Human brucellosis (HB) remains a serious public health concern owing to its resurgence across the globe and specifically in China. The timely detection of this disease is the key to its prevention and control. We sought to describe the differences in the demographics of high-risk populations with detected cases of HB contracted from active versus passive sources. We collected data from a large sample population from January to December 2018, in Jining City, China . We recruited patients that were at high-risk for brucellosis from three hospitals and Centers of Disease Control and Prevention (CDCs). These patients were classified into two groups: the active detection group was composed of individuals receiving brucellosis counseling at the CDCs; the passive detection group came from hospitals and high-risk HB groups. We tested a total of 2,247 subjects and 13.3% (299) presented as positive for HB. The positive rates for active and passive detection groups were 20.5% (256/1,249) and 4.3% (43/998), respectively ($p<0.001$). The detection rate of confirmed HB cases varied among all groups but was higher in the active detection group than in the passive detection group when controlled for age, sex, ethnicity, education, career, and contact history with sheep or cattle ($p<0.05$). Males, farmers, those with four types of contact history with sheep or cattle, and those presenting fever, hyperhidrosis and muscle pain were independent factors associated with confirmed HB cases in multivariate analysis of the active detection group. Active detection is the most common method used to detect brucellosis cases and should be applied to detect HB cases early and avoid misdiagnosis. We need to improve our understanding of brucellosis for high-risk populations. Passive HB detection can be supplemented with active detection when the cognitive changes resulting from brucellosis are low. It is important that healthcare

providers understand and emphasis the timely diagnosis of HB.

21 **Abstract**

22    Human brucellosis (HB) remains a serious public health concern owing to its resurgence

23 across the globe and specifically in China. The timely detection of this disease is the key to its

24 prevention and control. We sought to describe the differences in the demographics of high-risk

25 populations with detected cases of HB contracted from active versus passive sources. We

26 collected data from a large sample population from January to December 2018, in Jining City,

27 China. We recruited patients that were at high-risk for brucellosis from three hospitals and

28 Centers of Disease Control and Prevention (CDCs). These patients were classified into two

29 groups: the active detection group was composed of individuals receiving brucellosis counseling

30 at the CDCs; the passive detection group came from hospitals and high-risk HB groups. We

31 tested a total of 2,247 subjects and 13.3% (299) presented as positive for HB. The positive rates

32 for active and passive detection groups were 20.5% (256/1,249) and 4.3% (43/998), respectively

33 ($p<0.001$). The detection rate of confirmed HB cases varied among all groups but was higher in

34 the active detection group than in the passive detection group when controlled for age, sex,

35 ethnicity, education, career, and contact history with sheep or cattle ($p<0.05$). Males, farmers,

36 those with four types of contact history with sheep or cattle, and those presenting fever,

37 hyperhidrosis and muscle pain were independent factors associated with confirmed HB cases in

38 multivariate analysis of the active detection group. Active detection is the most common method

39 used to detect brucellosis cases and should be applied to detect HB cases early and avoid

40 misdiagnosis. We need to improve our understanding of brucellosis for high-risk populations.

41 Passive HB detection can be supplemented with active detection when the cognitive changes

42    resulting from brucellosis are low. It is important that healthcare providers understand and

43    emphasis the timely diagnosis of HB.

**Introduction**

45

46    Human brucellosis (HB) is one of the most understudied tropical diseases. It is caused by the

47    genus *Brucella* and results in large economic losses in the livestock industry and incredible

48    illness in humans who contract the disease [1-3]. The disease is transmitted to humans through

49    close contact with sick animals or the consumption of contaminated raw meat or dairy products

50    [4, 5]. The threat of brucellosis varies among occupational groups and the general population [6].

51    Brucellosis is the most prevalent and tenth most prevalent disease among impoverished

52    populations in a study of 76 animal diseases and syndromes, respectively [7]. HB patients

53    present with fever, sweating, fatigue, osteoarticular pain [8, 9] and a variety of other

54    complications if not treated in a timely manner [10]. Chronic HB results in a wide range of

55    pathological conditions, including spondylitis, endocarditis, and meningoencephalitis, and can

56    affect most organs [11]. HB remains one of the most significant public health concerns in the

57    world. The World Health Organization (WHO) estimates that a quarter of cases are unreported

58    with 500,000 registered cases per year. The number of unreported cases with unspecified clinical

59    symptoms is estimated to be ten times higher than this figure [12]. HB has been on the rise since

60    2000 and is the only traditional statutory infectious disease in China where the current incidence

61    level is higher than the historical record. Brucellosis morbidity has increased since the middle-

62    and late-1990s and is one of the top ten total cases of Class A and B national notifiable infectious

63    diseases reported in the mainland of China [13, 14]. Shandong was among the top 10 provinces

64    reporting cases of HB but the disease has been reported in all cities in Shandong province since

65    2005 [15]. It is crucial to reduce this disease's morbidity through early detection and treatment.

