjö (57.7°N, 14.7° E) and Stockholm (59.3°N, 18.1°E). The Nässjö  
21 population is free of mite infection (Webberley et al. 2006b), whereas there is an annual  
22 epidemic of the infection in Stockholm, leading to nearly all beetles becoming infected  
23 (Ryder et al. 2014; Ryder et al. 2013). Females from these populations were allowed to mate  
24 with sympatric males, and progeny reared in the laboratory. This rearing was conducted  
25 concurrently for both populations to standardize environment. The resulting adult ladybirds

1 were maintained in single sex dishes and allowed to mature for 30 days before experimental  
2 analysis of rejection behaviour and mating rate. During this time, they were provided with an  
3 ample supply of pea aphid food daily to ensure the beetles were in reproductive condition by  
4 the time the experimental observations commenced. All behavioural observations occurred in  
5 the absence of mites to avoid any direct impact of mites on the mating behaviour of their host  
6 (although none have previously been observed: (Webberley et al. 2002))

7  
8 Rejection behaviour and mating rate were analysed over daily mating trials carried out over a  
9 five day period. ‘Pools’ of five females and five males were created for each population. In  
10 each case males were from same population as females, but unrelated to them. Within each  
11 pool, males and females were mixed and allowed to mate once three days before the  
12 experiment. This was intended to reduce artefactual behaviour resulting from single sex  
13 confinement. Subsequently, females from each pool were offered a male for 30 minutes at the  
14 same time each day for a five day period, with each female being offered a different male  
15 every day (see Table 1 for block design).

16 During each mating trial, each pair was placed in a clean Petri dish at 21°C for the duration of  
17 the observation, and the presence of the following behaviour observed:

- 18 a) The number of interactions between male and female
- 19 b) The presence and duration of rejection behaviour during these interactions. Rejection  
20 behaviour was categorised into different intensity levels; no rejection observed; mild  
21 rejection (<1 minute); moderate rejection (1-5 minutes) and intense rejection (>5  
22 minutes).
- 23 c) Whether interactions resulted in mating

1 From these measures, the likelihood of a female rejecting mating, the intensity of rejection,  
2 and the probability of successful mating occurring were calculated.

3 Four replicate groups were used, resulting in 20 females being tested for each population.

4

5

## 1 RESULTS

2

3 *Experiment 1: Is rejection of mating by a female an efficient means of preventing transmission*  
4 *of C. hippodamiae infection?*

5 Transmission rates from wild caught infectious male and female individuals to uninfected  
6 partners with which they mated were high, with only one of 26 females not acquiring  
7 infection during mating with an infectious male partner, and one of 35 males not acquiring  
8 infection from an infectious female partner. In contrast, transmission was rare when mating  
9 was rejected, with one of seven females acquiring an infection following rejection of the  
10 infectious male, and one of three males acquiring infection having been rejected by an  
11 infectious female. Statistical analysis revealed no evidence for an interaction term between  
12 sex of infected host and mating/rejection behaviour on mite transfer probability. Statistical  
13 analysis with the interaction term dropped revealed no effect of donor sex on transmission  
14 probability (GLM factor host sex,  $p=0.288$ ), but a significant effect of the factor  
15 'rejected/mated' (GLM factor mated/rejected,  $p<0.0001$ ). Thus rejection behaviour by the  
16 female is protective against mite transfer both from an infected male, and additionally  
17 prevents transmission to an uninfected male partner.

18

19 *Experiment 2: Do female beetles from populations that carry the STI show a greater*  
20 *likelihood of rejecting mating and a lower mating rate?*

21 Mating was observed to be more common on day 1 than on other days in experiments  
22 involving both Stockholm and Nässjö (Figure 1). Combining over blocks, and between  
23 locations, mating was heterogeneous over the experiment ( $\chi^2=16.042$ ,  $df=4$ ,  $p=0.003$ ). This  
24 heterogeneity is associated with high mating rates on day 1 (after 3 days without mating  
25 activity); when day 1 is excluded, mating rates are homogenous over days 2-5 ( $\chi^2=0.276$ ,

1 df=3, p=0.964). Thus, in further analysis, day 1 mating is excluded, as the high mating rate  
2 on this day is likely to be associated with experimentally induced lack of mating opportunity.  
3 Of the 80 male-female interaction trials in each population observed after day 1, males  
4 approached females for mating in 64 cases for both populations. Where interactions occurred,  
5 most females exhibited some rejection behaviour in encounters after day 1, and this rejection  
6 was prolonged in over half of cases in both populations. There was no evidence that females  
7 from the two populations differed in the intensity of rejection behaviour following a male's  
8 attempt to mate ( $\chi^2=4.13$ , df=3, p=0.25) (Figure 2).

