The Tasman and Golden Bays (TBGB) are a semi-enclosed embayment system that support numerous commercial and recreational activities, and are the focal area for the national science challenge Sustainable Seas, aimed at developing tools and approaches for ecosystem based management in New Zealand. We present three ecosystem models of the TBGB ecosystem: an end-to-end ecosystem model using Atlantis, a size-structured model, and an Ecopath with Ecosim model. We describe the process of data compilation through to model validation and analyse the importance of knowledge gaps with respect to model dynamics and results. We compare responses in all three models to historical fishing, and analyse similarities and differences in the dynamics of the three models. We have assessed the Atlantis model's sensitivity to initial conditions, and influence from the oceanographic variables. We recommend that scenarios relating to ecosystem dynamics of the TBGB ecosystem incorporate initialisation uncertainty, oceanographic uncertainty, and compare responses across all three models where it is possible to do so.

Abstract

The Tasman and Golden Bays (TBGB) are a semi-enclosed embayment system that support numerous commercial and recreational activities, and are the focal area for the national science challenge Sustainable Seas, aimed at developing tools and approaches for ecosystem based management in New Zealand. We present three ecosystem models of the TBGB ecosystem: an end-to-end ecosystem model using Atlantis, a size-structured model, and an Ecopath with Ecosim model. We describe the process of data compilation through to model validation and analyse the importance of knowledge gaps with respect to model dynamics and results. We compare responses in all three models to historical fishing, and analyse similarities and differences in the dynamics of the three models. We have assessed the Atlantis model's sensitivity to initial conditions, and influence from the oceanographic variables. We recommend that scenarios relating to ecosystem dynamics of the TBGB ecosystem incorporate initialisation uncertainty, oceanographic uncertainty, and compare responses across all three models where it is possible to do so.

1 Introduction

The goal of incorporating a holistic approach to understanding the system-wide repercussions of how we manage our marine resources is admirable and ambitious (Long et al. 2015, Link and Browman 2017). Ecosystem Based Management (EBM) requires a range of tools, often including ecosystem models (Smith et al. 2017, Stecken and Failler 2016). Within ecosystems there are many processes at play, and the models developed to support Ecosystem Based Management vary in scope and complexity (Plagányi 2007, Fulton 2010, Collie et al. 2016). End-to-end ecosystem models which can deal with bottom-up and top-down system controls have become popular for exploring scenarios involving human induced impacts including fishing and climate change (Rose, 2012).

The Tasman and Golden Bays (TBGB) is an appropriate focal area for Ecosystem Based Management as it supports a diverse range of marine, land and human activities, with economic, social and customary value (Sustainable Seas, 2019). The TBGB ecosystem is a relatively shallow semi-enclosed embayment system at the north of South Island, New Zealand (Figure 1). Strong ocean currents enter the system from the Tasman sea bringing with them cold, nutrient-rich waters, which make the area highly productive (Chiswell et al., 2019). TBGB has large sheltered areas which are home to a diverse array of habitats including large seagrass beds, rocky reefs and large sandy outcrops, which support a rangewide variety of species, from small reef bound species to large migrating pelagic species (Handley, 2006; Stevenson and MacGibbon, 2018).

55

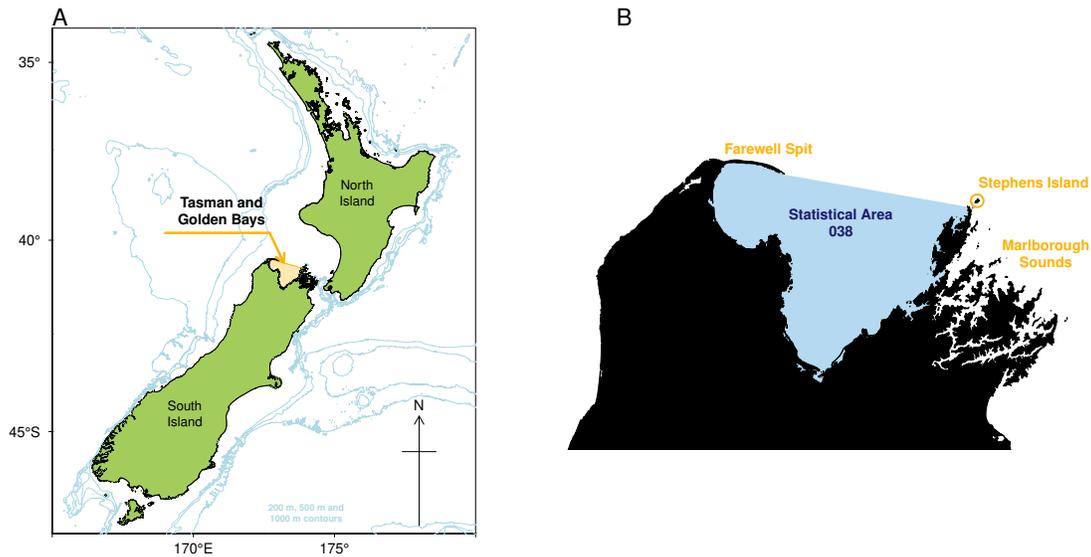

Figure 1: Map of New Zealand with Tasman and Golden Bays marked and shaded orange, including 200 m, 500 m, and 1000 m isobaths (A). Map of Tasman and Golden Bays with fisheries Statistical Area 038 (blue shaded) and Farewell Spit, Stephens Island and Marlborough Sounds (orange labels) (B).

56 TBGB supports numerous commercial fisheries (for finfish and invertebrates), an active
 57 recreational fishery (Fisheries New Zealand, 2020), and marine farming activities (Handley,
 58 2006). The area is a popular destination for tourists, for example the Abel Tasman National
 59 Park is particularly popular for hiking, camping and water sports. Much of the land surround-
 60 ing the bays has been modified by horticulture, forestry, and residential development.

61

62 Studies of the TBGB ecosystem include trawl surveys (MacGibbon and Stevenson, 2013;
 63 Stevenson and MacGibbon, 2018), fishery characterisations and stock assessments (Starr and
 64 Kendrick, 2017a,b; Parsons et al., 2018; Langley, 2018; Williams et al., 2014), bioregionalisation
 65 (Handley et al., 2018), habitat and fishing effects (Handley et al., 2014), oceanography from
 66 observations and modelling (Chiswell et al., 2019), benthos and anthropogenic effects (Handley,
 67 2006), sedimentation (van der Linden, 1969), and tidal circulation (Tuckey et al., 2006).

68

69 There are key ecological questions around historical shifts in the TBGB ecosystem. The
 70 bays used to support a large scallop fishery, but scallop recruitment has failed in recent years
 71 (Williams et al., 2014, 2015; Tuck et al., 2018). In a review of drivers of shellfish production,
 72 Michael et al. (2015) suggests food (primary production), suspended sediments and turbidity,
 73 changes to benthic communities and sediment, effects of fishing, and disease are all potential
 74 key drivers. There is also a large snapper fishery, which has experienced marked variations

75 in productivity over time, and is currently producing relatively high catches (Langley, 2018).
76 Snapper are known to be temperature dependent, with high year classes found to be correlated
77 with high sea surface temperature (SST), in particular high autumn SST (Francis, 1993).

78
79 We have developed three ecosystem models as part of a tool-kit for exploring and under-
80 standing the TBGB ecosystem. Each model varies in complexity and scope, model development
81 and validation demands, and applicability to different types of questions or scenarios. Each
82 model developed has used a different framework: TBGB_AM uses Atlantis (Audzijonyte et al.,
83 2017, 2019; Pethybridge et al., 2019), TBGB_EwE uses Ecopath with Ecosim (EwE) (Chris-
84 tensen and Walters, 2004; Christensen et al., 2005), and TBGB_SS is a size spectrum ecological
85 model using the multispecies implementation of the R package *mizer* (Scott et al., 2014; Blan-
86 chard et al., 2014).

87
88 Atlantis is an end-to-end ecosystem modelling approach that can be used to create an en-
89 vironment in which different scenarios can be played out to test for different results and learn
90 how a system may be reacting to changes within it. Reviewed as one of the best modelling
91 frameworks for exploring ‘what-if’ type questions (Plagányi, 2007), it includes the ability to
92 compare social, conservation, and economic outcomes. With sufficient data, this modelling
93 approach can be extremely useful for management strategy evaluation (Plagányi, 2007), and
94 has been applied to multiple marine systems (from single bays to millions of square kilome-
95 tres) in Australia, the United States, Europe, South Africa and New Zealand (Savina et al.
96 (2005), Fulton et al. (2007), Link et al. (2010), Ainsworth et al. (2015), Smith et al. (2015),
97 Sturludottir et al. (2018), Ortega-Cisneros et al. (2017), McGregor et al. (2019)). Atlantis is a
98 deterministic simulation model such that for a given parameter set and model specification, the
99 model outputs are identical. Atlantis models are too complex to statistically fit to observations,
100 although subsets of key parameters can be estimated using statistical methods outside of the
101 model. Analysing and understanding the model dynamics and potential weaknesses is essential
102 before the model can be used to learn about the system.

103
104 EwE is trophodynamic modelling software which uses a mass-balance approach to describe
105 ecosystem based, marine food web interactions (Christensen and Walters, 2004; Christensen
106 et al., 2005). EwE works sequentially, where first an Ecopath model is populated and balanced
107 at a specified point in time, then Ecosim is used to simulate the model through time (Walters
108 et al., 1997). The Ecopath model is balanced by assuming that the energy removed from each
109 species group, through fishing or predation, for example, must be balanced with the energy
110 consumed by that group (Christensen and Pauly, 1992). Ecosim is then added to dynamically
111 simulate ecosystem-based changes over time. Ecosim uses foraging arena theory (Walters and
112 Juanes, 1993), which assumes only a portion of the prey biomass is available to the predators.
113 This partitioning of prey resources can be used as a proxy for spatial dynamics, and also has

114 a stabilizing effect on ecosystem dynamics through providing refuge to prey groups (Walters
115 et al., 1997). EwE models can be used for exploring impacts of fishing in conjunction with envi-
116 ronmental shifts or trends, and for exploring optimal fishing policies (Christensen and Walters,
117 2004). EwE models have more recently been used to produce time-series predation mortality
118 for use in single-species stock assessment (Bentley et al., 2019).

119
120 The multi-species size spectrum model specifies individual traits for each species group, and
121 also utilizes the size spectrum model for predator-prey interactions. Prey selection is a func-
122 tion of predator size, prey size, and the prey-species preference for a given predator. With this
123 model, we can predict species' size distributions, abundance, productivity and predator-prey
124 interactions. Hence, it is possible to evaluate trade-offs based on responses in community and
125 foodweb structure, population status, diversity, and fisheries yield (Blanchard et al., 2014).
126 The possible trade-offs that we can explore with this model are limited to fishing effects such
127 as focusing fishing effort on different parts of the system, and basic environmental effects such
128 as variations in primary productivity.

