The recovery of marine life from the end-Permian mass extinction event provides a test-case for biodiversification models in general, but few studies have addressed this episode in its full length and ecological context. This study analyses the recovery of marine level-bottom communities from the end-Permian mass extinction event over a period of 15 Ma, with a main focus on the previously neglected main phase during the Middle Triassic. Our analyses are based on faunas from 37 lithological units representing different environmental settings, ranging from lagoons to inner, mid- and outer ramps. Our dataset comprises 1562 species, which belong to 13 higher taxa and 12 ecological guilds. The diversification pattern of most taxa and guilds shows an initial Early Triassic lag phase that is followed by a hyperbolic diversity increase during the Bithynian (early middle Anisian) and became damped later in the Middle Triassic. The hyperbolic diversity increase is not predicted by models that suggest environmental causes for the initial lag phase. We therefore advocate a model in which diversification is primarily driven by the intensity of biotic interactions. Accordingly, the Early Triassic lag phase represents the time when the reduced species richness in the wake of the end-Permian mass extinction was insufficient for stimulating major diversifications, whereas the Anisian main diversification event started when self-accelerating processes became effective and stopped when niche-crowding prevented further diversification. Biotic interactions that might drive this pattern include interspecific competition but also habitat construction, ecosystem engineering and new options for trophic relationships. The latter factors are discussed in the context of the resurgence of large carbonate platforms, which occurred simultaneously with the diversification of benthic communities. These did not only provide new hardground habitats for a variety of epifaunal taxa, but also new options for grazing gastropods that supposedly fed from microalgae growing on dasycladaceans and other macroalgae. Whereas we do not claim that changing environmental conditions were generally

unimportant for the recovery of marine level-bottom communities, we note that their actual role can only be assessed when tested against predictions of the biotic model.

## 12 Abstract

13 The recovery of marine life from the end-Permian mass extinction event provides a test-case for  
14 biodiversification models in general, but few studies have addressed this episode in its full length  
15 and ecological context. This study analyses the recovery of marine level-bottom communities  
16 from the end-Permian mass extinction event over a period of 15 Ma, with a main focus on the  
17 previously neglected main phase during the Middle Triassic. Our analyses are based on faunas  
18 from 37 lithological units representing different environmental settings, ranging from lagoons to  
19 inner, mid- and outer ramps. Our dataset comprises 1562 species, which belong to 13 higher taxa  
20 and 12 ecological guilds. The diversification pattern of most taxa and guilds shows an initial  
21 Early Triassic lag phase that is followed by a hyperbolic diversity increase during the Bithynian  
22 (early middle Anisian) and became damped later in the Middle Triassic. The hyperbolic diversity  
23 increase is not predicted by models that suggest environmental causes for the initial lag phase.  
24 We therefore advocate a model in which diversification is primarily driven by the intensity of  
25 biotic interactions. Accordingly, the Early Triassic lag phase represents the time when the  
26 reduced species richness in the wake of the end-Permian mass extinction was insufficient for  
27 stimulating major diversifications, whereas the Anisian main diversification event started when  
28 self-accelerating processes became effective and stopped when niche-crowding prevented further  
29 diversification. Biotic interactions that might drive this pattern include interspecific competition  
30 but also habitat construction, ecosystem engineering and new options for trophic relationships.  
31 The latter factors are discussed in the context of the resurgence of large carbonate platforms,  
32 which occurred simultaneously with the diversification of benthic communities. These did not  
33 only provide new hardground habitats for a variety of epifaunal taxa, but also new options for  
34 grazing gastropods that supposedly fed from microalgae growing on dasycladaceans and other  
35 macroalgae. Whereas we do not claim that changing environmental conditions were generally  
36 unimportant for the recovery of marine level-bottom communities, we note that their actual role  
37 can only be assessed when tested against predictions of the biotic model.

## 38 Introduction

39 The end-Permian mass extinction was the most severe extinction event in Earth's history and  
40 witnessed the extinction of 81% (*Stanley, 2016*) to 96% (*Raup, 1979*) of marine species. The  
41 aftermath of this event provides a unique test case to study how life rediversified after such a  
42 massive loss of species richness and which evolutionary processes were involved. In this study,  
43 these processes were analyzed in the ecological context in which they occurred. Previous studies  
44 with a similar scope concentrated on the Early Triassic (e.g. *Schubert & Bottjer, 1995; Twitchett*  
45 *& Wignall, 1996; Hofmann et al., 2013; Hofmann, Hautmann & Bucher, 2015; Foster et al.,*  
46 *2015; Hautmann et al., 2015; Foster et al. 2017; Foster, Danise & Twitchett 2017*), the time  
47 interval of ca. 4 Ma after the end-Permian mass extinction. These studies revealed, among other  
48 things, that (1) the recovery of the nekton (e.g. ammonoids and conodonts; *Orchard, 2007;*  
49 *Brayard et al., 2009; Brayard & Bucher, 2015*) is remarkably different from that of the benthos  
50 (*Hofmann, Hautmann & Bucher, 2013; Hofmann et al., 2013; Hofmann et al., 2014;*  
51 *Friesenbichler et al. 2019*), (2) the main recovery phase of the benthos did not start before the  
52 Middle Triassic (*Nützel, 2005; Hautmann, 2007; Hofmann et al., 2014; Friesenbichler et al.,*  
53 *2021*), (3) benthic ecosystem recovery was not completed before the end of the Middle Triassic  
54 (*Hausmann & Nützel, 2015*) and (4) the resurgence of large carbonate platforms and the recovery  
55 of reefs during the Middle Triassic (e.g. *Gaetani et al., 1981; Senowbari-Daryan et al., 1993;*

56 *Flügel, 2002*) possibly played an important role in the shift of taxonomic composition of benthic  
57 communities (*Friesenbichler et al., 2019*). Despite the fact that the Middle Triassic was  
58 obviously a crucial time for the recovery of benthic marine communities, corresponding studies  
59 (e.g. *Payne, 2005; Payne et al., 2006; Song et al., 2011; Velledits et al., 2011; Foster & Sebe,*  
60 *2017; Friesenbichler et al., 2019; Friesenbichler et al., 2021*) are still scarce. Relevant questions  
61 in the ecological-evolutionary context include: Was the delay in benthic recovery caused by  
62 adverse environmental conditions during the Early Triassic (e.g. *Hallam, 1991; Wignall &*  
63 *Twitchett, 1996; Pruss & Bottjer, 2004; Song et al., 2014*), or is it an intrinsic aspect of the  
64 diversification dynamics in a largely vacated ecospace (*Hautmann et al., 2015*)? How did  
65 community structures, ecological guilds and ecosystems change during the Middle Triassic, and  
66 how did these changes translate into observed diversification patterns? Did the resurgence of  
67 large carbonate platforms affect the guild structure, and if yes, which evolutionary processes  
68 were involved in the colonization of this new habitat type? What was the relative role of biotic  
69 processes such as interspecific competition, habitat alteration, ecosystem engineering and niche  
70 construction versus abiotic environmental conditions as controlling factors in diversification and  
71 ecosystem evolution? To which diversification model do the empirical patterns conform, and  
72 which conclusions does this imply for the diversification of life in general?

## 73 **Materials & Methods**

74 This study is based on data of macroinvertebrate occurrences compiled at the species level from  
75 palaeontological studies on Early and Middle Triassic lithological units (*Data S1*). We preferred  
76 this approach over using data from the Palaeobiology Database because it allowed us to control  
77 the correctness of the data. The evaluated studies include primarily monographs with well  
78 documented faunal lists, but we also considered studies that provide detailed information about  
79 macroinvertebrate occurrences including taxonomic assignments. Prime criteria for our selection  
80 of studies are the quality of documentation and the coverage of time intervals and environments.  
81 Moreover, we sought to include the most diverse lithological unit of each time interval as  
82 representatives for the maximum diversity that was possible at a given stage of recovery (see  
83 below).

84 We did not include any species for which we haven't studied the original description and figures.  
85 Taxa reported from thin sections or polished slabs were not considered because taxonomic  
86 assignments of these taxa were in most cases difficult to verify. The complete dataset includes 37  
87 lithological units comprising 1562 species belonging to gastropods (695 species), bivalves (587  
88 species), brachiopods (147 species), crinoids (33 species), echinoids (31 species), crustaceans  
89 (25 species), ophiuroids (12 species), scaphopods (nine species), serpulids (eight species),  
90 microconchids (six species), asteroids (four species), bryozoans (four species) and  
91 polyplacophores (one species; *Data S1*). Our approach led to a certain overemphasis of European  
92 lithological units (27) in comparison to those from Asia (five) and America (five units from the  
93 USA), but the prevailing cosmopolitanism of marine faunas of this time (*Kristan-Tollmann &*  
94 *Tollmann, 1982; Schubert & Bottjer, 1995*) justifies the priority of the quality of the  
95 documentation over geographic coverage.

## 96 **Data preparation**

97 The investigated lithological units represent different environments (*Data SI*). Investigated  
98 environments include lagoons (including carbonate platform interiors), inner ramps (above the  
99 fair-weather wave base), mid-ramps (between the fair-weather wave base and the storm wave  
100 base) and outer ramps (below the storm wave base). The assignment of faunas to a particular  
101 environment is based on the information given by the original authors or inferred from the  
102 geological and sedimentological context. Studies on lithological units that represent a range of  
103 different environments were only considered if the distribution of species within these  
104 environments was clear. Therefore, we did not include the Ladinian part of the Cassian  
105 Formation (Italy; *Urlich, 2017*) in our analyses, although it probably represents the highest  
106 benthic diversity of this time interval.

107 From the collected studies, fossil lists were compiled for each lithological unit. If information  
108 about one lithological unit was taken from more than one study, attention was paid on possible  
109 synonyms.

110 Each species was assigned to an ecological guild, usually based on information given by the  
111 original authors. In cases where such information was missing, the ecology was inferred from  
112 functional morphology, mode of life of Recent species and information from the literature.  
113 Species included in this study represent shallow to moderately deep infaunal suspension-feeders,  
114 shallow infaunal deposit-feeders, deep infaunal suspension-feeders, endobysate  
115 suspension-feeders, epibysate suspension-feeders, free-lying suspension-feeders, cemented  
116 epifaunal suspension-feeders, pedunculate suspension-feeders, epifaunal herbivores and/or  
117 detritus feeders, epifaunal carnivores, erected epifaunal suspension-feeders and epifaunal  
118 detritivore-suspension-feeders (Tab. 1). Gastropods, echinoids and ophiuroids were collectively  
119 assigned to epifaunal herbivores and/or detritus-feeders and epifaunal detritivore-  
120 suspension-feeders, respectively. We are aware that this might be an over-generalization, but the  
121 shell morphology of these taxa does not provide evidence for more specialized feeding in extinct  
122 species, and the ecology of Recent species justifies this assignment for most species. Species  
123 with uncertain ecology were considered for calculating species richness but were not included in  
124 the ecological analyses.

