Abstract

The Tasman and Golden Bays (TBGB) are a semi-enclosed embayment system in New Zealand that supports numerous commercial and recreational activities. We present three ecosystem models of the TBGB ecosystem with varying levels of complexity, aimed at contributing as tools to aid in understanding this ecosystem and its responses to anthropogenic and natural pressures. We present data compilation through to model validation and analyse knowledge gaps with respect to model dynamics and results. We compare responses in all three models to historical fishing, and analyse similarities and differences in the dynamics of the three models. We assessed the most complex of the models against initialisation uncertainty and sensitivity to oceanographic variability and found it most sensitive to the latter. We recommend that scenarios relating to ecosystem dynamics of the TBGB ecosystem include sensitivities, especially oceanographic uncertainty, and compare responses across all three models where it is possible to do so.

1 Introduction

End-to-end ecosystem models which can deal with bottom-up and top-down system controls have become popular for exploring scenarios involving human induced impacts including fishing and climate change (Rose, 2012). These models can be included as useful tools in providing a holistic approach to understanding system-wide repercussions of how we manage our marine resources (McGregor et al. 2019, Smith et al. 2017, Stecken and Failler 2016).

The Tasman and Golden Bays (TBGB) is an appropriate focal area for Ecosystem Based Management as it supports a diverse range of marine, land and human activities, with economic, social and customary value (Sustainable Seas, 2019). The TBGB ecosystem is a relatively shallow semi-enclosed embayment system at the north of South Island, New Zealand (Figure 1) and is the focal area for the national science challenge Sustainable Seas, aimed at developing tools and approaches for ecosystem based management. Strong ocean currents enter the system from the Tasman sea bringing with them cold, nutrient-rich waters, which make the area highly productive (Chiswell et al., 2019). TBGB has large sheltered areas which are home to a diverse array of habitats including large seagrass beds, rocky reefs and large sandy outcrops, which support a rangewide variety of species, from small reef bound species to large migrating pelagic species (Handley, 2006; Stevenson and MacGibbon, 2018).

TBGB supports numerous commercial fisheries (for finfish and invertebrates), an active recreational fishery (Fisheries New Zealand, 2020), and marine farming activities (Handley, 2006). The area is a popular destination for tourists, for example the Abel Tasman National

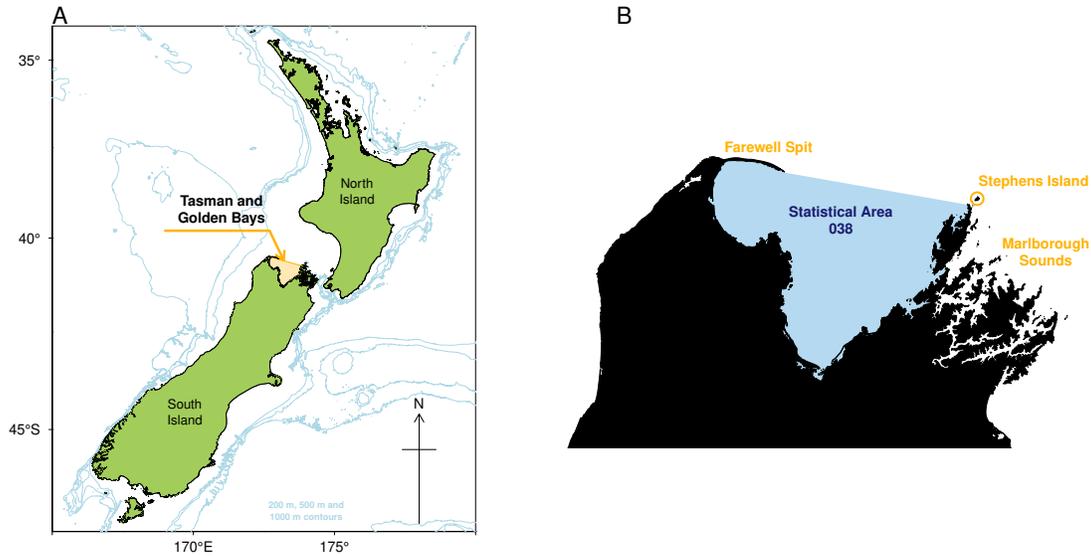

Figure 1: Map of New Zealand with Tasman and Golden Bays marked and shaded orange, including 200 m, 500 m, and 1000 m isobaths (A). Map of Tasman and Golden Bays with fisheries Statistical Area 038 (blue shaded) and Farewell Spit, Stephens Island and Marlborough Sounds (orange labels) (B).