66    HB is often misdiagnosed, or the diagnosis is delayed due to the disease's atypical symptoms

67    [16]. Cases that are not diagnosed and treated in a timely manner will become chronic and

68    reoccur, so a timely diagnosis is necessary.

69    The Jining CDC and county-level CDC agencies monitor HB cases in accordance with the

70    requirements of the Shandong CDC in China. These centers have assisted medical institutions in

71    the diagnosis and treatment of HB for 6 consecutive years since 2013. CDC agencies provide

72    serological testing and individual brucellosis counseling when HB is suspected. Patients

73    presenting clinical symptoms may choose to go to the hospital to be tested and treated. High-risk

74    populations are administered regular tests by the CDC for routine monitoring since they are

75    considered to be passive sources of the disease. We conducted this study to evaluate the

76    effectiveness of HB disease-detection using active sources, as determined by individual

77    brucellosis counseling, and passive sources, based on hospital and CDC reporting.

78

79    **Materials and Methods**

80    **Study population**

81    We enrolled participants from different testing sources who tested for HB from January to

82    December 2018, in Jining City (Figure 1). We obtained 1,249 participants from the eight CDC

83    centers in Jining City. Participants were tested to determine whether they were active HB cases.

84    These subjects were classified as the active detection group. The other 998 participants were

85    obtained from the three hospitals or CDC staff using passive means, such as a medical diagnosis

86    (n=480) or staff reporting for HB disease detection (n=518). These cases were classified as the

87  passive detection group and were obtained from suspected cases that were diagnosed in the

88  hospital or from high-risk rural groups identified through CDC surveillance.

89  **Case definition and data collection**

90  Brucellosis cases were subject to a defined brucellosis diagnosis (2012 edition) [17]. Suspected

91  cases were identified as being any patient with acute or insidious fever, clinical manifestations of

92  HB, and an epidemiological link with infected animals, contaminated food, or contact with a

93  confirmed case. Confirmed cases were defined as having a titer of greater than 1:100 in the test-

94  tube agglutination test (SAT), or a patient sample titer of more than 1:50 with a course of disease

95  lasting more than 1 year. We collected a blood sample of at least 3 mL from each participant

96  using a vacutainer needle. We performed the Rose Bengal plate test (RBPT) and serum

97  agglutination test (SAT) as previously reported [1]. All the reagents were configured and

98  provided by the Shandong CDC.

99  A self-designed questionnaire was used to collect information, including socio-demographic

100 characteristics, animal exposure, and clinical manifestations (Supplemental Table 1).

101 **Data management and analysis**

102 Data was entered using EpiData 3.1 software. We performed a descriptive analysis of the

103 independent variables for age, sex, nation, education, career, and history of contact. Quantitative

104 variables were expressed as mean with standard deviation (SD) or median with interquartile

105 range (IQR) according to the normality of the variable. Categorical data were analyzed using a

106 chi-square or Fisher exact test. Univariate analysis was done to evaluate the associations between

107 patients' characteristics and other variables. Covariates associated with $p$ value $\leq 0.2$ in the

108   univariate analysis were entered into a multivariate logistic regression model with the stepwise

109   method to obtain the final predictive model of covariates independently associated with HB. We

110   estimated the odds ratio (OR) and 95% confidence interval (95% CI). The area under the curve

111   (AUC) was used to evaluate the prediction accuracy of the model by receiver operating

112   characteristic curve (ROC) analysis. A two-sided $p$ value of less than 0.05 was considered

113   significant. All statistical analyses were done using SPSS software (version 22.0).

114   **Ethics statement**

115   The research protocol was approved by the Peking University Institutional Review Board

116   (IRB00001052-20008). The Research Ethics Committee waived the informed consent

117   requirement because data were legally obtained from the CDC. All the data were analyzed

118   anonymously.

119

120   **Results**

121   **Participant characteristics**

122   The median age of the study participants was 48 (IQR 37-56) years and there were 1,504

123   (66.9%) males studied (**Table 1**). The majority (2,174, 96.7%) of the patients were of Han

124   nationality and 1,195 (53.2%) participants had a median education level (with 9 years education).

125   Approximately half of the participants (1,121, 49.9%) were farmers and 1,565 (69.7%)

126   participants had contact history with sheep or cattle. There were significant differences in age,

127   ethnicity, education, career, and contact history with sheep or cattle between the active and

128   passive detection groups and the participants from the hospital and CDC in the passive detection

129    group (all *p*<0.05). There were more clinical manifestations, including fever, arthralgia,

130    debilitation, hyperhidrosis and muscle pain, observed in the active detection group than in the

131    passive detection group (*p*<0.05).