125 Time resolution is provided at the substage level. For lithological units that extend across  
126 substages, we assumed constant diversity across substages if the literature suggests that this  
127 assumption is justified (e.g. data from the Germanic basin; *Schmidt, 1928; Schmidt, 1938*).

## 128 **Data analyses**

129 Conventional diversity studies (e.g. *Sepkoski, 1984; Sepkoski, 1997*) through deep time have  
130 relied on higher taxonomic levels (genera, families, orders) as surrogates for the species level;  
131 however this approach may cause a strong bias (*Benton, 2001*). Unfortunately, compiling reliable  
132 global species level curves is virtually impossible because of the higher incompleteness of the  
133 fossil record for species than for higher taxa and the necessity of eliminating synonyms. We  
134 suggest here a feasible solution for circumventing these problems. We use the maximum species  
135 richness among all lithological units in a given time interval as a surrogate for the potentially  
136 highest recovery stage that biosphere could reach at this time point after the end-Permian mass  
137 extinction (Figs 1 and 2). In other words, for each substage and ecological guild, the lithological  
138 unit that contains the highest number of species was used as a reference point. Using this

139 approach, synonyms are not a major issue because it is irrelevant for the diversity of a given  
140 lithological unit whether the same species is described from another lithological unit under a  
141 different name.

142 Furthermore, we investigated relative changes in the ecological composition throughout the  
143 Early and Middle Triassic (Figs 3 and 4). For this purpose, the guild-species diversity (number of  
144 species per guild) for each substage was calculated. To do so, we summarized the number of  
145 species that occurred in all lithological units per substage. The sum of species was corrected for  
146 double counts, meaning that a species that occurred in several lithological units per substage was  
147 only counted once.

## 148 Results

149 Figure 1 shows the huge differences in species richness between Early and Middle Triassic  
150 benthic communities that hold across different environments (Fig. 2). The apparent decrease of  
151 species richness in the Longobardian (late Ladinian; Figs 1 and 2) is an artefact of the scarcity of  
152 data that would disappear e.g. if time-resolved data from the Ladinian part of the Cassian  
153 Formation were available (see Methods). Currently, only one lithological unit represents the  
154 middle and late Longobardian in Figs 1 and 2. Scarce data may also underlie changes in  
155 guild-species diversity seen in the Smithian (early Olenekian) and the Aegean (early Anisian;  
156 Fig. 3).

157 Epifaunal herbivores and/or detritus feeders (i.e. gastropods) diversified most quickly in the  
158 Middle Triassic. Shallow to moderately deep and deep infaunal, endobysate, epibysate,  
159 free-lying, cemented and pedunculate suspension-feeders as well as shallow infaunal  
160 deposit-feeders started diversifying at the same time (Fig. 5) but their species richness levelled  
161 out at lower plateaus.

162 Bivalves, gastropods and brachiopods were the most diverse taxa in Early and Middle Triassic  
163 benthic communities (*Data S1*). Bivalves had a relatively low and constant species richness  
164 throughout the Early Triassic and diversified quickly in the Bithynian (early middle Anisian)  
165 followed by a plateau (Figs 6A and 7). Except for the Smithian Sinbad Formation, the species  
166 richness of gastropods was low in the Early Triassic and started to increase rapidly in the  
167 Bithynian and their species richness started to exceed that of bivalves from the Pelsonian (late  
168 middle Anisian) onwards (Figs 6B and 7). Brachiopods also diversified in the Bithynian but not  
169 to the same extent as bivalves and gastropods did, and their species richness maintained a Middle  
170 Triassic plateau (Figs 6C and 7). Especially gastropods but also brachiopods were relatively  
171 diverse in lithological units that are associated with carbonate platforms (red lines in Figs 6B and  
172 6C). Fig. 6D shows a change in taxonomic composition from bivalve-dominated Early Triassic  
173 to increasingly more gastropod-dominated Middle Triassic faunas. Almost all lithological units  
174 associated with carbonate platforms are dominated by gastropods, which was already noticed by  
175 *Friesenbichler et al. (2019)*.

176 The guild-species diversity of epifaunal herbivores and/or detritus-feeders (i.e. gastropods)  
177 changed strongest among all ecological guilds during the studied time interval. During the Early  
178 Triassic they were the third most diverse guild but they started to diversify quickly during the  
179 Bithynian and became almost instantaneously the dominating guild in Middle Triassic benthic

180 communities (Fig. 3). The only environment where this trend is not observed are outer ramps,  
181 where their species richness remained constant (Figs 2D and 4D). Figures 5A and 5B show that  
182 their rapid diversification started in the Bithynian and continued throughout the Anisian.

183 Epibyssate suspension-feeders (chiefly pteriomorphian bivalves) were the most diverse guild in  
184 the Induan and the Spathian (late Olenekian). During the Bithynian their absolute richness  
185 increased whereas their relative richness decreased (Figs 1, 3, 5C and 5D) and continued to  
186 decrease slightly throughout the Middle Triassic. This decrease is also apparent in lagoons, inner  
187 and mid-ramps, whereas in outer ramps their relative diversity increased slightly (Fig. 4).

188 Shallow to moderately deep infaunal suspension-feeders (bivalves and inarticulate brachiopods)  
189 were among the most diverse guilds during the Early Triassic but their relative richness  
190 decreased gradually after the Aegean (Figs 1 and 3). The same trend occurred in the  
191 guild-species diversity in lagoons, mid- and outer ramps; however, in mid-ramps the relative  
192 species richness of shallow to moderately deep infaunal suspension-feeders was higher in the late  
193 Illyrian (late Anisian) to late Fassanian (early Ladinian) interval than in the late Pelsonian to  
194 early Illyrian (Figs 4A, 4C and 4D). In inner ramp settings, the relative amount of shallow to  
195 moderately deep infaunal suspension-feeders decreased already during the Spathian. Their main  
196 recovery phase started in the Bithynian but the diversification rate seemed to slow down  
197 afterwards (Figs 5C and 5D).

198 At the beginning of the Spathian, the relative richness of endobyssate suspension-feeders  
199 (bivalves) started to increase, but after the Aegean, it decreased continuously (Fig. 3). The same  
200 trend occurred in lagoons and outer ramps. In inner and mid-ramp settings, the relative amount  
201 of endobyssate suspension-feeders was more or less constant after the Spathian (Fig. 4). The  
202 species richness of endobyssate suspension-feeders increased constantly during the Early  
203 Triassic, followed by a rapid rise in species richness in the Bithynian. However, after this  
204 increase their species richness remained constant (Figs 5C and 5D).

205 The relative amount of pedunculate suspension-feeders (articulate brachiopods) fluctuated. They  
206 were relatively diverse during the Griesbachian (early Induan) and after the Bithynian but in  
207 between they were rather uncommon. After the early Illyrian they became gradually less diverse  
208 (Fig. 1). In Early Triassic mid-ramp settings, they are only recorded from the Griesbachian. Their  
209 relative importance was high during the Bithynian, but afterwards they became less common. In  
210 outer ramps from the Early Triassic, this guild is only reported from the Griesbachian and  
211 Dienerian (late Induan); however, in Middle Triassic outer ramps pedunculate suspension-  
212 feeders were the most diverse guild (Fig. 4D). They experienced a rapid rise in diversification in  
213 the Bithynian (Figs 5C and 5D).

214 Other guilds were rather uncommon during the Early and Middle Triassic or not represented in  
215 all time slices (Figs 1 and 3). Deep infaunal suspension-feeders (siphonate bivalves) are first  
216 reported from the Spathian (Fig. 3) and showed a weak increase in species richness in the  
217 Bithynian (Figs 5E and 5F). The species richness of shallow infaunal deposit-feeders (i.e.  
218 nuculid bivalves and scaphopods) and free-lying epifaunal suspension-feeders (bivalves)  
219 increased in the Bithynian but stayed constant during the remaining of the Middle Triassic (Figs  
220 5E and 5F). Cemented epifaunal suspension-feeders (e.g. oysters, serpulids, microconchids) and  
221 erected epifaunal suspension-feeders (i.e. crinoids) also started to diversify during the Bithynian,

222 but their later diversification pattern is poorly documented (Figs 5G and 5H). Epifaunal  
223 detritivore-suspension feeders (i.e. ophiuroids) and epifaunal carnivores (i.e. asteroids and  
224 crustaceans) started to diversify in the Aegean or Bithynian (Figs 5G and 5H).

225 A remarkable aspect of the guild analysis is that the explosive Anisian diversity increase was not  
226 associated with the evolution of new benthic guilds, confirming previous observations by *Foster*  
227 & *Twitchett (2014)*.

## 228 Discussion

### 229 Possible biases

230 Our data indicate an explosive increase in benthic diversity at the beginning of the Middle  
231 Triassic that followed an extended Early Triassic lag phase (Fig. 1). Can this pattern result from  
232 a bias in preservation, rock exposure or research history?

233 A preservation bias in Early Triassic strata has often been proposed as a possible reason for the  
234 generally low species richness at that time (e.g. *Erwin, 1996; Wignall & Benton, 1999; Peters &*  
235 *Foote, 2002; Nützel & Schulbert, 2005; Hautmann et al., 2011*), but well preserved Early  
236 Triassic benthic faunas have been reported worldwide, e.g. from the western USA (*Batten &*  
237 *Stokes 1986; Hautmann & Nützel 2005; Nützel & Schulbert 2005; Pruss, Payne & Westacott,*  
238 *2015; Brayard et al. 2017*), South China (*Kaim et al., 2010; Hautmann et al., 2011; Hautmann*  
239 *et al., 2015; Foster et al. 2019*), Russia (*Shigeta et al., 2009*) and Pakistan (*Wasmer et al. 2012;*  
240 *Kaim et al., 2013*); even silicified faunas are known from the Early Triassic of Oman (*Twitchett*  
241 *et al., 2004; Wheeley & Twitchett, 2005; Oji & Twitchett, 2015*) and Svalbard (*Foster, Danise &*  
242 *Twitchett, 2017*). However, all these well preserved Early Triassic benthic communities are  
243 much less diverse than communities from comparable settings in the Middle Triassic, so their  
244 low diversity is probably a primary signal.

245 Except for taxonomic oversplitting and synonyms (see Methods), the history of research and the  
246 size of exposure influence our knowledge on species richness. In our data, the most extreme  
247 potential bias in this respect is between the stratigraphically adjacent data points from the  
248 Bithynian *Tubiphytes*-Limestone Member (Romania) and the Jena Formation (Germany), which  
249 corresponds to the strongest increase in diversity within the studied time interval. The described  
250 fauna from the *Tubiphytes*-Limestone Member comes from only 1.5 m<sup>3</sup> of rock material  
251 (*Grădinaru & Gaetani, 2017; Nützel, Kaim & Grădinaru, 2018; Friesenbichler et al., 2021*), and  
252 rarefaction analysis indicates that the bivalve fauna is actually insufficiently sampled  
253 (*Friesenbichler et al., 2021*). In contrast, the Germanic Triassic looks back on a long history of  
254 research and is represented by a large outcrop area, which should correspond to a significantly  
255 higher completeness of sampled biodiversity. However, correcting the data point from the  
256 *Tubiphytes*-Limestone Member towards a higher diversity would solely shift the starting point of  
257 the main diversity increase from the middle to the early Bithynian, but not alter the overall shape  
258 of the diversity trajectory.