129
130 In this paper, we describe and evaluate TBGB_AM, which is the first end-to-end ecosystem
131 model for the Tasman and Golden Bays, New Zealand, as well as the two alternative ecosystem
132 models; TBGB_EwE and TBGB_SS. We present analyses of the models, comparing both state
133 and dynamics to each other and to current knowledge, and make recommendations on the
134 appropriate use of each model.

136 2 Methodological Approach

137 Model development primarily focused on the Atlantis model for the TBGB ecosystem. The
138 alternative models using the Ecopath with Ecosim (EwE) and multi-species size-structured
139 model frameworks were developed as simplifications of TBGB_AM, and have been assessed
140 with respect to TBGB_AM where it was possible to do so. TBGB_AM has been tested with
141 respect to initialisation uncertainty, realised growth and mortality rates, variability from the
142 assumed oceanographic variables, and connectivity analysis following the methods of McGregor
143 et al. (2019, 2020). All three models and associated R scripts are available on Github McGregor
144 (2019).

145
146 The process of developing these models was not linear, but rather iterative and incremen-
147 tal. There were six main stages to the development, each of which was re-visited until we were
148 satisfied with the performance of the models and our understanding of their dynamics. The
149 main stages can be summarised as:

150 1.) Model design: data and model inputs were collated and defined and the base TBGB_AM
151 developed.

- 152 2.) Alternative models: two alternative ecosystem models were developed; one size-structured
153 and one Ecopath with Ecosim.
- 154 3.) Calibration: the base historical TBGB_AM was calibrated without fishing such that this
155 model had stable biomass trajectories over the 1900–2016 model period, realistic diets, growth
156 rates, natural mortalities, with these compared to the alternative models where appropriate.
- 157 4.) Sensitivity analyses: TBGB_AM was tested for sensitivity to uncertainty in the initial
158 conditions and oceanographic variables. Simulations were explored aimed at understanding
159 connectivity and influence between the species groups.
- 160 5.) Fishing: historical fishing was included in all three models using forced catch removals.
- 161 6.) Skill assessment: comparisons to abundance indices and biomass estimates were carried
162 out for all models, including between-model comparisons.

163
164 Sections 3–8 cover each of these six main stages, followed by Section 9: Bringing it together,
165 compares the performance and dynamics as they relate to the three models.
166

167 3 Model design

168 An Atlantis model simulates the ecosystem through time, calculating each new state based on
169 the previous state and the events of the current timestep. This section describes the physical,
170 biological, ecological, and fishing components of TBGB_AM. Further details on Atlantis can
171 be found in the Atlantis user manual (Audzijonyte et al., 2017).
172

173 3.1 Model area

174 The TBGB area comprises waters in Tasman and Golden Bays, at the northern end of South
175 Island, New Zealand (Figure 1). The area is bounded in the north by a line connecting the
176 eastern tip of Farewell Spit and Stephens Island at the northern extreme of the Marlborough
177 Sounds, and by the coastal margin within the bays (but excluding estuaries and Croisilles
178 Harbour). It equates to Statistical Area 038, one of many areas used to define the location of
179 commercial fish catches in the New Zealand EEZ (Mackay et al., 2005).
180

181 An Atlantis model requires the modelled region to be split into polygons and depth layers.
182 Each polygon/depth layer is referred to as a cell. The intention of the splits is to capture
183 important aspects of the region but at a simplified level such that modelling the region over
184 many years becomes possible (i.e. balancing detail with computational efficiency). The mod-
185 elled area was divided into 25 polygons (Figure 2, which represent the main physical and
186 biochemical structure of the ecosystem (Handley et al., 2018) and the historical footprint of
187 fishing activity (Figure 4). There is one additional boundary polygon which flanks the northern

188 boundary and allows for the exchange of water, nutrients and biota from the dynamic model
 189 domain. All model polygons were further divided into water column depth layers, ranging from
 190 one layer in some nearshore polygons to five layers for the deepest polygons. The defined depth
 191 layers are shown in Figure 2. In addition to the water column layers, each polygon contains
 192 one epibenthic and one sediment layer.

193

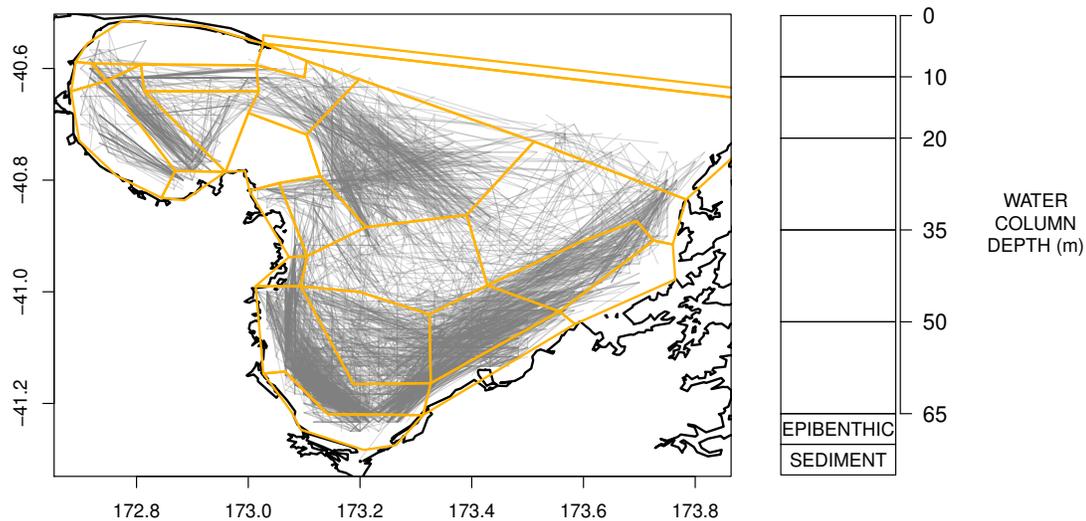

Figure 2: Polygons as defined for TBGB_AM with historical trawl footprint (grey, left) and depth layer bins (right).

194

3.2 Time

195 The model was run with a 35 year burn-in period (1865–1899) followed by a 115 year modelled
 196 period (1900–2014). The burn-in period allows for the model to adjust from potentially unstable
 197 initial conditions due to uncertainty of some of the parameters and age distributions for the
 198 age resolved groups, to a state that is more stable. A 35 year period was chosen as it covered
 199 initial fluctuations of most species groups in the model. All results presented here are from
 200 the modelled period 1900–2014. The model used 12 hour timesteps to allow for changes in
 201 temperature, light and feeding patterns between night and day.

202

3.3 Oceanography

203 Salinity, temperature and water exchange between cells were forced in TBGB_AM using out-
 204 puts from a ROMS (Regional Oceanographic Modelling System) model that covered six years
 205 2008–2013 (inclusive) (Chiswell et al., 2019). Water flows across each cell face cause the move-
 206 ment of nutrients (such as ammonia and nitrate) available to primary producers. The speed

207 and direction of currents influence the spatial distribution of plankton groups. Water tem-
208 peratures influence biological processes such as respiration (Hoegh-Guldberg and Bruno, 2010)
209 (for more details, see Appendix A). The base TBGB_AM presented here repeated the available
210 ROMS variables as a six-year cycle. Averaging the ROMS variables across these years was not
211 considered due to the water exchange between cells, as these change every 12-hour timestep
212 in strength and direction, and averaging them could easily result in implausible physical dy-
213 namics. We ran sensitivities varying the order of ROMS years or repeating one ROMS year to
214 help understand the effects of inter-annual oceanographic variability on this model, following
215 the methods applied in McGregor et al. (2019).

216

217 3.4 Species groups

218 TBGB_AM uses 51 species groups to model the biological processes. Species groups were de-
219 fined based on broadly similar form, habitat, and diet. Of these 51 groups, 12 vertebrates, two
220 invertebrates, and one algae comprise single species; all other groups comprised two or more
221 species. The single-species groups are either highly abundant (such as barracouta or seagrass),
222 very distinctive (like fur seals), or for which there are key ecological questions that may require
223 investigation on their own (like snapper and scallops). The main component species of the
224 groups are shown in Tables 1–4. Species group names are intended to be informative but not
225 necessarily restrictive. For example, an ‘invertivores’ species group would eat primarily inver-
226 tebrates, but may also consume a small proportion of vertebrate prey. All vertebrate groups
227 and five invertebrate groups were modelled with age-structure using up to 10 age-classes and
228 varying number of years per age-class, depending on the longevity of the primary species in
229 the group. Within each age-class, the model simulated numbers of individuals and the average
230 weight (mg N) of individuals within each age class. Weights were split into structural (S_N)
231 and reserve (R_N) components following the definition in Broekhuizen et al. (1994) where re-
232 serve weight is the part that can be used during periods of starvation, which includes flesh,
233 fat, reproductive components and other soft tissue. Primary producers and remaining inverte-
234 brate groups were modelled as biomass pools (mg N m^{-3}) with no age-structure. Weights and
235 biomass-pools were tracked in mg N as nitrogen is the currency used to track the transfer of
236 energy in Atlantis models (Audzijonyte et al., 2017). Initial conditions for the species groups
237 were estimated or inferred depending on data and information available. Details on the species
238 groups initial conditions and biological parameters are in Appendix B.

239

Table 1: List of vertebrate species groups for TBGB-AM. Names in bold at the start of each multispecies group indicates the most dominant species in that group, and it is the species from which productivity parameters for that group were derived. Lifespan is the assumed maximum number of years an individual in that group may live. Ben, benthic; invert, invertivore; lrg, large; mesopel, mesopelagic; pisc, piscivore; sml, small.