9 There was also no evidence for variation in overall propensity to mate between ladybirds  
10 from Nässjö (mite free in nature) and Stockholm (mite present in nature) (Figure 1). Across  
11 days 2-5, there was no evidence of an association between population and remating rate  
12 ( $\chi^2=0.627$ , df=1, p=0.428). We additionally reanalysed mating propensity to create a more  
13 ecologically relevant statistic. The confined experiment of the Petri dish allows males the  
14 ability to interact with female repeatedly, which is unlikely to occur in the field. An  
15 'environmental' mating rate based on the result of the first interaction between male and  
16 female only was therefore calculated, which discounted mating if this took more than five  
17 minutes to achieve. The 'environmental' mating rate for Stockholm and Nässjö was half that  
18 of the overall mating rate (Figure 3). Analysis indicates there was no evidence of association  
19 between location and 'environmental' mating rate ( $\chi^2=0.295$ , df=1, p=0.587).

## 20 DISCUSSION

21 Sexually transmitted infections are common in nature, and are frequently harmful to female  
22 hosts (Lockhart et al. 1996). Models predict that the presence of STIs should therefore select  
23 on female mating behaviour. Past work has failed to reveal any choice of mates associated  
24 with STI avoidance (Abbot & Dill 2001; Nunn 2003; Webberley et al. 2002). However, there

1 has been no test of the hypothesis that selection will promote avoidance of STIs through  
2 reducing propensity to remate (Boots & Knell 2002; Kokko et al. 2002). In this study, the  
3 mating biology of ladybirds from two populations were compared, one from Stockholm  
4 (where the STI is naturally present) and one from Nässjö (which is naturally uninfected). The  
5 mating rate did not differ significantly between the two populations. Combined with previous  
6 observations of lack of mate choice for uninfected partners, the data do not support the  
7 hypothesis that STIs have selected on female mating behaviour in this species, despite  
8 rejection of mating being partly effective at preventing STI transmission.

9 Failure to find a difference in remating rates between the two populations could have three  
10 sources. First, there may be no difference. Second, there may be a difference but the effect  
11 size is small (our experiment would not detect a 20% difference in mating rate). However, we  
12 would note that mating rate was quantitatively higher in beetles from Stockholm (mite  
13 present population) than Nässjö (mite absent). Third, the experiment may not be suitable to  
14 detect a difference, for instances if it is removed from natural conditions. 'Naturalness' is  
15 always a problem for laboratory study. Despite an experimental design that attempted to  
16 replicate natural mating environment e.g. temperature, lighting, there were possibly critiques  
17 of spatial confines, repeated interaction and ineffective behaviour. However, consideration of  
18 the first interaction only did not alter the conclusion that mating/rejection did not vary  
19 between populations. Thus, it is currently most parsimonious to conclude there are no fixed  
20 biological differences in mating propensity between these two populations.

21 We are thus confident that the presence of a sterilizing STI that reaches high prevalence has  
22 not led to the evolution of alteration of mating system between these two populations. Why  
23 has an intuitive evolutionary path not been taken? One possibility is that a high mating rate is  
24 required for female fertility, such that females who refuse to mate incur a cost. However,  
25 *Adalia* females mated singly have equivalent fertility, measured over 20 days, to females

1 mated every two days (Haddrill et al. 2007). Thus, there is ample scope for a female's risk of  
2 mite induced infertility to be reduced before sperm-depletion associated infertility is  
3 observed. A second possibility is that local adaptation is not possible in this species.  
4 However, the presence of variation in the frequency of colour pattern variants in this species  
5 on equivalent spatial scales (Brakefield 1984) make us confident gene flow is not sufficient to  
6 impede local adaptation. A third hypothesis is that selection to prevent STI does operate in  
7 the way expected, but there are other factors differing between the populations that influence  
8 mating rate evolution. It is possible that there is a counterbalancing selective force working in  
9 opposition to the effect of the STI. The source of such selection is not obvious (the two  
10 populations use similar habitat and have similar sex ratio), but such a hypothesis cannot be  
11 ruled out. Finally, the prediction that STIs select for lower mating rate applies to female  
12 hosts, in which there are smaller benefits to each additional mating, and in this species, higher  
13 costs of infection (sterility). Selection on males is not expected to act in the same way, as  
14 each mating provides significant fitness benefits, and the STI is only weakly costly to male  
15 hosts (Ryder et al. 2007). If mating rate is determined by males, then the STI is less likely to  
16 drive mating system evolution.

17 In summary, our experiment demonstrated rejection was efficient at preventing STI  
18 transmission, but did not occur more commonly in beetles derived from populations where  
19 the STI was common. This study, combined with previous analysis indicating STI infected  
20 beetles were not disadvantaged in acquiring mates (Webberley et al. 2002), produces no  
21 support for the hypothesis that mating behaviour evolves in response to the presence of a  
22 sterilizing STI. An intriguing possibility is that STIs are most commonly observed in species  
23 in which evolution to resist STI transmission is inhibited.

24 **ACKNOWLEDGEMENTS.** We wish to thank Tom Price for comments on the manuscript,  
25 and Tom Heyes for technical support.