### 259 Extrinsic or intrinsic control?

260 The observation of an Early Triassic lag phase in the recovery from the end-Permian mass  
261 extinction is not new. *Schubert & Bottjer (1995)* were among the first to demonstrate this delay

262 in rediversification based on regional data of post-extinction communities in the western USA.  
263 They suggested that the “long pre-radiation period” could be due (1) to the extraordinarily  
264 magnitude of the end-Permian mass extinction and/or (2) the persistence of environmental stress.  
265 The first explanation implies an evolutionary slow-down of diversification rates that correlates  
266 with the extinction magnitude, possibly because there is a positive feedback between species  
267 richness and rates of speciation, which becomes ineffective if diversity falls below a critical  
268 threshold (Solé *et al.*, 2010; Hautmann *et al.*, 2015). The second (environmental) explanation has  
269 found disproportionately more attention in the literature, which offers manifold scenarios of  
270 poisonous, acidic, oxygen deficient and lethally hot oceans that prevented life from  
271 re-diversifying after the great dying at the end of the Permian (e.g. Wignall & Twitchett, 1996;  
272 Payne *et al.* 2007; Joachimski *et al.*, 2012; Sun *et al.*, 2012; Song *et al.*, 2014). Support for the  
273 second explanation has been sought in the demonstration of adverse environmental conditions  
274 during the Early Triassic from geochemical or palaeontological proxies (e.g. Payne *et al.*, 2010;  
275 Sanei, Grasby & Beauchamp, 2012; Schobben *et al.*, 2014; Tian *et al.*, 2014; Rothman *et al.*,  
276 2014; Wei *et al.*, 2015), but the idea of pervasive hostile conditions in the Early Triassic has also  
277 been criticized for being at variance with a variety of observations. These include: (1) benthic  
278 communities from various environmental settings and palaeogeographically distant regions show  
279 little indications for unusual environmental stress (Twitchett *et al.*, 2004; Hautmann *et al.*, 2011;  
280 Hautmann *et al.*, 2015; Hofmann, Hautmann & Bucher, 2013; Hofmann *et al.*, 2013; Hofmann *et al.*  
281 *et al.*, 2014); (2) ichnofaunas were diverse and complex soon after the extinction event in different  
282 palaeolatitudes (Beatty, Zonneveld & Henderson, 2008; Hofmann *et al.*, 2011); (3) shell sizes of  
283 many Early Triassic gastropods reached large sizes (Brayard *et al.*, 2010; Brayard *et al.*, 2011a;  
284 Brayard *et al.*, 2015); (4) diversification of ammonoids was extremely rapid (Brayard *et al.*,  
285 2009); (5) biomass productivity of marine benthos was high in spite of low taxonomic diversity  
286 (Brosse *et al.*, 2019) and (6) marine apex predators were present throughout the Early Triassic  
287 (Scheyer *et al.*, 2014). This criticism does not deny the existence of environmental stress in the  
288 Early Triassic, but it suggests that it was locally and temporarily restricted and had differential  
289 impacts on the benthos and nekton.

290 Another class of explanations assumes that a breakdown of primary production in the Early  
291 Triassic caused a collapse of the food pyramid. According to these models, the low diversity in  
292 the Early Triassic corresponds to a time of reduced primary production (e.g. Grasby *et al.*, 2020)  
293 and the recovery of marine life required a successive rebuilding of trophic levels (Chen &  
294 Benton, 2012, p. 379). However, Chen & Benton (2012) suggested that this model predicts a  
295 logistic rediversification curve, which would be at variance with the extended Early Triassic lag  
296 phase. Palaeontological data also demonstrate the presence of apex predators in the Early  
297 Triassic (Chen & Benton, 2012; Scheyer *et al.* 2014), which indicates that trophic levels between  
298 the base and the top of the food pyramid were at least partly intact. We add here that low primary  
299 production per se does not provide an explanation for low diversity. Theory rather predicts that  
300 selection for fitness in resource-poor environments favours specialized, efficient populations and  
301 therefore results in high diversity (Valentine, 1971). The high diversity of Recent coral reefs and  
302 deep-sea communities (Grassle & Maciolek, 1992; Veron *et al.*, 2009) are well-known examples  
303 that conform to this prediction.

304 In contrast to the idea of environmentally driven delay (EDD) models, the biotic interaction (BI)  
305 model does not only provide an explanation for the delayed recovery but it also makes a  
306 prediction for the diversification pattern that followed the initial lag phase. Mathematically, the

307 BI model can be written as a differential equation that can be solved numerically. It contains a  
308 hyperbolic term that accounts for the positive feedback of species interactions on rates of  
309 diversification, which is usually combined with a damping term that limits the increase when the  
310 effects of niche pre-emption and ecological crowding become dominant (*Solé et al., 2010*,  
311 equation 10; *Hautmann et al., 2015*, equation 1). In contrast to the more familiar logistic model  
312 (*Sepkoski, 1978; Sepkoski, 1984*), the shape of the resulting curve is decidedly asymmetrical  
313 (compare Figs 8A and 8C). It displays an extended early (left) branch, which represents the  
314 prolonged lag phase when feedback processes were ineffective due to low species richness,  
315 followed by an explosive increase that stops relatively suddenly when ecospace is filled (Fig.  
316 8C). However, the exact shape of the curve depends upon two parameters: (1) the starting  
317 diversity that can be expressed as percentage of the carrying capacity or as the percentage of  
318 surviving species, and (2) the proportionality factor, which represents the feedback strength.  
319 Depending on these two parameters, which are insufficiently known, the shape of the hyperbolic  
320 damped diversification curve can appear relatively similar to a logistic shape under certain  
321 conditions, but a qualitative difference between the two models always remains. This difference  
322 can be visualized in semilogarithmic plots, where a hyperbolic curve is reflected by an initial  
323 increase in the slope of the diversification curve, whereas a logistic curve is represented by a  
324 decreasing slope (Figs 8B and 8D).

325 The majority of the semilogarithmic plots presented in this study (Figs 5 and 7) is conform to the  
326 hyperbolic-damped (= BI) model. This applies to the diversification curves of bivalves,  
327 gastropods and brachiopods in general, bivalves from mid-ramp settings, as well as shallow  
328 infaunal deposit-feeders (i.e., nuculid bivalves and scaphopods) and free-lying epifaunal  
329 suspension feeders (some bivalves), with their sudden increase in species richness during the  
330 Bithynian that is followed by a plateau, which indicates a hyperbolic-damped increase in species  
331 richness. Likewise, the diversification trends of gastropods in mid-ramp settings, epibyssate  
332 suspension-feeders (some bivalves), epifaunal herbivores and/or detritus-feeders (i.e.,  
333 gastropods), erected epifaunal suspension-feeders (i.e., crinoids) and pedunculate  
334 suspension-feeders (i.e., articulate brachiopods) show a sudden increase in species richness in the  
335 Bithynian, which is as indicative of a hyperbolic trajectory. The data from some other guilds do  
336 not provide an unequivocal support for either the hyperbolic or the logistic model. This concerns  
337 shallow to moderately deep infaunal, endobyssate and cemented epifaunal suspension-feeders  
338 (e.g., some bivalves, serpulids) as well as epifaunal detritivore-suspension-feeders (i.e.,  
339 ophiuroids). The remaining taxa and guilds (i.e., brachiopods of mid-ramp settings, deep infaunal  
340 suspension-feeders and epifaunal carnivores like asteroids and crustaceans) do not match with  
341 any model, possibly because of their scarcity in our dataset.

342 A conclusion from these observations is that they suggest a strong effect of biotic interactions on  
343 rates of diversification. This is the prime difference to the standard logistic model, which makes  
344 a neutral assumption with respect to biotic interactions. In the logistic model, the initially  
345 exponential increase is solely an effect of an increasing number of species that each have  
346 constant diversification rates. This assumption is clearly incompatible with the explosive  
347 diversification revealed in our dataset (Fig. 1). Notably, this is not an isolated observation. *Miller*  
348 *& Sepkoski (1988)* found “hyperexponential bursts” in the Phanerozoic diversity curve of  
349 bivalves during the Ordovician diversification and following the end-Permian and  
350 end-Cretaceous mass extinctions, which likely represent times of hyperbolic increase. *Markov &*

351 *Korotayev (2007)* even proposed that the Phanerozoic biodiversity curve from which *Sepkoski*  
352 *(1978, 1984)* derived his model is actually better described by a hyperbolic model.

353 Implicit in these finds is that we cannot expect an early rediversification if the feedback  
354 mechanism between richness and rates of diversification was ineffective after an extreme  
355 diversity crash, whether or not the environment was favourable. Does this conclusion refute the  
356 EDD model? It partly does, because it means that at least a portion of the lag phase is always  
357 attributed to BI. It is therefore incorrect to ascribe the full length of the lag phase to EDD.  
358 However, it is currently also uncertain whether the full length of the Early Triassic lag phase can  
359 be explained solely by the BI model. The length of the lag phase in this model depends upon two  
360 parameters, the starting diversity and the proportionality factor, which are not precisely known. It  
361 is therefore possible that adverse environmental conditions delayed or interrupted the early  
362 recovery whereas the BI model explains a subsequent extension of the lag phase. Clarifying the  
363 exact parameters in the BI model equation for different taxa is required for estimating the length  
364 of the intrinsic delay and thus the potential for EDD as an additional explanation for the Early  
365 Triassic lag phase.

366 From an evolutionary viewpoint, the most relevant aspect is the nature of biotic interactions that  
367 cause positive feedbacks between species richness and rates of diversification. *Solé et al. (2010)*  
368 were vague with respect to possible feedback processes, suggesting that increasing numbers of  
369 ecological interactions might provide the context for new opportunities to speciate, but they also  
370 noted that this process might operate too slowly to explain explosive diversification.  
371 Alternatively, they proposed that the growing number of potential interactions might drive the  
372 increase in the number of species. *Hautmann et al. (2015)* reconsidered the problem and  
373 identified interspecific competition as a potential main driver of hyperbolic-damped  
374 diversification curves. Accordingly, promotion of niche differentiation is the dominant outcome  
375 of interspecific competition until a critical level of ecological saturation has been reached, at  
376 which further division of niche space requires increasingly elaborated adaptations that are more  
377 and more unlikely to evolve. Above such a saturation limit, outcompeting of existing species  
378 becomes the prevalent effect of competition, which damps further diversification. A strength of  
379 this model is that it correctly predicts different diversification trajectories for taxa with  
380 supposedly different intensities of interspecific competition, for which slowly recovering  
381 bivalves contrasted by explosively rediversifying ammonoids have been cited as an example  
382 (*Hautmann et al., 2015*). The fact that the phase of the hyperbolic diversity increase was not  
383 associated with the origin of new guilds further supports the competition-driven scenario,  
384 because competition is most intense between species with similar lifestyles. However, *Hautmann*  
385 *et al. (2015)* also noted that many other aspects in addition to competition affect actual patterns  
386 of diversification. In the following, we discuss some possible additional factors that were linked  
387 to the resurgence of carbonate platforms in the Middle Triassic.