Species group	Main species	Lifespan (years)
Barracouta	Barracouta	10
Carpet shark	Carpet shark	20
Demersal fish	Giant stargazer , Ling, Yellow-eyed mullet, Sea perch, Rattails, Grey mullet, Silver dory, Lookdown dory, Northern bastard cod, Goatfish, Scaly gurnard, Pigfish, Spotted stargazer, Two saddle rattail, Oblique banded rattail, Opalfish, Brown stargazer, Cucumber fish, Swollenhead conger, Giant boarfish, Capro dory, Silverside, Globefish	20
Elasmobranch invert	Rough skate , Skates undefined, Dark ghost shark, Smooth skate, Other sharks and dogfish, Elephant fish, Eagle ray, Stingray, Short-tailed black ray	10
Elasmobranch pisc	Thresher shark , Electric ray, Seal shark, Seven-gilled shark, Bronze whaler shark, Blue shark, Mako shark, Sharks undefined	20
Flatfish	Sand flounder , Greenback flounder, Lemon sole, New Zealand sole, Yellow-belly flounder, Witch, Black flounder, Turbot, Brill, Speckled sole	5
Kahawai	Kahawai	30
Leatherjacket	Leatherjacket	5
Mackerels	Jack mackerel (Yellow-tail) , Jack mackerel (Greenback), Jack mackerel (Peruvian), Blue mackerel	20
Mesopel fish invert	Blue warehou , Silver warehou, Bluenose	20
Pelagic fish lge	Trevally , Albacore, Hoki, Hake, Porcupine fish, Kingfish, Frostfish, Gemfish, Sunfish, Skipjack tuna, Oilfish, Southern boarfish, Ray's bream	50
Pelagic fish sml	Pilchard , Redbait, Anchovy, Garfish, Sprats, Whitebait, Ahuru	10
Pinniped	Fur seals	20
Red gurnard	Red gurnard	20
Red cod	Red cod	5
Reef fish invert	Butterfish , Blue moki, Marblefish, Trumpeter, Banded wrasse, Scarlet wrasse, Wrasse (undefined), Red moki, Copper moki, Seahorse, Spotty, Porae, Long-finned boarfish, Spiny seadragon, Southern bastard cod	10
Reef fish pisc	John dory , Blue cod, Conger eel, Hapuku, Hagfish	10
Rig	Rig	20
School shark	School shark	50
Seabird	Seabirds, shorebirds, & black swans	20

Snapper	Snapper	50
Southern spiny dogfish	Southern spiny dogfish	30
Tarakihi	Tarakihi	40

Table 2: List of invertebrate species groups for TBGB_AM. Description includes main species. Lifespan is the maximum number of years an individual in that group may live. Those groups with no value for lifespan are modelled as biomass pools and hence do not have a lifespan defined as this is only relevant when modelling numbers. Carniv, carivore; Invert comm, commercial invertebrates; herb, herbivore; scav, scavenger; Macro-benth, macrozoobenthos; Meiobenth, meiobenthos; Zoo, zooplankton.

Species group	Description	Lifespan (years)
Benthic Carniv	Some gastropod molluscs, polychaetes & crustaceans	
Benthic grazer	Benthic animals that consume diatoms and sea grass	
Carniv Zoo	Planktonic animals (size 2–20 cm)	
Cephalopod	Arrow squid , Octopus, Broad squid	2
Deposit feeder	Detritivores, e.g., some gastropod molluscs, polychaetes, echinoderms (including holothurians) & crustaceans	
Dredge oysters	Dredge oyster	4
Filter other	Non-commercial benthic filter feeders, e.g., sponges, bryozoans, ascidians, turbellarians, bivalves, hydroids	
Gelat Zoo	Salps, ctenophores, jellyfish	
Invert comm Herb	Paua , Kina	6
Invert comm Scav	Rock lobster , Paddle crab, Whelks, Sea cucumber	8
Macrobenth other	Non-commercial benthic organisms (size >1 mm), e.g., polychaetes, echinoderms, sea anemones, crustaceans	
Meiobenth	Benthic organisms (size 0.1–1 mm), e.g., nematodes, some small crustaceans	
MesoZoo	Planktonic animals (size 0.2–20 mm)	
MicroZoo	Heterotrophic plankton (size 20–200 μm)	
Mussels	Greenlip mussel , Horse mussel	2
Scallops	Scallop	2
Surf clams	Cockle , King clam, Pacific oyster, Pipi, Mactra	2

Table 3: List of phytoplankton and algae species groups for TBGB_AM.

Species group	Description
Diatoms	Diatoms (large phytoplankton)
Macroalgae	Macroalgae
Microphytobenthos	Unicellular benthic algae
Pico-phytoplankton	Small phytoplankton

Table 4: List of bacteria and detritus species groups for TBGB_AM.

Species groups	Description
Carrion	Dead and decaying flesh

Labile detritus	Organic matter that decomposes at a fast rate
Pelagic bacteria	Pelagic bacteria
Refractory detritus	Organic matter that decomposes at a slow rate
Sediment bacteria	Sediment bacteria

3.5 Predation

Simulated predation was a four step process which occurred within each cell and at each timestep. From the predator's perspective the steps modelled can be summarised as: 1.) Am I allowed to eat it? 2.) Is it in the same place at the same time as me? 3.) Does it fit in my mouth? 4.) How much can I eat? Full details are in the Atlantis User's Guide (Audzijonyte et al., 2017). In step 4 we applied the Holling Type II functional response to all age-structured species groups in this model, thus influencing the amount of prey consumed by prey abundance, and the predators search rate and handling time.

Diets of each species group were summarised in categories Algae, Bacteria, Bird, Cetacea, Coelenterate, Crustacean, Detritus, Echinoderm, Elasmobranch, Microzooplankton, Mollusc, Phytoplankton, Polychaete, Teleost, and Tunicate similar to that done in the diet study of Stevens et al. (2011) (Figure 3). While this summary misses the temporal, spatial, age and size components of the predator-prey interactions, it is useful to check overall diets. For example, warehou (mesopel fish Invert) eat mostly salps (tunicates) as expected; school shark eat mostly fish as expected; flatfish (mostly flounder and sole) eat mostly benthic invertebrates; and invert comm herb (paua and kina) eat mostly algae. Trophic levels were calculated for each species based on their diets at the prey species group level, summarised over model space, time and species age-classes. The resulting trophic levels ranged from 1 for the primary producers through to 5.49 for elasmobranch piscivores (Figure 4). The trophic levels are generally higher than they should be which is due to combining juvenile and adult diets in the trophic level calculation. For example, elasmobranch piscivores predate on juvenile barracouta, but the contribution of barracouta to the trophic level of elasmobranch piscivore uses the trophic level of barracouta averaged over all age-classes, which will be higher than the juvenile trophic level. The effect is confounded throughout the foodweb, as barracouta adults (to continue with this example) also predate on juvenile pelagic fish large, which will artificially increase the trophic level of barracouta.

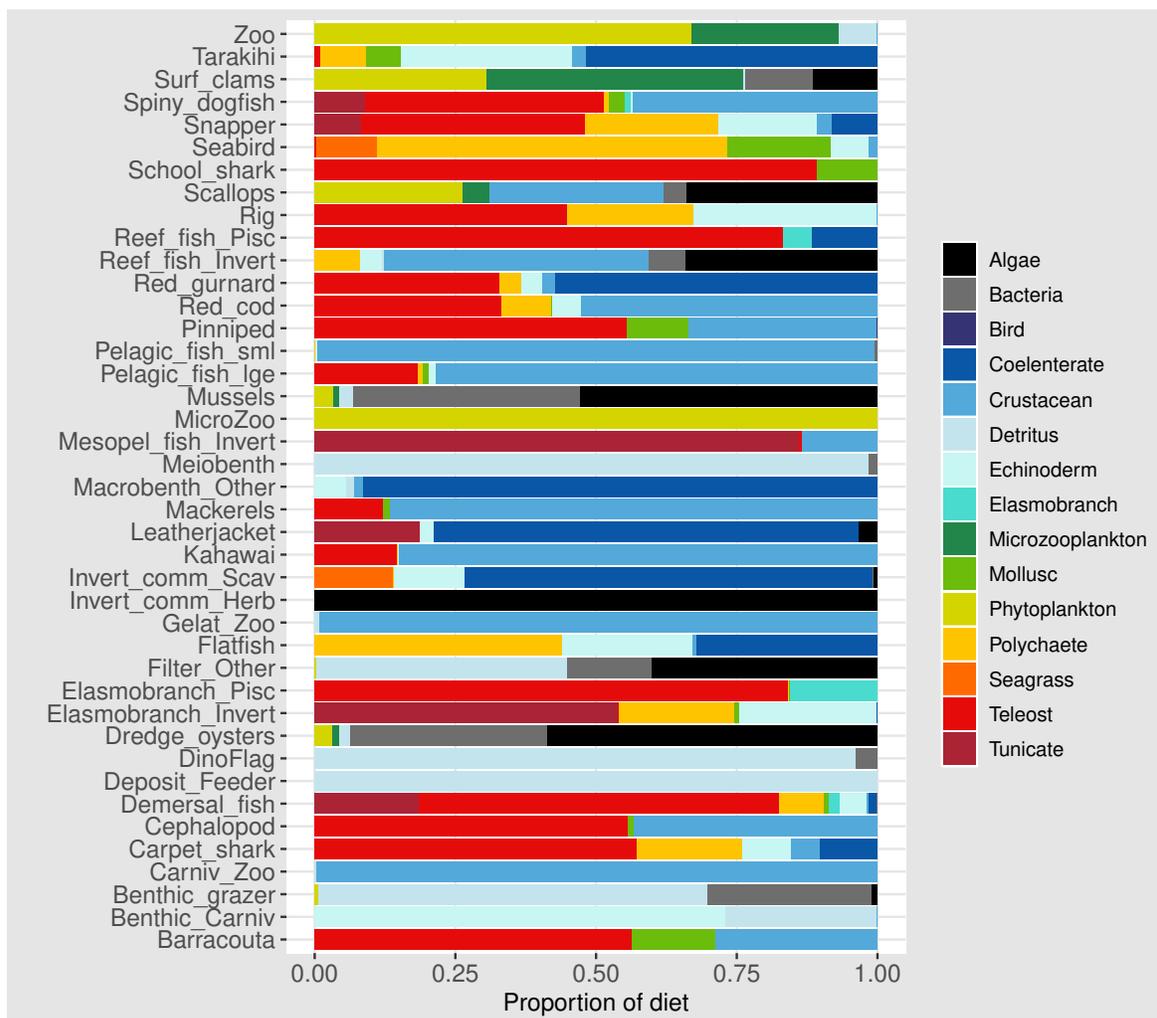

Figure 3: Summary of the proportion of prey groups in the diets of species groups (Tables 1 and 2) over model years 1900–2014 from the fished model where the proportion is by mg N consumed.