132    **Detection of HB**

133    Among the 2,247 participants tested for HB, 299 (13.3%, 95% CI 11.9%-14.8%) were positive

134    and confirmed as having HB. Positive HB cases in the active and passive detection groups were

135    20.5% (256/1,249, 95% CI 18.3%-22.8%) and 4.3% (43/998, 95% CI 3.1%-5.8%), respectively

136    (*p*<0.001). The percentage of positive HB tests varied for all participants, although there were

137    more positive cases in the active detection group than in the passive detection group when

138    accounting for age, sex, ethnicity, education, career, and contact history with sheep or cattle

139    (*p*<0.05) (Table 2). There was an increase in positive HB tests as age increased and years of

140    education decreased either in the active or passive detection group (*p*<0.001 for both). Male

141    participants of Hui ethnicity who were farmers had higher percentages of positive HB tests in the

142    active detection group, which was similar to the passive detection group results. The percentage

143    of positive HB tests due to contact with sheep or cattle was 16.0% (95% CI 14.3%-18.0%),

144    which was greater than the 7.0% (95% CI 5.2%-9.2%) among those with no contact. Exposure to

145    animal slaughter showed the highest percentage of positive HB tests (21.1%, 95% CI 16.3%-

146    26.5%), followed by exposure through sales (18.5%, 95% CI 12.7%-25.7%), processing (17.4%,

147    95% CI 9.3%-28.4%), and cultivation (14.3%, 95% CI 12.3%-16.4%). Similar results were

148    observed among the two detection groups.

149    There was a 7.7% (95% CI 5.5%-10.5%) positive HB rate obtained from the hospital among the

150   passive detection group, which was greater than the 1.2% (95% CI 0.4%-2.5%) obtained from

151   the CDC ($p<0.001$). The former was higher than the latter with variations in age, sex, ethnicity,

152   education, career, and contact history with sheep or cattle but most of the differences were not

153   significant due to the small sample size.

154   Participants with hyperhidrosis tended to have the highest percentage of positive HB tests

155   (30.0%), followed by muscle pain (28.4%), arthralgia (20.9%), debilitation (20.0%), and fever

156   (19.3%). These results were mirrored in the active detection group. Positive HB tests in the

157   passive detection group, including arthralgia (16.8%), muscle pain (14.7%), hyperhidrosis

158   (13.5%), debilitation (13.0%) and fever (6.3%), were lower than in the active detection group.

159   **Factors associated with the risk of HB**

160   Multivariate analysis determined that the male sex, farmer, four types of contact history with

161   sheep or cattle, and the presentation of fever, hyperhidrosis, and muscle pain were

162   independently-associated factors with confirmed HB. The active detection group's population

163   source with an AUC of 0.802 (0.777-0.827) (all $p<0.05$) is shown in **Table 3**. Selling lamb and

164   beef presented the highest risk of HB (OR=3.54, 95% CI 2.06-6.08) in the four types of contact

165   history with sheep or cattle. HB risk factors in the active detection group were the male sex,

166   farmer, two types of contact history with sheep or cattle (slaughter and selling), and the

167   presentation of fever, arthralgia and debilitation with an AUC of 0.760 (95% CI 0.732-0.788)

168   (**Table 3**). HB risk within the passive detection group was significantly associated with younger

169   age, cultivation of sheep or cattle, and arthralgia with an AUC of 0.673 (95% CI 0.639-0.706)

170   (all $p<0.05$). The cultivation of sheep or cattle and hyperhidrosis were associated with the risk of

171   HB infection in the passive detection group (**Supplemental Table 2**).

172

173   **Discussion**

174   HB is a major public health crisis in China. Although its true incidence remains largely

175   unknown, it is conservatively estimated to vary from less than 0.03 to more than 160 individuals

176   per 100,000 [16, 19, 20]. It is important to have early detection and treatment of suspected cases.

177   We investigated whether the detection rate of HB was higher in the active detection group than

178   in the passive detection group. The active detection group was typically aware of the CDC's role

179   as an institution for the detection of brucellosis, suggesting that the active detection method was

180   better able to detect HB based on greater HB awareness for this high-risk population.

181       A meta-analysis reported low levels of awareness and knowledge of HB among high-risk

182   groups in Asia and Africa [21], which was thought to be affected by many factors and is an

183   obstacle for public health. Raising awareness of brucellosis is of great significance for

184   controlling HB. HB prevention was publicized to high-risk populations in the study area to assist

185   in early detection and improve the awareness of HB. Those who were knowledgeable about HB

186   were more likely to use a detection service when clinical symptoms that may be related to HB

187   first appeared. This might be due to the fact that the positive rate was high than among the high-

188   risk population in the active detection group. Thus, active detection is effective for the early

189   detection of HB and publicity and education about HB may be effective in the affected areas.