### 388 **Habitat construction and biotic interactions on resurging large carbonate platforms**

389 The recovery of large carbonate platforms after the end-Permian mass extinction started in the  
390 Anisian (early Middle Triassic; *Gaetani et al., 1981; Senowbari-Daryan et al. 1993; Berra,*  
391 *Rettori & Bassi, 2005*), and coincided with the main diversification of most benthic marine  
392 invertebrate taxa (Figs 5 and 7). One of the oldest Triassic carbonate platforms is represented by  
393 the *Tubiphytes*-Limestone Member of the Caerace Formation in Romania. This Bithynian

394 biostrome is dominated by the micro-encruster *Tubiphytes* and large volumes of synsedimentary  
395 cements (Popa, Panaiotu & Grădinaru, 2014) and provided the basis for a rich hardground  
396 community that is much more diverse than contemporaneous level-bottom faunas (Grădinaru &  
397 Gaetani, 2017; Forel & Grădinaru, 2018; Nützel, Kaim & Grădinaru, 2018; Friesenbichler et  
398 al., 2021). Its high amount of newly described species is potentially related to the new habitat  
399 type. This applies to the dominant taxa, i.e., epibyssate bivalves, gastropods and brachiopods  
400 (*Data S1*) that were well adapted to the hardgrounds provided by the *Tubiphytes*-microbial  
401 buildup (Friesenbichler et al., 2021). Further Middle Triassic *Tubiphytes*-dominated buildups are  
402 known from the Iranian carbonate mounds of Nakhlak (late Bithynian; Berra et al., 2012), the  
403 Italian Camorelli platform (Bithynian-Pelsonian; Gaetani & Gorza, 1989) and Dont Formation  
404 (Pelsonian-Illyrian; Blendinger, 1983; Fois & Gaetani, 1984), the Hungarian Aggtelek reef  
405 (Pelsonian-Ladinian; Velledits et al., 2011; Velledits, Hips & Péro, 2012) and Chinese reefs  
406 (Anisian; Enos, Wei & Yan, 1997; Lehrmann 1999; Enos et al., 2006; Payne et al., 2006a;  
407 Payne et al. 2006b; Lehrmann et al. 2007). The latter flourished on the Great Bank of Guizhou,  
408 an isolated carbonate platform in the Nanpanjiang Basin, and represent the oldest Triassic  
409 platform margin reefs (Lehrmann, Wei & Enos, 1998; Payne et al. 2006a; Payne et al. 2006b).

410 Reefs existed throughout the Triassic, but their composition changed stepwise (see Martindale,  
411 Foster & Velledits, 2019). The oldest Triassic reefs are represented by microbial-metazoan reefs  
412 that formed immediately after the end-Permian mass extinction (e.g. Lehrmann et al., 2001;  
413 Flügel, 2002; Pruss et al., 2006; Wu et al., 2007; Kiessling & Simpson, 2011; Kershaw et al.,  
414 2011; Ezaki, Liu & Adachi, 2012; Yang et al., 2015, Friesenbichler et al. 2018). The first  
415 metazoan reefs are reported from the Olenekian (late Early Triassic) and represent small sponge  
416 biostromes and bivalve build-ups (Pruss, Payne & Bottjer, 2007; Brayard et al., 2011b;  
417 Marengo et al., 2012). Reefs developed quickly in the middle Anisian (Flügel, 2002) and in  
418 addition to *Tubiphytes* other organisms such as sphinctozoans (segmented calcareous sponges),  
419 dasycladacean algae, corals, and in some cases also bivalves became important reef-builders  
420 (Flügel, 2002; Fürsich & Hautmann, 2005; Senowbari-Daryan & Link, 2011). These organisms  
421 acted as ecological engineers and created new niches that provided opportunities for additional  
422 species. Well-documented examples are bivalve-crinoid reef mounds from the Trochitenkalk  
423 Formation (middle Illyrian, Germany; e.g. Hagdorn, 1978; Sellwood & Fürsich, 1981; Hagdorn  
424 & Mundlos, 1982; Flügel, 2002; Hagdorn, 2004; Hagdorn & Nitsch, 2009), where shell beds  
425 were incrustated by cementing bivalves that provided hardgrounds for the colonization by crinoids.  
426 These dm-scaled bioherms provided new habitats for brachiopods, serpulids, other bivalves and  
427 boring worm-like organisms.

428 The sudden increase in species richness of gastropods is another feature of the Middle Triassic  
429 main stage of marine recovery (Figs. 1, 2, 3, 4, 5A, 5B, 6B and 7) that was at least partly linked  
430 to the resurgence of large carbonate platforms. As shown by Friesenbichler et al (2019, fig. 14),  
431 the ratio of gastropod versus bivalve species is much higher in carbonate platforms than in other  
432 settings. However, the data of Friesenbichler et al. (2019b) might even underestimate the true  
433 signal. Roden et al. (2020) compared the diversity of the Cassian Formation, an exceptional  
434 Triassic lagerstätte, with the diversity of the Wetterstein Formation, which is environmentally  
435 comparable and approximately of the same age. They found that all mollusks were  
436 underrepresented in the Wetterstein Formation by factor 7 in comparison to the Cassian  
437 Formation, but gastropods by the astonishing factor 87. The cause for the affinity of gastropods  
438 to carbonate platform facies remains speculative, not at least because the life habit and feeding

439 mode of gastropods cannot be deduced from the shell morphology. In spite of this limitation, we  
440 put forward the hypothesis that the quick diversification of gastropods in carbonate platform  
441 environments might have been related to the proliferation of dasycladacean algae, which were  
442 dominant carbonate producers in many settings where gastropods became diverse.

443 Palaeoecological studies have previously suggested that at least some Triassic gastropods lived  
444 in association with macroalgae (Fürsich & Wendt, 1977; Sellwood & Fürsich, 1981; Stiller,  
445 2001; Hagdorn, 2004; Nützel & Schulbert, 2005; Diedrich, 2010; Urlichs, 2014). This  
446 conclusion was derived from the ecology of Recent macroalgae (e.g. Davies, 1970; Taylor,  
447 1971; Thomassin, 1971; Brasier, 1975; Poulicek, 1985; Sánchez-Moyano et al., 2000; Chemello  
448 & Milazzo, 2002; Antoniadou & Chintiroglou, 2005; Pitacco et al., 2014; Duarte et al., 2015;  
449 Chiarore et al., 2017), on which gastropods grazed (e.g. Underwood, 1980; Johnson & Mann,  
450 1986; Williams, 1993) and thereby enhance the photosynthetic capacity of the host algae (Amsler  
451 et al., 2015). The Triassic fossil record of non-calcifying algae is virtually non-existent, but the  
452 diversification and abundance of dasycladaceans at the beginning of the Middle Triassic is well  
453 established. In our dataset, only 5 out of 37 lithological units contain information about the  
454 number of Dasycladacea species associated with the investigated faunas (e.g., Salomon, 1895;  
455 Ogilvie Gordon, 1927; Schmidt, 1928; Schmidt, 1938; Granier & Grgasović, 2000; Russo et al.,  
456 2000; Emmerich et al., 2005; Piros & Preto, 2008). Given the small number of datapoints, the  
457 positive correlation between the richness of dasycladaceans and gastropods is statistically not  
458 robust ( $r^2 = 0.25$ ;  $p = 0.32$ ), but it is strengthened by an indirect line of evidence. Middle Triassic  
459 gastropod diversity decreased towards deeper water settings (Figs 2 and 4), along with declining  
460 light. Because light limits the distribution of algae, it is certain that this trend was matched by  
461 decreasing macroalgae abundance.

## 462 Conclusions

463 Data on species richness from 37 Early and Middle Triassic lithological units containing  
464 level-bottom communities indicate that most of the analyzed taxa and guilds followed a  
465 hyperbolic-damped diversity trajectory, with an extended Early Triassic lag phase followed by  
466 an explosive increase in diversity at the beginning of the Middle Triassic that levelled out in the  
467 Ladinian. The Early Triassic delay in rediversification of benthic organisms has conventionally  
468 been attributed to ongoing environmental stress at that time, but the explosive (hyperbolic rather  
469 than exponential) diversity increase at the beginning of the Middle Triassic cannot be explained  
470 by relaxation of environmental stress. Our data therefore support a model in which the intensity  
471 of biotic interactions determines the rate of diversification. Accordingly, the Early Triassic delay  
472 in rediversification represents the time in which the intensity of biotic interactions was too low  
473 for driving a major diversification because of the dramatic loss of species during the  
474 end-Permian mass extinction. Conversely, the hyperbolic Middle Triassic diversity increase  
475 occurred when self-accelerating processes became effective, and it stopped when niche-crowding  
476 prevented further diversification. This pattern is in agreement with a competition-driven  
477 diversification model that predicts a reversal in the effects of interspecific competition on  
478 diversification rates from accelerating to damping. Apart from interspecific competition, other  
479 ecological feedbacks might have stimulated the hyperbolic increase in diversity during the  
480 Anisian. Carbonate platforms, which reappeared simultaneously with the main stage of benthic  
481 rediversification, provided the ecological context for rich hardground communities. The  
482 coincidence of the resurgence of carbonate platforms and the evolution of reef-builders with the

483 main diversification of benthic faunas suggests a positive loop effect, which is confirmed by  
484 several case studies. When reefs diversified, other reef-builders became abundant and acted as  
485 ecological engineers and niche constructors, providing new habitats for additional species. The  
486 quick diversification of gastropods in Middle Triassic carbonate platforms might be related to the  
487 proliferation of macroalgae, which provided much improved opportunities for grazing. A  
488 strength of the biotic interaction model is that it correctly predicts both an extended lag phase  
489 and a hyperbolic increase in diversity thereafter, whereas environmental scenarios fail to predict  
490 the second aspect.

## 491 **Acknowledgments**

492 EF is deeply grateful to Alexander Pohle for interesting and helpful discussions and his loving  
493 support. Christian Klug is thanked for helpful discussions. The paper benefitted from  
494 constructive reviews by William Foster, Alexander Nützel and an anonymous reviewer. Helpful  
495 inputs by editor Diogo Provente are gratefully acknowledged. This work was supported by the  
496 SNF grant 200020-162402/1 (to MH).

# Figure 1

Maximum species richness throughout the Early and Middle Triassic.