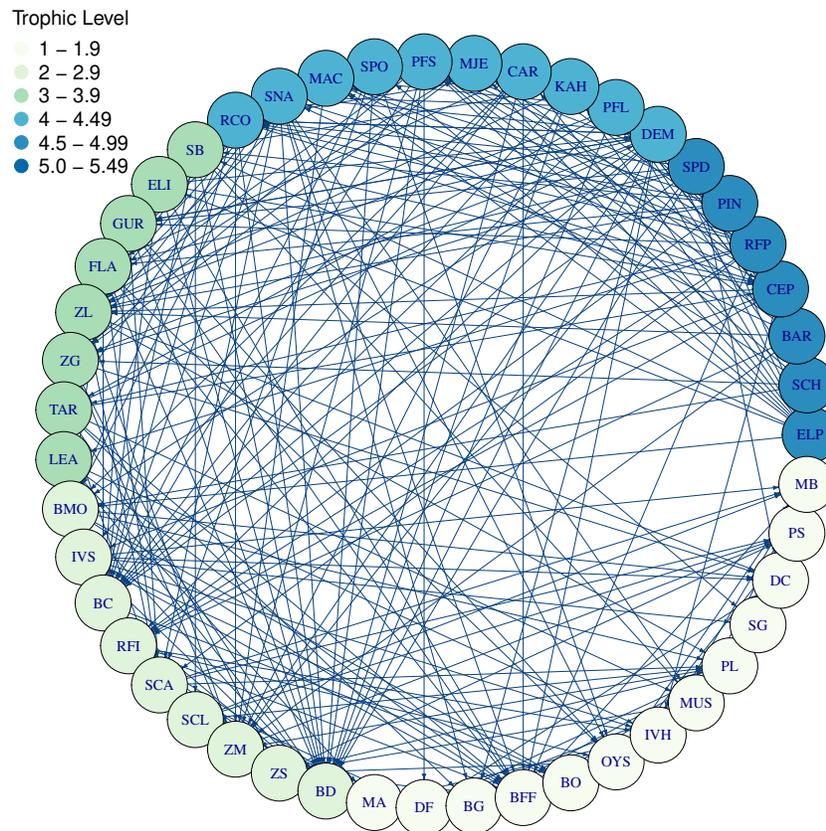

Figure 4: Foodweb coloured by trophic level from TBGB_AM diets summarised from 1900–2014, all model polygons and depth layers, and all species' age-classes.

4 Alternative models

The alternative models were developed as simplifications of TBGB-AM, although there are additional differences due to the structure of the respective frameworks.

4.1 TBGB_SS

The multi-species size spectrum model was constructed in R (R Core Team, 2020). The foundation for the work is the modelling framework *mizer* version 2.0.3, see (Scott et al., 2014). This is available freely as an R package (Delius et al., 2020). For instructions on installing *mizer* and running models, see the *mizer* vignette (Delius et al., 2020). The earliest example of using *mizer* to model a multi-species system was by Blanchard et al. (2014), focusing on twelve common pelagic fish species in the North Sea.

As the first step of setting up the size spectrum model for TBGB, the species list was reduced to those for which a consensus was reached that they fed in a size-based way, and hence it was appropriate to use the size spectrum modelling framework to simulate their life processes. This meant not including the following species from the model: fur seals, seabirds, benthic carnivores, benthic grazers, carnivorous zooplankton, detritivores, dredge oysters, benthic filter feeders, paua, rock lobster, benthic organisms, planktonic animals, heterotrophic plankton, greenlip mussels, scallops and cockles.

Seven parameters are needed as inputs to the size-structured model for each species. These include:

- the von Bertalanffy growth parameter k ;
- the allometric length-weight scaling multiplier a ;
- the allometric length-weight scaling exponent b ;
- the asymptotic body weight w_{inf} ;
- the maturity weight w_{mat} ;
- the preferred predator : prey mass ratio β ;
- the width of the feeding kernel σ .

The first five of these parameters are available directly from the Atlantis model. For the feeding parameters (β and σ) information was taken from the Atlantis model about the prey species of both adults and juveniles for each species. For the mass of the species doing the feeding, we used asymptotic mass for adults and maturity weight for juveniles. We then approximated the weight of the prey as half of the asymptotic mass

302 for the prey of adults, and half of the maturity weight for the prey of juveniles. We
303 then calculated the predator : prey mass ratio β by dividing the former by the latter
304 and taking the average over both juveniles and adults, and calculated the width of the
305 feeding kernel σ by taking the \log_{10} of the standard deviation of all the mass ratios.

306
307 Following this, we calculated the species interaction matrix. We used the spatial
308 overlap of species from the TBGB_AM to estimate the likelihood of interaction be-
309 tween three size combinations of predators and preys (adult predators - adult prey,
310 adult predators - juvenile prey and juvenile predators - juvenile prey), with the juvenile
311 predator - adult prey combination ignored. We then calculated the normalised (0 to
312 1) overall interaction for each species predator-prey pair using the average of the three
313 predator-prey size combinations.

314
315 Using the above parameters and interaction matrix with the software package *mizer*,
316 the following parameters were calculated for each species:

- 317 • $h_i(w)$, the maximum intake rate of an individual of species i and weight w ;
- 318 • γ_i , the search volume for species i at 1g weight;
- 319 • ks_i , a constant multiplier for metabolic rate.

320 Also, an extensive description of the default parameter values (where are challenging
321 to calculate empirically) is provided in (Delius et al., 2020). As part of the model set
322 up, the carrying capacity of the resource spectrum was reduced to 70% of that of the
323 North Sea model (Blanchard et al., 2014), as it was observed that feeding levels (even
324 for large individuals) in the TBGB model were too dependent upon the resource rather
325 than other species.

326
327 The final step for the model was to tune free parameters related to reproduction
328 (e_{repro} and R_{max}) to fit the unfished (virgin) biomasses of species to those generated in
329 the Atlantis model. The decision was taken to fix e_{repro} to 1 for all species, and modify
330 R_{max} for each species until a good fit was observed for all species biomasses. Pearson's
331 coefficient was used to measure closeness of fit between model biomasses and those of
332 the Atlantis model.

333 4.2 TBGB_EwE

334 TBGB_EwE was developed in two parts, a mass balanced model (Ecopath) and a simu-
335 lation model (Ecosim). TBGB_EwE included the same 51 species functional groups used

336 in TBGB_AM and were modelled as biomass pools (in t/km²). Diet and prey prefer-
337 ences, fishing mortality and initial conditions were all based on those used in TBGB_AM.

338
339 TBGB_EwE used a simpler spatial structure than that used for TBGB_AM, where
340 all functional groups were assumed to inhabit the entire study area. The vulnerability
341 of prey groups to predation and predatory searching rates was used as a proxy for the
342 variability of preys and the different levels of interaction between species (predators and
343 prey). Diet import was also used as a proxy for spatial dynamics in terms of migration,
344 where a proportion of the total diet could be apportioned to being outside the study area.

345
346 Realised diets in EwE rely on the assumption that what is consumption for one
347 group is mortality for another. Ecotrophic efficiency is used as indication of how heavily
348 a group is being preyed upon and whether enough individuals are available to die of
349 old age. Diet must be input as the proportion of each prey group in a predator's diet.
350 These proportions can be varied to allow for successful mass balance but builds basis
351 of consumption rates and system dynamics. The relative proportion of prey groups in
352 predator diets was different to those used in TBGB_AM, but since the dietary compo-
353 nents remained the same, realised diets were comparable. The single biggest difference
354 between the two diets related to modelling bacterial groups which affected the diets of
355 those groups that consume bacteria.

356
357 Although it is possible to model age structure in EwE, this functionality was not used
358 for TBGB_EwE, since interactions between adults and juveniles are not well simulated.
359 For example, if there is less food for juveniles or more mortality (both resulting in less
360 juvenile biomass) the adult population remains unaffected.

361 **4.3 Comparison of alternative models**

362 Neither of the alternative models developed have space explicitly defined. They do,
363 however, both use an availability term which acts as a proxy for some spatial dynamics
364 such as providing refuge from predators or fishing that might be expected from spatial
365 separation. TBGB_SS sets an availability term for each pair of species groups that de-
366 fines how much they are expected to spatially overlap. These were estimated using the
367 spatial overlap from the base TBGB_AM, averaged over the model years 1900–2014.
368 These availabilities were not age- or size- structured, whereas the spatial distributions
369 are in TBGB_AM.

370

371 Species groups were another key difference. TBGB_EwE modelled the same 51
372 species groups used in TBGB_AM, although as biomass pools (in t/km²) with no
373 age structure. TBGB_SS modelled all 21 of the vertebrate species groups defined for
374 TBGB_AM, as well as cephalopods. For these groups, the size-structured nature of this
375 framework allows for variation in growth rates, diet and predation vulnerability through-
376 out each groups' life span, from egg to adult. However, the size-structured model does
377 not explicitly define or capture the dynamics of benthic invertebrate functional groups.

378
379 Historical catches were forced in all three models, but in slightly different ways due
380 to the structure of the models. TBGB_AM removed numbers of fish to match historical
381 tonnes caught, and these were calculated within TBGB_AM based on the weights of
382 individuals at each age class, with the total catch removed apportioned to age-classes
383 based on selectivities defined by age-class. TBGB_EwE removed catches as biomass,
384 and there was no age-structure, so no selectivities with respect to age or size were re-
385 quired. TBGB_SS removed catches using an F time-series for each species group, which
386 was based on estimates from TBGB_AM. TBGB_SS had knife-edge selectivity such that
387 fish were only caught at or above the size at maturity.

388
389 During model calibration, each of the models focused on different aspects of the
390 model. TBGB_SS focused mostly on adjusting reproductive outputs for each species,
391 and the planktonic primary production to achieve virgin biomasses matching those in
392 the TBGB_AM model. TBGB_AM focused mostly on prey availabilities, and also ad-
393 ditional (non predation) mortality for higher trophic levels. TBGB_EwE focused on
394 balancing energy inputs (production) with outputs (consumption).

395 396 5 Calibration

397 Calibration of TBGB_AM included ensuring stable biomass trajectories when apply-
398 ing no fishing; realistic realised diets; realistic growth and mortality (size-at-age and
399 proportions-at-age), following the methods and recommendations of Pethybridge et al.
400 (2019), and McGregor et al. (2019).

401
402 Biomass trajectories should reach a quasi-equilibrium when modelled with constant
403 oceanography and no fishing (Kaplan and Marshall, 2016). While oceanography is not
404 constant in our non-fishing model as it changes by year (Section 3.3), most of the age-

405 structured groups should maintain their dynamic stability. For the TBGB_AM base
406 model, all biomass trajectories remained within 20% of their coefficients of variation
407 (CVs) over the simulated 1900–2014 model period. Biomass trajectories for all age-
408 structured groups from the un-fished model are in Appendix C.

409
410 Atlantis simulates growth rates of age-structured groups as a function of consump-
411 tion. If growth is too slow, there may be insufficient food available, the feeding search
412 rate could be too low or handling time too high, and the reverse of these when growth
413 is too fast. In the TBGB_SS model growth is also a function of consumed prey, taking
414 into account metabolism and movement (Scott et al., 2018). Allocation of consumed
415 prey to reproduction is set such that growth approximates the von Bertalanffy curve at
416 a constant feeding level (Hartvig et al., 2011). Simulated growth rates of age-structured
417 species groups were assessed by comparing the simulated size-at-age with those expected
418 based on growth curve estimates from the literature (Table ??), and those resulting
419 from the size-spectrum model. The full growth curves are in Appendix D, and sum-
420 mary figures of the maximum expected size for each species functional group (L_∞) are
421 in Figure 5. We used the upper 90th percentile for weight, converted to length using
422 the length-to-weight conversion parameters (Table ??), from TBGB_AM outputs from
423 1900–2014 as L_∞ , and the maximum size from the base un-fished model at equilib-
424 rium for TBGB_SS. While many were in line with the literature, both models generally
425 produced smaller expected maximum sizes to what the literature suggest for the larger
426 species such as elasmobranch piscivores and school sharks, and TBGB_AM generally
427 produced larger expected maximum sizes for smaller species groups such as pelagic fish
428 small, cephalopods and mackerels.