190       We found a much lower HB detection rate in the passive detection group, including two

191   different participant sources from hospitals and the local CDC. However, the cause of the low

192   detection rate of HB between participants from these two sites may be different. The participants

193   from hospitals had similar clinical symptoms but had less contact history with sheep or cattle

194   compared to the participants from the local CDC. This result revealed a low detection rate and

195   may cause a high rate of HB misdiagnosis based solely on clinical manifestation. Participants

196   from the local CDC, however, had a higher frequency of contact history with sheep or cattle but

197   seldom presented with clinical manifestations of HB compared to the participants from hospitals.

198   These results revealed a low detection rate of HB based on contact history with sheep or cattle.

199   Active detection methods avoid the disadvantages of the two passive detection methods and

200   should be utilized on a larger scale. Active detection is also an important way to detect cases by

201   doctors from hospitals, considering the 7.7% detection rate in the hospital. Primary healthcare

202   workers should be aware of the symptoms of acute and chronic brucellosis when treating patients

203   [22]. The passive detection of HB by the CDC was more successful in a specific population.

204         Our findings showed that sex, career, contact history with sheep or cattle, and the

205   presentation of specific symptoms (fever, hyperhidrosis and muscle pain) were HB risk factors.

206   This is in agreement with findings from other studies [23-25].

207         Males had the highest disease incidence which may be a reflection of their occupational

208   exposure to livestock in a pastoral economy where females typically have less exposure to

209   livestock [26]. Farmers, who were typically older, developed HB more frequently. It is common

210   for the elderly in rural areas in northern China to raise cattle and sheep through family farming.

211   Our results indicated that efforts, such as increased publicity, education for farmers in contact

212   with cattle, and raising awareness of disease prevention through personal protection, must be

213   taken for the high-risk population.

214      Brucellosis is one of the most common zoonotic infections and contact with sheep or cattle is

215   the most important HB risk factor. Of the four types of contact history with sheep or cattle, the

216   sale of livestock showed the highest OR of HB, which may be related to longer exposure time to

217   lamb or beef. Slaughtering and processing also showed higher ORs than cultivation. The HB

218   detection rates in the slaughter, selling, and processing population will be lower when the

219   detection of *Brucella* before slaughter is improved.

220      We analyzed the characteristics of a high-risk population to improve the use of limited

221   healthcare resources and achieve better prevention and control of HB as diagnosing Brucella in

222   the laboratory is not in wide use. It is necessary to improve the monitoring of those with clear

223   occupational exposure history, especially those with clinical symptoms such as hyperhidrosis for

224   better passive detection. Patients can improve their awareness of HB through health education

225   and then proceed to active detection methods for better early diagnosis. Meeting the medical

226   needs of active cases is the priority for treatment of HB. Behavioral intervention should be

227   strengthened to improve treatment compliance and prevent chronic cases and recurrence of the

228   disease. The two detection methods have different focuses in the prevention and control of HB.

229   Passive detection mode sensitivity is low, but it is an important supplement when the cognitive

230   impairment of brucellosis is still low. The current brucellosis surveillance pattern in China

231   includes a passive surveillance system based on the epidemic and an active surveillance system

232   in key areas that include monitoring stations [27]. It is necessary to choose the appropriate

233   detection strategy of HB to improve the accuracy of monitoring data.

234    Our study provides valuable information about HB detection in Jining City, however, there

235    were some limitations. First, our study did not account for more high-risk population for HB in

236    the community when the population did not visit the health facilities including hospitals and

237    CDCs. Second, we did not investigate the subjects' awareness and knowledge of HB, which may

238    be related to the risk of contracting HB. Third, we did not culture for *Brucella spp.* to give a gold

239    standard result, which may have a certain bias on our reported prevalence.

240    We determined three measures for the control and prevention of HB in this region. First, the

241    public should be provided with more health education to improve the level of self-protection and

242    the awareness of timely diagnosis and treatment. Second, hospital healthcare providers should be

243    more aware of HB for a timely and accurate diagnosis. Third, the CDC, as the prevention and

244    control department of HB, should improve the breadth and depth of brucellosis detection and

245    screening to accurately diagnosis HB cases.

246    **Conclusion**

247    HB is a serious public-health problem owing to its resurgence in China and across the

248    globe. We clearly demonstrated that the active detection model more accurately detects cases of

249    HB than the passive detection model. We also revealed that those who had contact with sheep or

250    cattle had the highest risk of contracting HB. These results may help policy makers develop

251    appropriate prevention and control strategies.