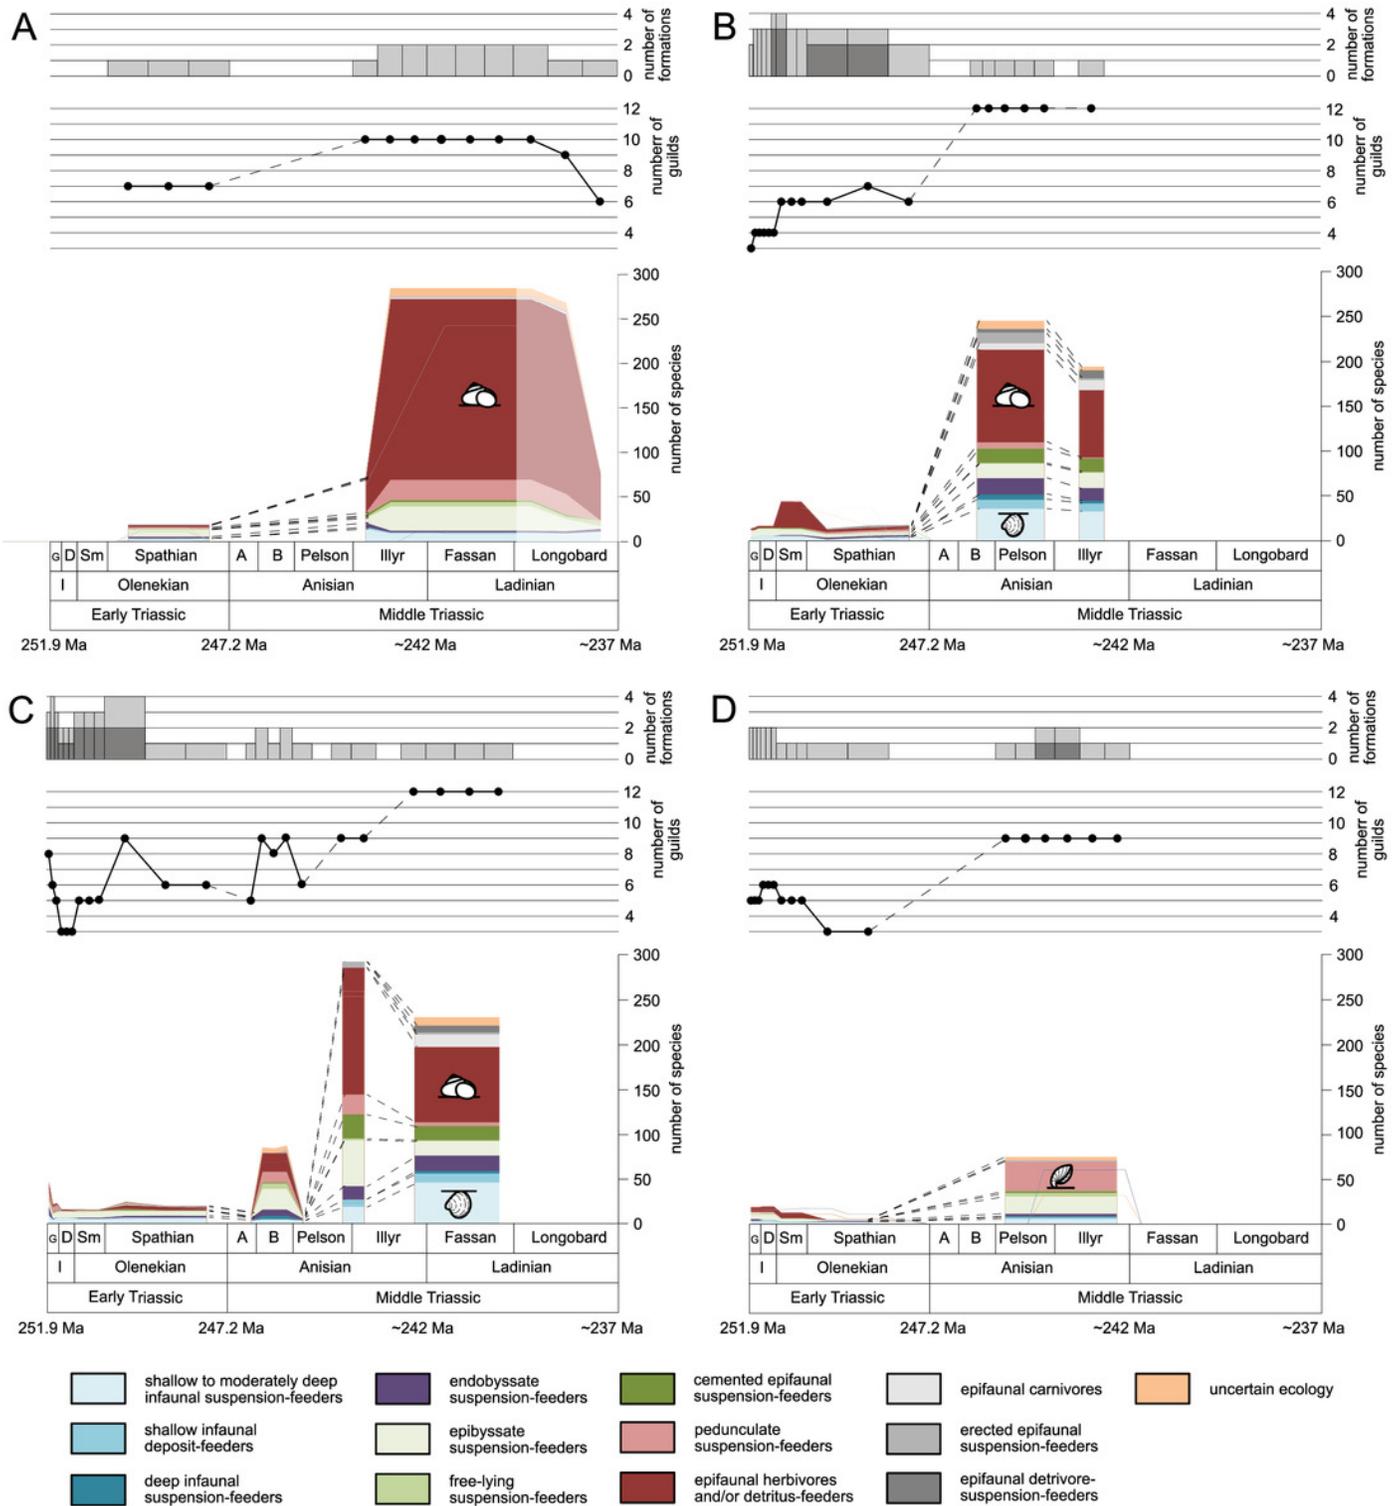

The Longobardian is palish to indicate that the decrease of species richness is not a primary signal. Light grey bars on top indicate the number of lithological units representing each time interval. In cases where information does not come from all lithological units representing the corresponding time interval, the actual number of lithological units from which information comes from is indicated by dark grey bars. Abbreviations: A = Aegean, B = Bithynian, D = Dienerian, Fassin = Fassanian, G = Griesbachian, I = Induan, Illyr = Illyrian, Longobard = Longobardian, Pelson = Pelsonian, Sm = Smithian. Absolute ages according to (Cohen *et al.*, 2013, updated). Information about the relative duration of substages come from Nawrocki & Szulc (2000), Götz, Szulc & Feist-Burkhardt (2005), Jattiot *et al.* (2018) and Li *et al.* (2018). Symbols for ecological guilds redrawn after Aberhan (1994). See text for further explanation.

## Figure 2

Maximum species richness in different environments.

(A) lagoons, (B) inner ramps, (C) mid-ramps and (D) outer ramps. The Longobardian is palish to indicate that the decrease of species richness is not a primary signal. Light grey bars on top indicate the number of lithological units representing each time interval. In cases where information does not come from all lithological units representing the corresponding time interval, the actual number of lithological units from which information comes from is indicated by dark grey bars. Due to our data selection, the following guilds are not shown in this figure although reported in polished slabs: shallow infaunal deposit-feeders in late Griesbachian-Smithian and middle Spathian inner ramps (one species, respectively) and Smithian mid-ramps (one species), cemented epifaunal suspension-feeders in early-middle Spathian inner ramps (one species) and Dienerian-Smithian outer ramps (two species), epifaunal herbivores and/or detritus-feeders in early-middle Spathian (two species) and late Pelsonian-early Illyrian (five species) outer ramps. Abbreviations, symbols for ecological guilds and information about the relative duration of substages as in Figure 1. See text for further explanation.