429
430 Natural mortality in the model consists of mortality intrinsic within the model from
431 predation, starvation, and light, oxygen or nutrient deprivation, and additional forced
432 mortality. The latter was applied for modelled species groups that would not otherwise
433 suffer sufficient natural mortality within the model, such as those that have little known
434 predation. Age-structured simulated natural mortality rates from the stable base model
435 were compared to estimates of M from the literature where available (Table ??) by
436 comparing the proportions-at-age with the corresponding exponential decay curve. The
437 overlaid simulated and ‘observed’
438 were generally very similar (Appendix E), although kahawai stood out as having less
439 natural mortality in the model than the literature would suggest, as did (although to a
440 lesser extent) mesopelagic fish invertivores.

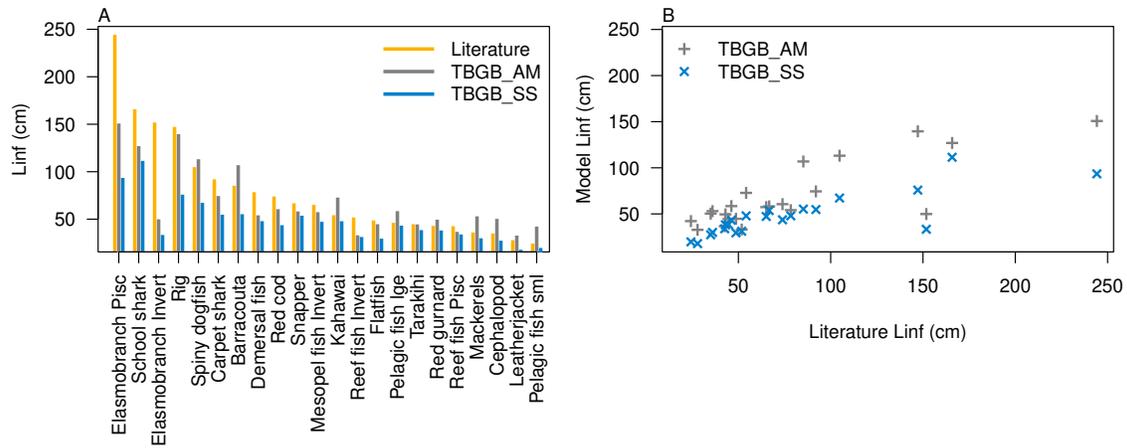

Figure 5: L_{∞} from the literature (orange bars), TBGB_AM (grey bars) and TBGB_SS (blue bars) (A), and TBGB_AM L_{∞} plotted against literature L_{∞} (grey pluses) and TBGB_SS L_{∞} plotted against literature L_{∞} (blue crosses) (B).

441

6 Sensitivity analyses

442

A sensitivity analysis of the TBGB_AM was carried out to assess the uncertainty of the model inputs, the propagation of this uncertainty to the outputs and therefore its effects on model performance. This analysis was performed on the following components of the TBGB_AM

443

6.1 Initial conditions

444

Initial conditions were perturbed for TBGB_AM following the methods of McGregor et al. (2020). The resulting simulations were then used for assessing responses of TBGB_AM to historical fishing, thus allowing us to present these results as envelopes of plausibility rather than single trajectories. The species groups with the largest between-run CVs by the end of the simulation period (2000–2014) were generally lower in the foodweb, such as zooplankton, deposit feeders and picophytobenthos (Figure 6). In addition to these, scallops and flatfish also featured among those with high CVs, and for both of these it was due to an apparently fine line between the stock crashing under fishing pressure, or persisting (Figure 7).

445

446

447

448

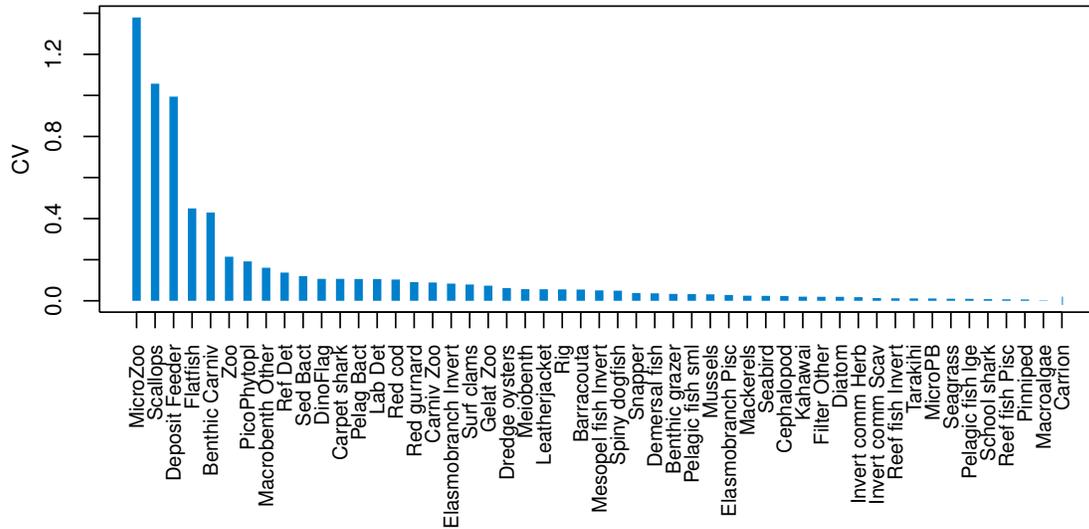

Figure 6: Between-run CVs from 2000–2014 that resulted from perturbing the initial conditions of TBGB_AM.

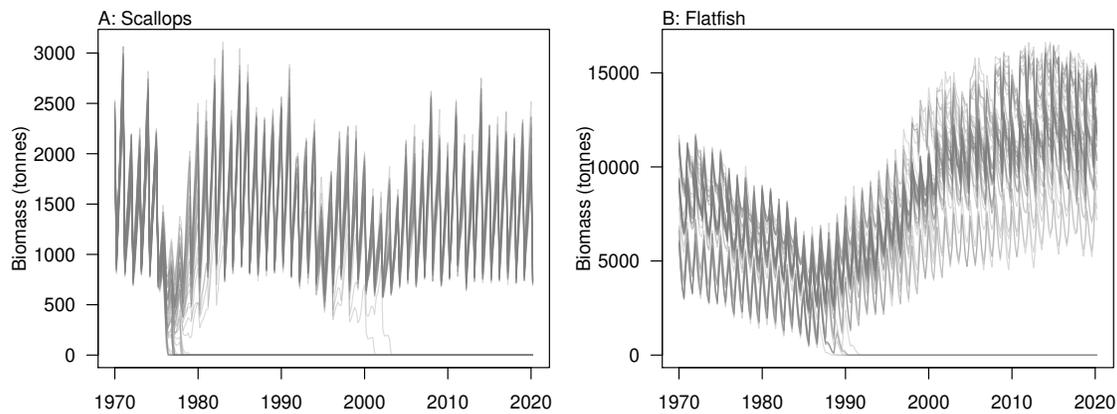

Figure 7: Simulated biomass trajectories from TBGB_AM under perturbed initial conditions for A: scallops and B: flatfish.

459 6.2 Oceanographic variability

460 Oceanographic variables from a ROMS (Regional Oceanographic Modelling System)
 461 model for years 2008–2013 were used to define temperature, salinity and flux (water ex-
 462 change). As our model spanned more than these years, we needed to recycle the ROMS
 463 variables in some way. This section applies the methods defined in McGregor et al.
 464 (2019), which has two goals: 1.) establishing confidence intervals for our model simu-
 465 lations with respect to oceanographic variability; 2.) assessing the effect of repeating
 466 oceanographic variables from any one year, and whether these take the model outside

of the established confidence intervals.

To retain realistic within-year dynamics, the ROMS variables from each year were kept together as a unit, and the years covered by the ROMS model were considered the samples. We ran two sets of simulations: the first sampled ROMS years at random with replacement for each model year simulated (bootstrapped the ROMS years) and repeated this for 50 model runs; the second repeated one ROMS year for all model years simulated and did a separate model run for each of the six ROMS years. In both cases, the 2008 ROMS was repeated for a 35-year burn-in period, followed by a 115 year simulation. The 2008 ROMS year was chosen for the burn-in period as this year seemed to be representative of the means from all ROMS years for sea temperature and salinity when averaged over the model area. The full set of figures with temperature and salinity from each ROMS year, overlaid with averages from all ROMS years are in Appendix A. Figure 8 shows the sum-of-squares between the values for each ROMS year and the average for salinity and temperature as well as the Pearson's correlations. The 2008 ROMS year had the lowest combined sum-of-squares, although correlation for salinity was not as high as the other years. Bootstrapping the ROMS years was used to establish confidence intervals with respect to between-year oceanographic variability. Repeating each ROMS year in turn was testing the effect of multiple years being different to the other years in some consistent way, such as cooler or warmer.

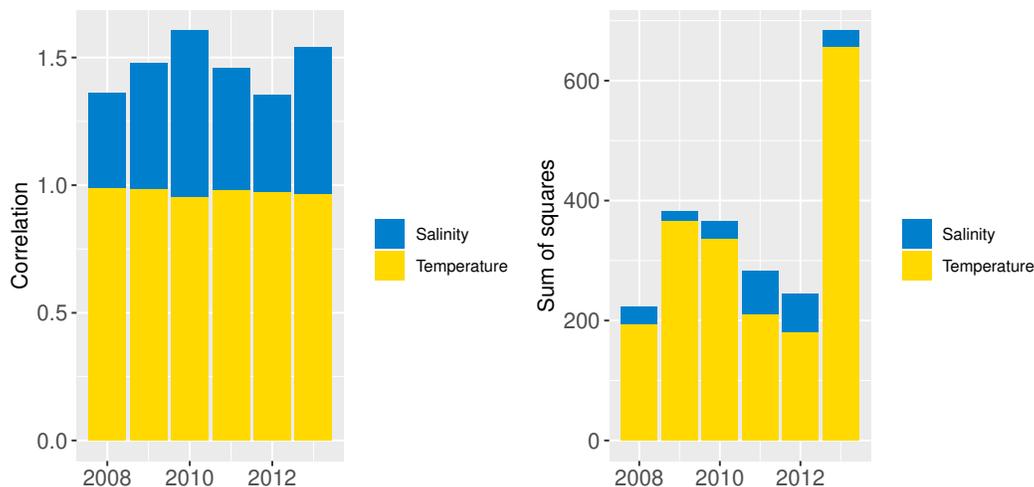

Figure 8: Correlation (left) and sum-of-squares (right) for salinity (blue) and sea temperature (yellow) variables for each ROMS year with respect to the relative averages from all ROMS years.

487

488 The established biomass confidence intervals established from varying the oceanographic variables were fairly narrow for most species groups, with CVs < 10% (Figure
 489 9). Of the exceptions, micro-zooplankton had the highest CVs extending up to almost
 490 250%, followed by deposit feeders, benthic carnivores, meso-zooplankto, dinoflagelettes,
 491 and pico-phytoplanton. That these groups were found to be most sensitive to oceanographic
 492 variability in the model is a plausible and sensible result. When we compared
 493 the between-run CVs, we found these varied more than when sampling ROMS years
 494 randomly (Figure 9), suggesting strong effects from repeating the ROMS variables from
 495 any one year. Dinoflagelettes, seagrass and meiobenthos all had greater between-run
 496 CVs from repeating ROMS years than from sampling ROMS years.
 497

498

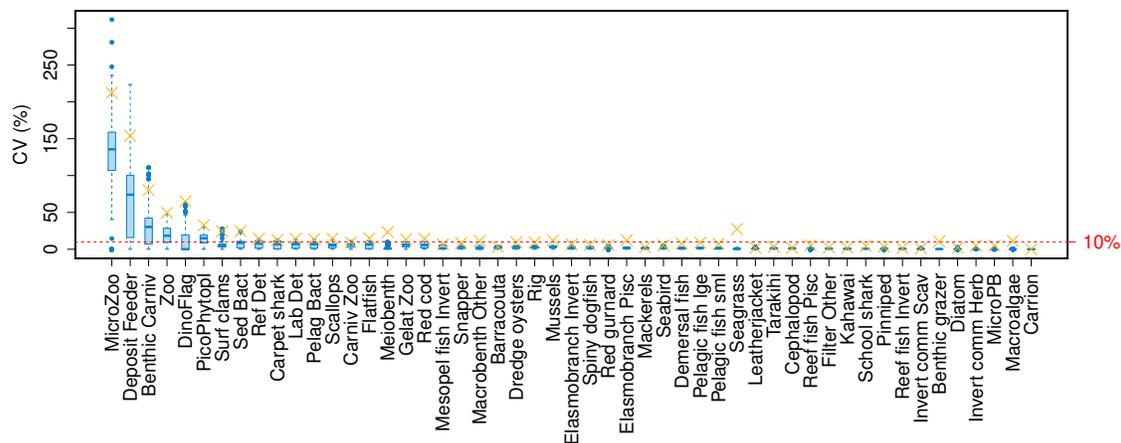

Figure 9: Between-run CVs for biomass output trajectories for each species group in TBGB_AM, from 50 model runs with ROMS years (2008–2013) sampled at random with replacement for each model year 1900–2014 (blue boxes) and upper 90% CIs for between-run CVs from repeating each ROMS year for the 1900–2014 model years (gold crosses).

499

6.3 Connectivity and influence

500

501

502

503

504

505

506

507

Understanding which species groups are most influential in the model is another test for realistic dynamics, and is another way we can compare the dynamics of the models. EwE models output several measures of keystoneity, with KS_3 recommended to be ‘best’ by Valls et al. (2015) following analyses of many variations on keystone ranking calculations. For TBGB_AM, we followed the simulation method applied in McGregor et al. (2019), but modified the keystoneity calculation to match that recommended in Valls et al. (2015) and applied in EwE (Equation 1). For the TBGB_AM simulations, we perturbed each species group in turn, then assessed the responses of the other groups

508 in the system. For each age-structured species group, we ran two simulations, one with
 509 a small additional mortality and one larger; $M(\text{per year}) + (0.1, 0.005)$. We assessed
 510 responses of the groups with respect to the Base Model at the completion of 50-year
 511 simulations using TBGB_AM, then compared the keystone rankings to those produced
 512 for TBGB_EwE.

$$KS_i = \log \left(\sqrt{\sum_{i \neq j} m_{ij}^2} \times drank_i \right) \quad (1)$$

514 m_{ij} is the impact of species i on species j ,

515 $drank_i$ is the rank of species i in descending order or biomass

516
 517 The top species for keystone-ness are not the same for TBGB_AM which has mus-
 518 sels, demersal fish, seabirds, and dredge oysters, and TBGB_EwE which has Reef fish
 519 piscivores, elasmobranch piscivores, pelagic fish large and snapper (Figure 10). The
 520 Pearson's correlation between the two sets of rankings is 0.19, suggesting a weak and
 521 likely insignificant correlation. If we lower the benchmark to within the same third for
 522 keystone ranking (e.g. top, middle, or bottom third for both models), 11 out of the 30
 523 age-structured species groups are within the same third; and seven are in the opposite
 524 third.

526 7 Fishing

527 Catch histories from 1900 to 2013 were estimated for all of the species groups that have
 528 been commercially exploited. Catches required partitioning to provide catch by species
 529 group, by month, by fleet, and by cell. The available catch data seldom provided this
 530 level of detail, so numerous assumptions were necessary to develop catch histories (more
 531 details in Supplementary Materials). The model operated on a one-day cycle, so catches
 532 were actually required for this time interval. However, it was considered that an esti-
 533 mation of catches by month (subsequently split into daily amounts) would be sufficient
 534 to describe the patterns of seasonal variation in commercial catch apparent for most of
 535 the species groups.

536
 537 Catch histories for the commercially exploited bivalve species (scallops, oysters, mus-
 538 sels and surf clams) were developed using the units tonnes meatweight (rather than
 539 greenweight (unshucked shellfish)). Meatweight landings of scallops have been recorded,

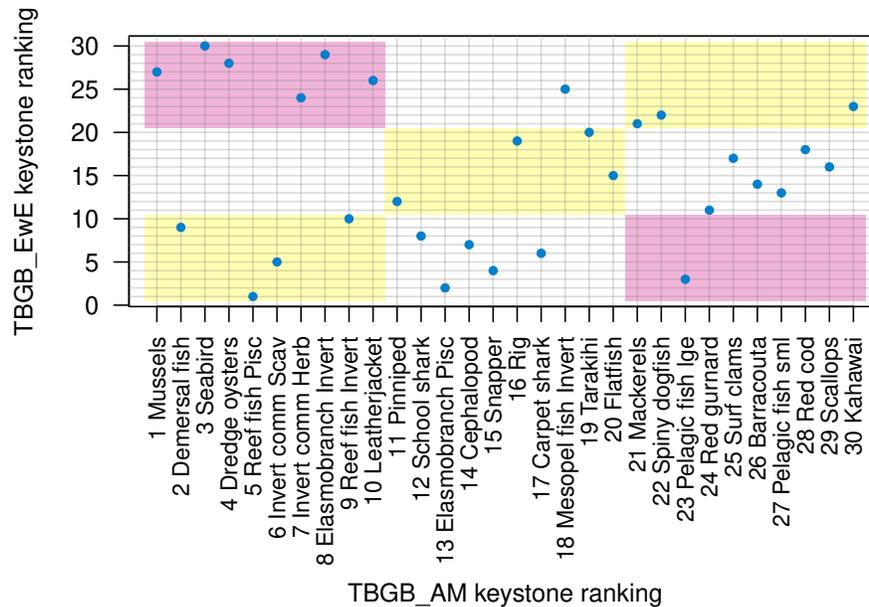

Figure 10: Keystone ranking from TBGB_AM (x-axis) and TBGB_EwE (y-axis) for all age-structured species groups, with numbers giving keystone ranking (1 is the most influential using Equation 1). Shading indicates species groups that are at least within the same third of keystone ranking in both models (e.g. top third, middle third, bottom third) (yellow), and those that are in opposite thirds (e.g. top third in TBGB_AM and bottom third in TBGB_EwE or top third in TBGB_EwE and bottom third in TBGB_AM) (red).

540 and the derivation of the catch history for this group is given below. Landings of the
 541 other three bivalve groups are recorded as greenweight. Catch histories for these were
 542 derived (in tonnes) for polygon and month as described above for wetfish from the FSU
 543 and QMS databases. The greenweights were then adjusted to meatweight using the
 544 following conversion factors: dredge oysters, 0.12; mussels, 0.25; surf clams, 0.18.

545
 546 The commercial catch history for scallops was developed using data from Williams
 547 et al. (2014). Data from 1978 onwards were reported by scallop reporting sector (see
 548 figure 3 of Williams et al. (2014)), and these were allocated to polygon and to month.
 549 Catch was allocated amongst months in each polygon using the proportions used to de-
 550 rive figure 10 of Williams et al. (2014). Catches from 1959 to 1977 were not available by
 551 area, so were allocated to polygons based on the mean distribution of catches after 1977.

552
 553 Reliable estimates of recreational catch from the TBGB region are sparse; Cole et al.
 554 (2006) estimated shellfish harvest in 2003–04, Davey et al. (2008) estimated harvest of
 555 snapper and blue cod in 2005–06, and a National Research Bureau survey estimated

556 catches of all species in 2011–12 (B. Hartill, NIWA, pers. comm.). Other estimates are
557 available (see Ministry for Primary Industries (2017)), but they are generally not consid-
558 ered reliable (B. Hartill, NIWA, pers. comm.). It is acknowledged that the recreational
559 catch in this area is very dynamic, with factors like weather and localised abundance of
560 species driving harvest levels.

562 8 Skill assessment

563 A research trawl survey series conducted in 11 years between 1992 and 2013 has sam-
564 pled in Tasman and Golden Bays (Stevenson and Hanchet, 2000; Stevens et al., 2017).
565 Biomass estimates from strata 17, 18, and 19 (approximating Statistical Area 038 which
566 is the TBGB_AM model area) were compared to the biomass outputs from TBGB_AM.
567 Three of the species groups (red gurnard (Starr and Kendrick, 2017a), snapper (Lang-
568 ley, 2018) and rig (Starr and Kendrick, 2017b)) have CPUE (catch per unit effort)
569 that we have also compared to the corresponding TBGB_AM biomass outputs. There
570 is a dredge survey for scallops in Tasman and Golden Bays, conducted annually in
571 May–June (Williams et al., 2014, 2015) for which the dredge efficiency was revised in
572 (Tuck et al., 2018). It is the revised biomass index we have used to compare with
573 the TBGB_AM scallop biomass. The full set of figures with survey biomass estimates
574 overlaid on TBGB_AM biomass outputs are in Appendix G. The three species groups
575 with corresponding CPUE and survey biomass estimates are presented in Figure 11.
576 As a quantitative measure of comparison, we calculated Pearson’s correlations (Table
577 5). We used Pearson’s which is one of the metrics used for other Atlantis model skill
578 assessments (McGregor et al., 2019; Sturludottir et al., 2018; Olsen et al., 2016). The
579 correlations between the model and survey range from 79% for school shark, down to
580 -79% for rig. Rig were also negatively correlated with the CPUE index at -37% (Ta-
581 ble 5). The rig survey biomass suggests the population was very low from 2000–2011,
582 whereas TBGB_AM was stable with a slight increase in biomass for these years. The
583 CPUE for rig also suggested a decline in the early 2000’s, followed by an increase which
584 is not apparent in the survey or TBGB_AM. The other negatively correlated species
585 were cephalopods (-15%), and tarakihi (-20%), neither of which had an apparent trend
586 in the survey biomass or the TBGB_AM biomass. Nine out of the 19 speices groups with
587 survey biomass estimates had positive correlations of greater than 20%. Only snapper
588 was positively correlated with CPUE (66%).