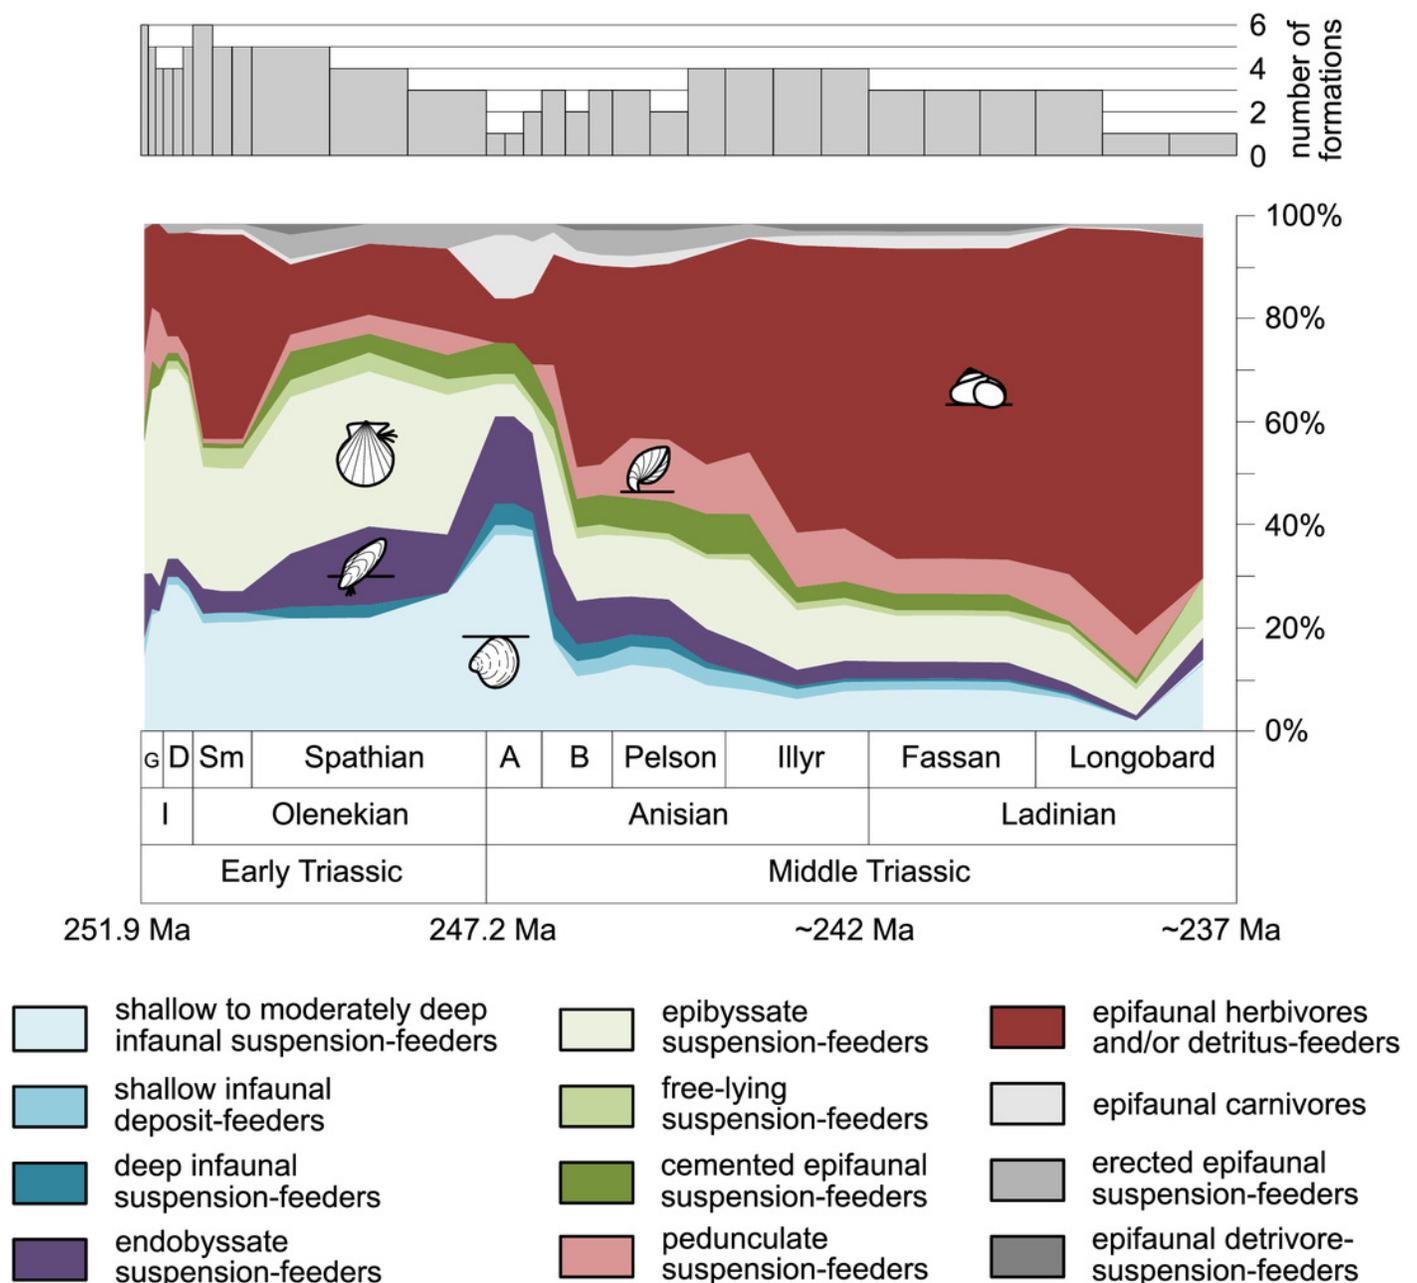

## Figure 3

Guild-species diversity throughout the Early and Middle Triassic.

Bars on top indicate the number of lithological units representing each time interval.

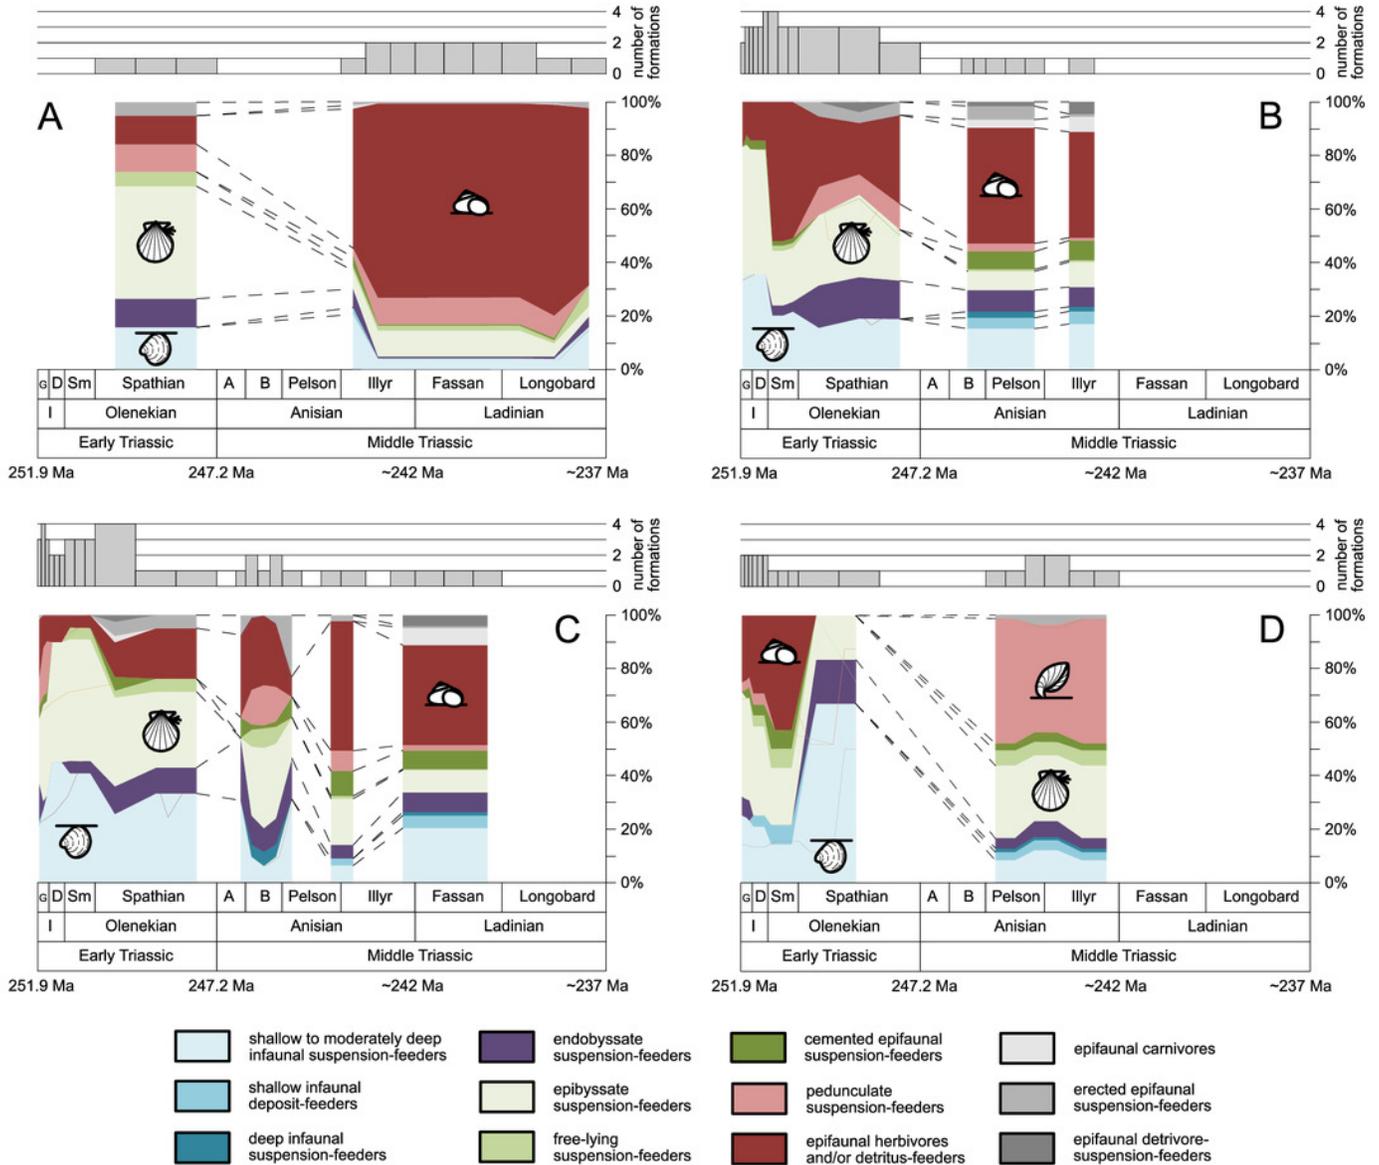

Abbreviations, symbols for ecological guilds and information about the relative duration of substages as in Figure 1. See text for further explanation.

## Figure 4

Guild-species diversity of different environments.