Table 5: Pearson's correlation between TBGB_AM spawning stock biomass (SSB) and survey biomass estimates (Survey) and fishery catch per unit effort (CPUE) (rounded to 2 significant figures). Invert, invertivore; mesopel, mesopelagic.

Species group	Survey	CPUE
Barracouta	-0.05	NA
Carpet shark	0.43	NA
Cephalopod	-0.15	NA
Demersal fish	0.48	NA
Elasmobranch Invert	0.16	NA
Elasmobranch Pisc	0.43	NA
Flatfish	0.3	NA
Leatherjacket	0.061	NA
Mackerels	-0.067	NA
Mesopel fish Invert	0.55	NA
Red cod	0.41	NA
Red gurnard	0.15	-0.059
Reef fish Pisc	-0.084	NA
Rig	-0.79	-0.37
Scallops	0.36	NA
School shark	0.79	NA
Snapper	0.13	0.66
Spiny dogfish	0.27	NA
Tarakihi	-0.2	NA

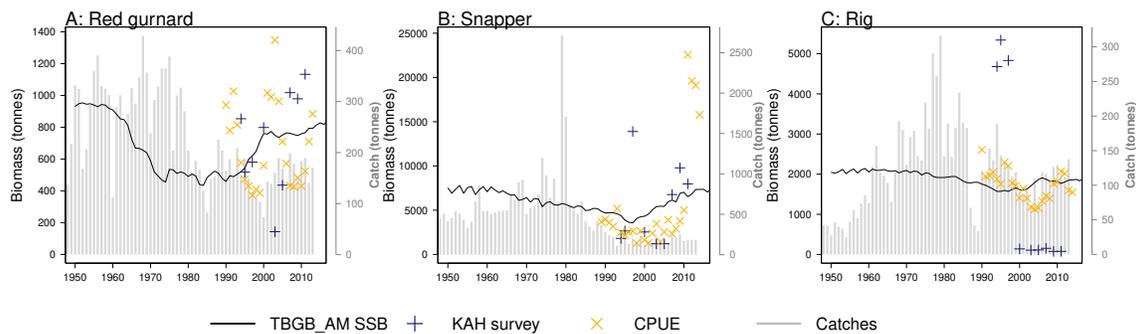

Figure 11: TBGB_AM estimated spawning stock biomass (SSB) (black solid), survey estimated biomass (midnight blue pluses), and CPUE (orange crosses) where available for the red gurnard (A), snapper (B), and rig (C). CPUE and survey biomass estimates were rescaled to match the mean of the TBGB_AM estimated SSB. Grey bars are estimated catches that were forced removals in TBGB_AM.

9 Bringing it together: comparing modelled ecosystem dynamics

9.1 Realised diets

We compared realised diets from the three models, using the base un-fished version, at equilibrium for TBGB_SS, and summarised over 1900–2014 and 1959–2014 for TBGB_AM and TBGB_EwE respectively. The full set of figures showing proportion of weight consumed prey species group for each of the three models are in Appendix H. We dropped plankton diet proportions for TBGB_SS as they swamped the diets due to large amounts of this being eaten when the animals are very small, as is the nature of a size-spectrum model. Having done this, the next smallest prey group (pelagic fish small) then dominated all diets. They were even the largest prey group for predators that don't generally consume small pelagic fish, such as reef fish invertivores, elasmobranch invertivores, carpet sharks and flatfish. As a result, the diets can only be similar between the size-structured model and the other two models for predators that eat a lot of small pelagic fish. The realised diets from TBGB_EwE don't seem to show any changes from the input diets, so these do not reflect anything of the model dynamics, but rather how the diets were specified for the model. The TBGB_AM realised diets are the most complex, and achieving realistic realised diets was one of the goals of model calibration. The results presented for the model comparison have been summarised over model space, time and species age, which loses a lot of the detail, but is a necessary abstraction for the purpose of comparison. We calculated Spearman's rank correlation of the diets as direction and monotonicity between diets seemed more appropriate than to test for a linear relationship. We assigned a value of -1 to any compared diets with zero overlap. There were five species groups where the size-structured model had zero overlap with the other two models due to these predators only eating pelagic fish small in the size-structured model, and not eating 'pelagic fish small' in the other two models. These were leather-jacket, rig, flatfish, reef fish invertivores and pelagic fish small. Between the Atlantis and EwE models, the invertebrates were more likely to have negatively correlated diets, with the exception being carpet shark, found to be eating more red cod in TBGB_AM and less demersal fish and invert commercial scavengers than in TBGB_EwE.

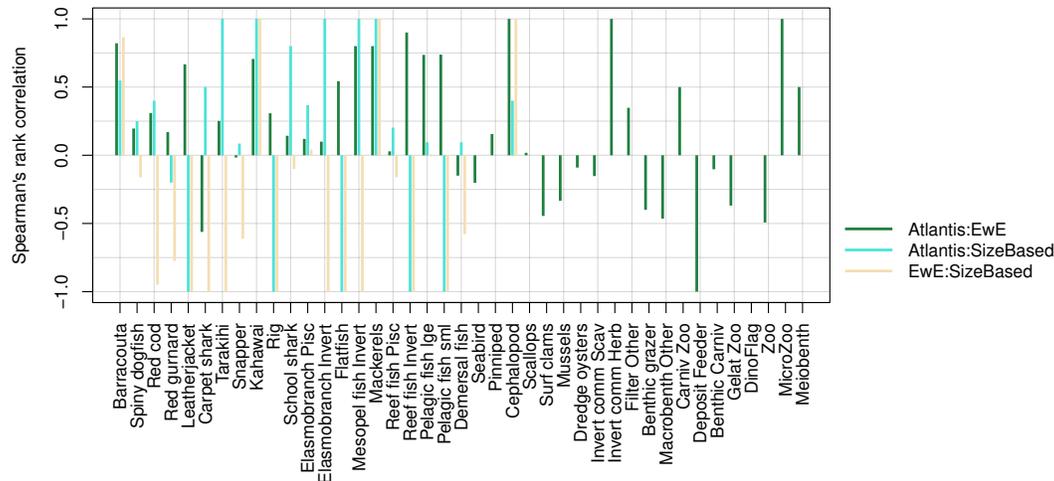

Figure 12: Spearman's rank correlation comparing realised diets from TBGB_AM with TBGB_EwE (dark green bars); TBGB_AM with TBGB_SS (aqua bars) and TBGB_EwE with TBGB_SS (beige bars). Diets with zero overlap were assigned a value of -1.

9.2 Trophic level

We compared trophic levels calculated from realised diets for TBGB_AM and TBGB_EwE. We did not calculate trophic levels for TBGB_SS due to the differences in diets, the limited number of species groups modelled, and the focus of the size-structured model on animals progressing through the trophic levels as they grow. While the latter is somewhat applicable to the Atlantis model as prey preferences are separately defined for juveniles and adults, and spatial, temporal, habitat and gape sizes allow for further differences in diet between age-classes, the coarse scale of up to 10 age-classes for each species group makes the realised diets and hence trophic levels more comparable with the EwE model. Nonetheless, there were some systemic differences in trophic level between TBGB_AM and TBGB_EwE, such as the higher trophic levels generally presenting with inflated trophic levels in the Atlantis model. For example, elasmobranch piscivores have trophic level 5.5 in TBGB_AM and 4.8 in TBGB_EwE. The difference seems to be largely due to the fairly high presence of macrobenth other in the TBGB_EwE diet that is not apparent in TBGB_AM. School shark also have a higher trophic level in TBGB_AM at 5.5 compared to 5.1 in TBGB_EwE, and this is likely due to larger proportions of cephalopods and gelatinous zooplankton in the TBGB_EwE diet, and the higher proportions of barracouta and mackerels in the TBGB_AM school shark diet. There is also a difference for bacteria as it was categorised as a predator in TBGB_EwE, but not in TBGB_AM in which we have given it a nominal close-to-zero trophic level of 0.01.

641 Bacteria are consumed in TBGB_AM, but not in TBGB_EwE, so the bacteria trophic
 642 level affected other trophic levels in TBGB_AM but not in TBGB_EwE.

643

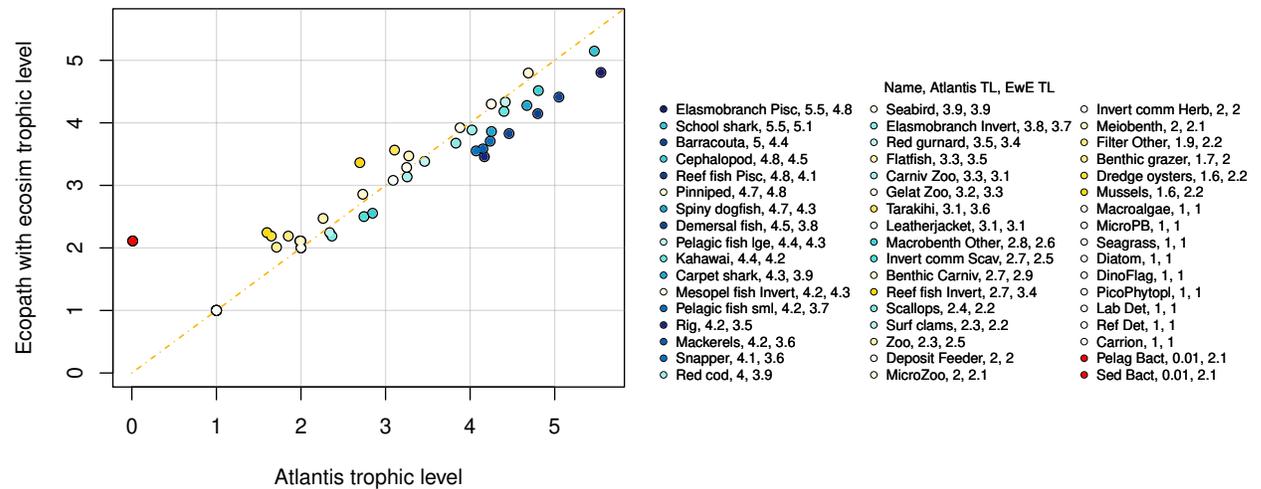

Figure 13: Trophic levels (TL) calculated from TBGB_AM (x-axis) and from TBGB_EwE (y-axis).