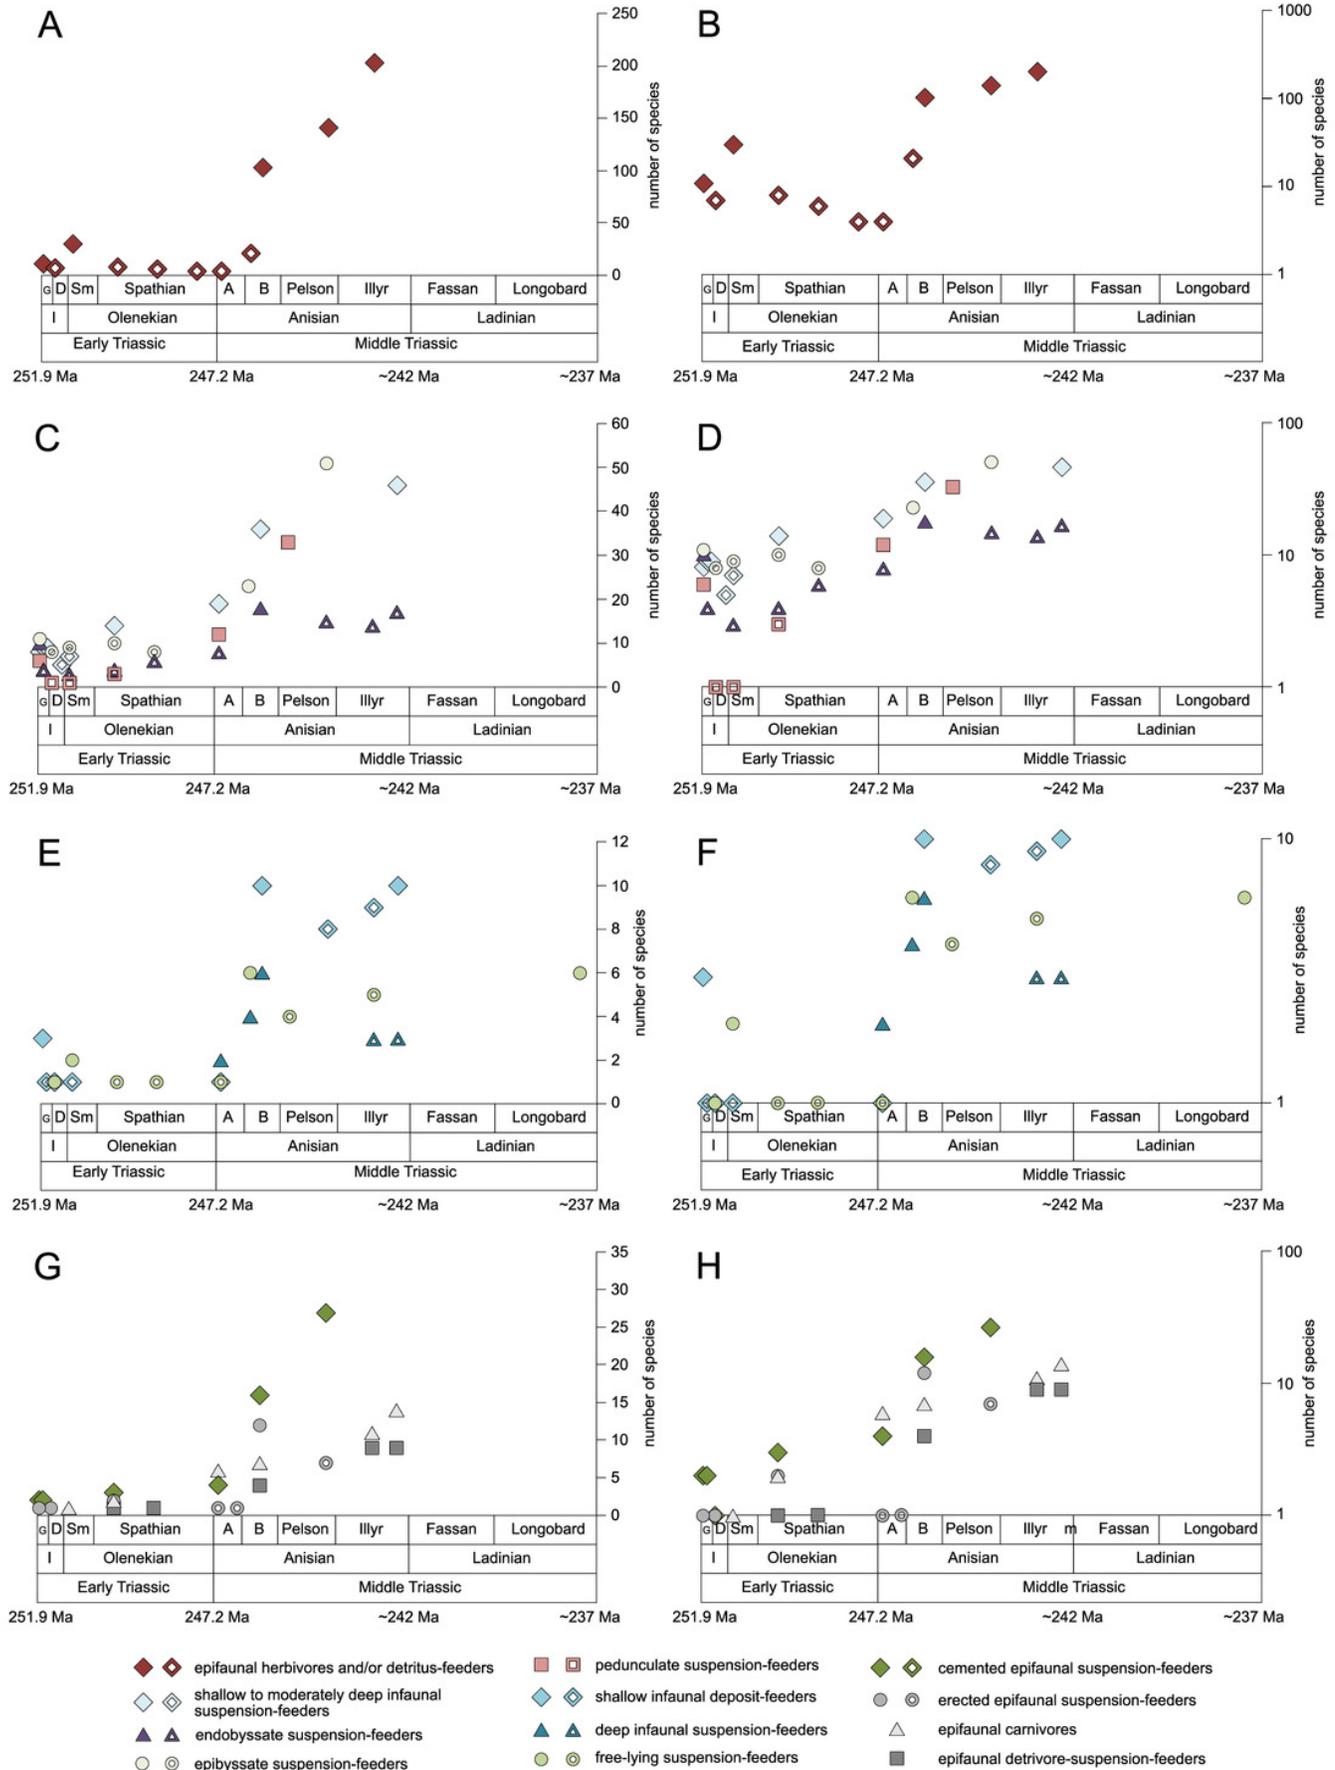

(A) lagoons, (B) inner ramps, (C) mid-ramps and (D) outer ramps. Bars on top indicate the number of lithological units representing each time interval. Due to our data selection, the following guilds are not shown in this figure although reported in polished slabs: shallow infaunal deposit-feeders in late Griesbachian-Smithian and middle Spathian inner ramps (one species, respectively) and Smithian mid-ramps (one species), cemented epifaunal suspension-feeders in early-middle Spathian inner ramps (one species) and Dienerian-Smithian outer ramps (two species), epifaunal herbivores and/or detritus-feeders in early-middle Spathian (two species) and late Pelsonian-early Illyrian (five species) outer ramps. Abbreviations, symbols for ecological guilds and information about the relative duration of substages as in Figure 1. See text for further explanation.

## Figure 5

Maximum species richness throughout the Early and Middle Triassic of ecological guilds.

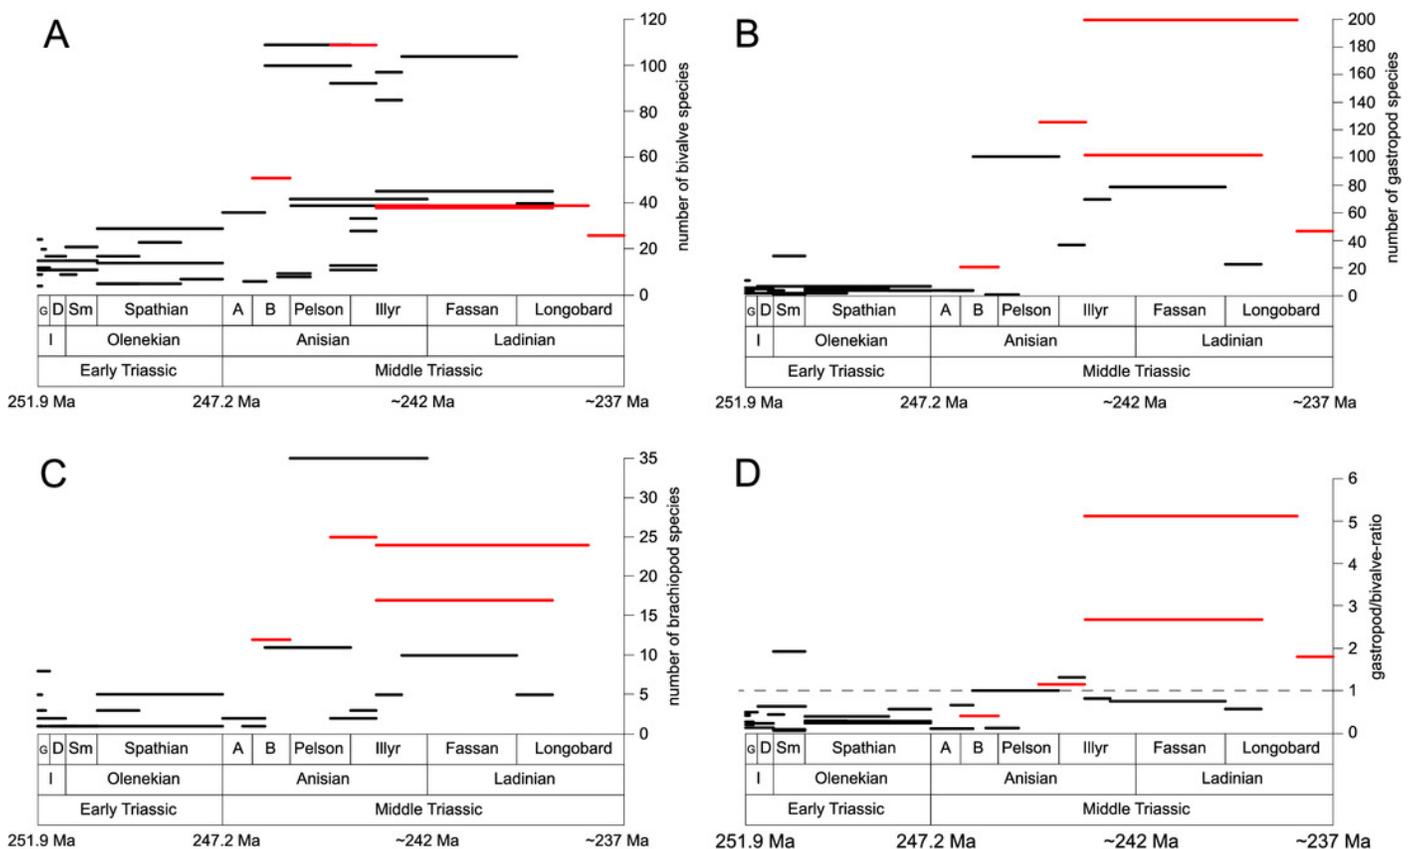

(A-B) epifaunal herbivores and/or detritus-feeders, (C-D) shallow to moderately deep infaunal suspension-feeders, endobysate suspension-feeders, epibysate suspension-feeders and pedunculate suspension-feeders, (E-F) shallow infaunal deposit-feeders, deep infaunal suspension-feeders, free-lying suspension-feeders and cemented microcarnivores, (G-H) cemented epifaunal suspension-feeders, erected epifaunal suspension-feeders, epifaunal carnivores and epifaunal-detritivore-suspension-feeders. Number of species illustrated with linear scale (A, C, E and G) and logarithmic scale (B, D, F and H). Filled symbols represent faunas that are more or as diverse as older ones, whereas empty symbols represent faunas that are less diverse than older ones. Abbreviations and information about the relative duration of substages as in Figure 1. See text for further explanation.