9.3 Responses to fishing

644

645 We forced historical fishing in all three models, then compared the resulting biomass
 646 trajectories. The overlaid figures are in Appendix I, and we have summarised the com-
 647 parisons using Pearson's correlation (Figure 14). Some of the species groups have very
 648 high (> 70%) correlation between all three models. These are elasmobranch inverti-
 649 vores, mackerels, mesopelagic fish invertivores, schools sharks, and spiny dogfish. There
 650 were no strong negative correlations between TBGB_EwE and TBGB_SS, but seven of
 651 the species groups had negative correlations of more than 50% between TBGB_AM and
 652 either TBGB_EwE or TBGB_SS. These were barracouta, carpet shark, elasmobranch
 653 piscivores, red gurnard, inert comm herbivores, leatherjacket and tarakihi. The ways
 654 in which they were different varied. For example, barracouta decreased under fishing
 655 for both TBGB_EwE and TBGB_SS, but gave no response for TBGB_AM, which could
 656 be due to migration in the Atlantis model buffering the effects of fishing. Carpet shark
 657 had fluctuations in biomass from 1980 in TBGB_SS that don't correspond to the time
 658 of direct fishing, and were not present for TBGB_AM or TBGB_EwE. There was a simi-
 659 lar situation for elasmobranch piscivores, with more variation with respect to time in
 660 TBGB_SS than would be expected as direct fishing effects, and that were not present in
 661 TBGB_AM or TBGB_EwE. Red gurnard increased during the period of heaviest fishing

662 in TBGB_AM, then declined under lighter fishing that followed, whereas the responses
 663 in TBGB_AM and TBGB_SS were more indicative of direct fishing effects as the biomass
 664 declined under heavy fishing then recovered under light fishing. Invert comm herbivores
 665 decreased briefly in years with higher catches in TBGB_AM, with quick recoveries,
 666 but gave no response to fishing in TBGB_EwE, and were not included in TBGB_SS.
 667 Leatherjacket had a slightly decreasing biomass trend in TBGB_SS and TBGB_EwE, but
 668 remained flat for TBGB_AM. Tarakihi declined under the heaviest fishing in TBGB_SS
 669 and TBGB_EwE and recovered under lighter fishing, while in TBGB_AM the biomass
 670 signal was almost opposite.

671

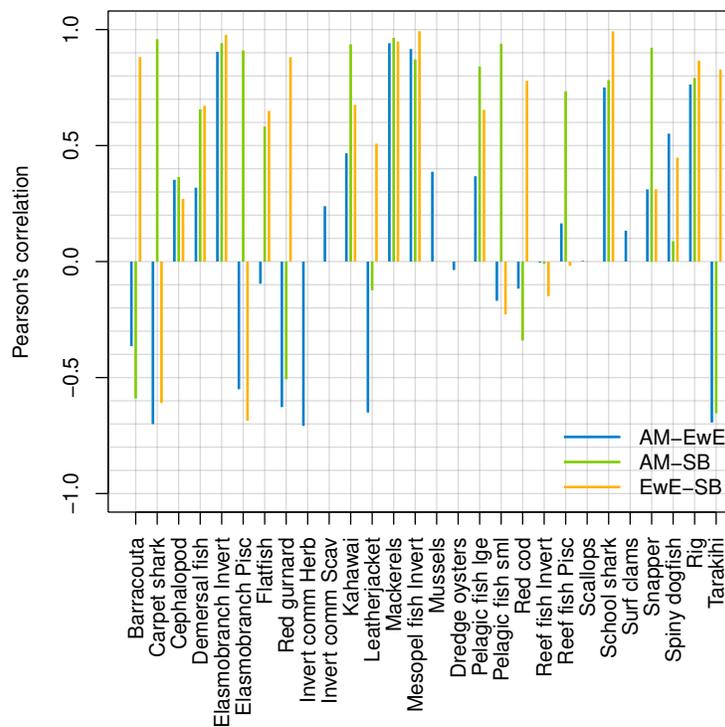

Figure 14: Pearson's correlation between model simulations in response to forced historical fishing.

672 9.4 Diversity

673 We calculated the modified version of Kempton's Q diversity index, as available in EwE
 674 (Christensen, 2009) to all three models. The response to historical fishing at the di-
 675 versity level was very similar between TBGBG_AM and TBGB_EwE, but different in
 676 TBGB_SS (Figure 15). All three models signal a decline in diversity under fishing, but
 677 whereas there is only a decline in TBGB_SS, both TBGB_AM and TBGB_EwE show

678 an initial increase in diversity under fishing which was then followed by a decline from
 679 the mid-late 1980s.

680

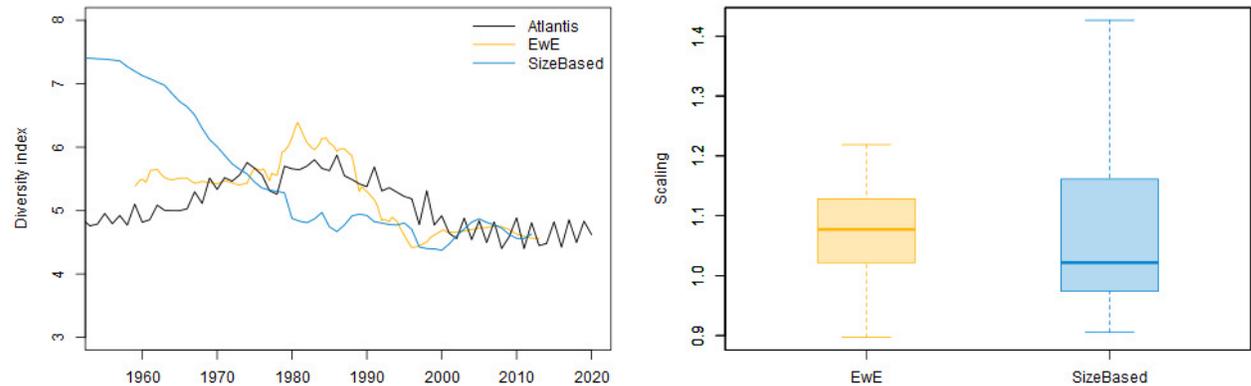

Figure 15: Diversity index for TBGB_AM (black line), TBGB_EwE (gold line) and TBGB_SS (blue line), scaled to the same mean (A) and scaling ranges given by TBGB_EwE diversity/TBGB_AM diversity (gold) and TBGB_SS diversity/TBGB_AM diversity (blue) (B).

681 10 Discussion

682 Key to this work, is to what degree the three developed ecosystem models of the TBGB
 683 ecosystem agree, and to what end they might be useful. Both of the terms ‘agree’ and
 684 ‘useful’ are open to interpretation. Testing for agreement between the models has been
 685 carried out in this study with respect to dynamics at the species group level, such as
 686 diets and growth rates, and with respect to dynamics at the system level such as trophic
 687 level and diversity. We will discuss model usefulness based on limitations due to model
 688 structure, intended purpose of the respective modelling frameworks, and concerns that
 689 have arisen through model validation and comparison carried out here.

690

691 At the species group level, diets could be compared across all three models, although
 692 they reflect slightly different aspects of the modelled dynamics. The TBGB_EwE diets
 693 were relatively unchanged from the input diets; although they underwent some adjust-
 694 ments during calibration, they cannot really be considered an output of the model.
 695 The size-structured model has far greater emphasis on diets of species when they are
 696 very small and only eat phyto- or zoo-plankton, or slightly bigger and eating small

697 pelagic fishes, and these aspects of life history are not included in the other two models.
698 TBGB_AM has species recruited to the model as juveniles into the youngest age-class,
699 but they could be several years old upon entering the model depending on the lifespan
700 of the species, due to the equal sized age-classes. TBGB_EwE doesn't model indi-
701 viduals, and has no age-structure, but diets have been defined to assume the species
702 group biomass pools resemble those corresponding to adult and juveniles combined in
703 the TBGB_AM. TBGB_AM diets are perhaps the most reflective of model dynamics,
704 as they are the result of spatial, temporal, growth, gape-size, life-stage, competition,
705 prey availability dynamics as well as prey preferences. The vertebrate species groups
706 generally had good diet correlation between TBGB_EwE and TBGB_AM. Interestingly,
707 this doesn't seem to have helped for the keystone analyses, which we would expect to
708 be linked with diets. Some of the vertebrate species groups had almost reverse keystone
709 rankings in the two models. Pelagic fish large and elasmobranch invertivores were both
710 high in one model and low in the other and both had positively correlated diets, pelagic
711 fish large over 50% correlation. Both also had very similar trophic levels.

712
713 That the diversity responses to historical fishing pressure were similar in TBGB_EwE
714 and TBGB_AM suggests these models have captured similar system-level dynamics. It
715 would be interesting to explore this further by projecting both models into the future
716 with varying catch levels, perhaps focused on subsets of the system. This activity might
717 also help us understand the difference in diversity under fishing for TBGB_SS. The end
718 result of reduced diversity was consistent across all three models, but the absence of an
719 initial increase in diversity in the size-structured model remains a mystery. Typically,
720 size-spectrum indicators relate to size (e.g. mean length, maximum length, proportion
721 of large fish) (Shin et al., 2005; Blanchard et al., 2014). There do not appear to be ex-
722 amples of calculating a diversity index such as Kempton's Q from size-spectrum models.

723
724 Varying the oceanographic variables through sampling ROMS years or repeating
725 a single ROMS year introduced greater variability in the model results than perturb-
726 ing the initial conditions. This suggests careful consideration needs to be made into
727 the forcing of the oceanographic variables for this Atlantis model. It may be helpful
728 to extend the ROMS model so a longer timeseries of forcing oceanographic variables
729 can be used. It also raises the question of possible effects from varying temperature
730 and perhaps productivity in TBGB_EwE to compare responses and flow-on effects. All
731 of these aspects will be important to consider for climate change scenarios. Climate
732 change scenarios are often driven through the oceanography, and how we apply this

733 is likely to be influential on results. While environmental effects can be simulated in
734 TBGB_EwE, changes in environmental variables would need to use proxies, such as
735 changes in primary productivity (e.g. Niiranen et al. (2013), Hoover et al. (2013)).
736 Climate change scenarios are less likely to be explored using TBGB_SS due to limited
737 scope for including oceanographic changes in this model, and the limited species groups.

738
739 As TBGB_AM is the most complete representation of the system out of the three
740 models developed here, there are unlikely to be scenarios that can be explored in one of
741 the alternative models but not in TBGB_AM. There may, however, be scenarios where
742 it makes more sense to explore in one of the simpler models due to shorter run-times
743 and ease of use. Especially if we were to transfer the EwE model to an R version using
744 *Rpath*. We could then load many simulations exploring fishing and climate change into
745 the future, and evaluate system-wide responses. We could use these results to define a
746 suitable subset of the scenarios to run in Atlantis.