## Figure 6

Species richness of the most diverse taxa and the gastropod/bivalve-ratio throughout the Early and Middle Triassic.

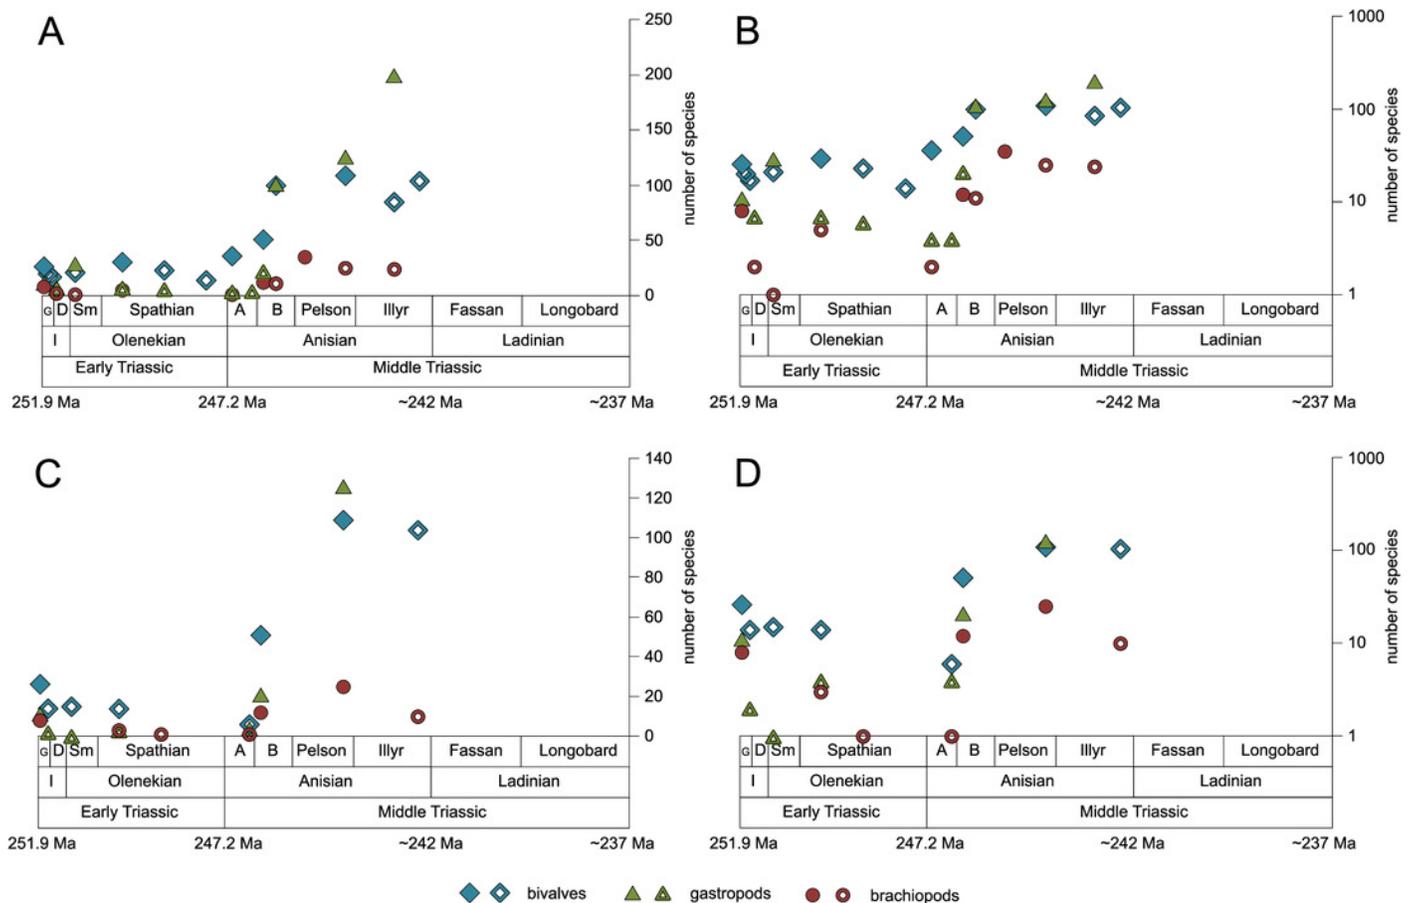

(A) bivalves, (B) gastropods, (C) brachiopods and (D) the gastropod/bivalve-ratio. Each line represents one lithological unit. Red lines mark lithological units and ratios associated with carbonate platforms. Abbreviations and information about the relative duration of substages as in Figure 1. (A) modified after *Friesenbichler et al. (2021)* and (D) modified after *Friesenbichler et al. (2019b)*. See text for further explanation.

## Figure 7

Maximum species richness throughout the Early and Middle Triassic of bivalves, gastropods and brachiopods.

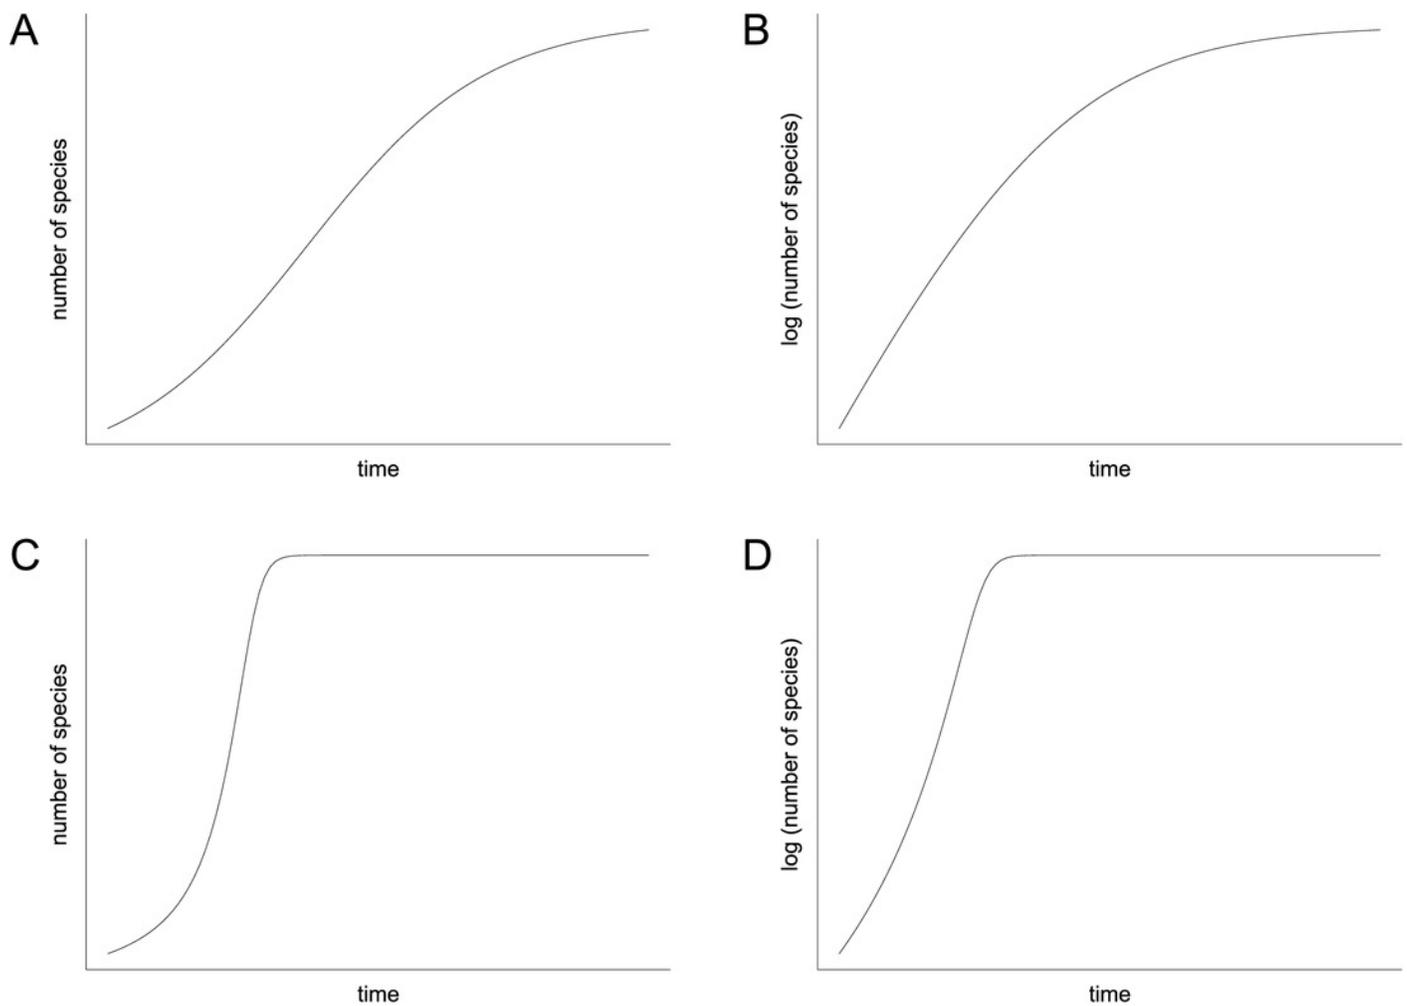

(A-B) in general and (C-D) in mid-ramps. Number of species illustrated with linear scale (A and C) and logarithmic scale (B and D). Filled symbols represent faunas that are more or as diverse as older ones, whereas empty symbols represent faunas that are less diverse than older ones. Abbreviations and information about the relative duration of substages as in Figure 1. See text for further explanation.

## Figure 8

Diversification curves.

(A-B) Logistic with number of species illustrated with linear scale (A) and logarithmic scale (B). (C-D) Hyperbolic-damped with number of species illustrated with linear scale (C) and logarithmic scale (D).

**Table 1** (on next page)

List of ecological guilds and representing taxa.

<b>Ecological guild</b>	<b>Taxa</b>
Shallow to moderately deep infaunal suspension-feeders	Bivalves, inarticulate brachiopods
Shallow infaunal deposit-feeders	Bivalves, scaphopods
Deep infaunal suspension-feeders	Bivalves
Endobysate suspension-feeders	Bivalves
Epibysate suspension-feeders	Bivalves
Free-lying epifaunal suspension-feeders	Bivalves
Cemented epifaunal suspension-feeders	Bivalves, serpulids, inarticulate brachiopods, bryozoans, microconchids
Pedunculate suspension-feeders	Articulate brachiopods
Epifaunal herbivores and/or detritus-feeders	Gastropods, echinoids, polyplacophors
Epifaunal carnivores	Asteroids, crustaceans
Erected epifaunal suspension-feeders	Crinoids
Epifaunal detritivore-suspension-feeders	Ophiuroids