55 Park is particularly popular for hiking, camping and water sports. Much of the land surround-
 56 ing the bays has been modified by horticulture, forestry, and residential development.

57
 58 Studies of the TBGB ecosystem include trawl surveys (MacGibbon and Stevenson, 2013;
 59 Stevenson and MacGibbon, 2018), fishery characterisations and stock assessments (Starr and
 60 Kendrick, 2017a,b; Parsons et al., 2018; Langley, 2018; Williams et al., 2014), bioregionalisation
 61 (Handley et al., 2018), habitat and fishing effects (Handley et al., 2014), oceanography from
 62 observations and modelling (Chiswell et al., 2019), benthos and anthropogenic effects (Handley,
 63 2006), sedimentation (van der Linden, 1969), and tidal circulation (Tuckey et al., 2006).

64
 65 There are key ecological questions around historical shifts in the TBGB ecosystem. The
 66 bays used to support a large scallop fishery, but scallop recruitment has failed in recent years
 67 (Williams et al., 2014, 2015; Tuck et al., 2018). In a review of drivers of shellfish production,
 68 Michael et al. (2015) suggests food (primary production), suspended sediments and turbidity,
 69 changes to benthic communities and sediment, effects of fishing, and disease are all potential
 70 key drivers. There is also a large snapper fishery, which has experienced marked variations
 71 in productivity over time, and is currently producing relatively high catches (Langley, 2018).
 72 Snapper are known to be temperature dependent, with strong year classes found to be corre-
 73 lated with high sea surface temperature (SST), in particular high autumn SST (Francis, 1993).
 74

75 We have developed three ecosystem models as part of a tool-kit for exploring and under-
76 standing the TBGB ecosystem. Each model varies in complexity and scope, model development
77 and validation demands, and applicability to different types of questions or scenarios. Each
78 model developed has used a different framework: TBGB_AM uses Atlantis (Audzijonyte et al.,
79 2017, 2019; Pethybridge et al., 2019), TBGB_EwE uses Ecopath with Ecosim (EwE) (Chris-
80 tensen and Walters, 2004; Christensen et al., 2005), and TBGB_SS is a size spectrum ecological
81 model using the multispecies implementation of the R package *mizer* (Scott et al., 2014; Blan-
82 chard et al., 2014).

83
84 Atlantis has been reviewed as one of the best modelling frameworks for exploring ‘what-if’
85 type questions (Plagányi, 2007), and has many applications globally (Savina et al. 2005, Fulton
86 et al. 2007, Link et al. 2010, Ainsworth et al. 2015, Smith et al. 2015, Sturludottir et al. 2018,
87 Ortega-Cisneros et al. 2017, McGregor et al. 2019). As a full end-to-end ecosystem model, it is
88 capable of including bio-physical components of an ecosystem, species functional groups, fishing
89 fleet dynamics, social and economic dynamics (Audzijonyte et al., 2017, 2019). With sufficient
90 data, this modelling approach can be extremely useful for management strategy evaluation
91 (Plagányi, 2007).

92
93 An Atlantis model is developed using components relating to the bio-physical, ecological,
94 and human use aspects of an ecosystem. This component structure allows for additional dy-
95 namics to be added incrementally. Initially, the spatial and temporal structure are defined, and
96 the model oceanography is forced using outputs from an ocean physics model. Initial conditions
97 are defined for nutrients, and growth rates for bacteria, detritus and primary producers. Follow-
98 ing this, other species functional groups can be added, which is when the complexity escalates
99 due to many interacting dynamics such as diets, movement, habitat preferences, feedback in
100 the microbial loop, ages, size, and trophic structure. Atlantis is a deterministic simulation
101 model such that for a given parameter set and model specification, the model outputs are
102 identical. Atlantis models are too complex to statistically fit to observations, so we are reliant
103 on analysing and understanding the model dynamics to assess the suitability of the model for
104 exploring a given scenario, and to assess the reliability of scenario outcomes. Analysing and
105 understanding the model dynamics and potential weaknesses is essential before the model can
106 be used to learn about the system.

107
108 EwE is trophodynamic modelling software which uses a mass-balance approach to describe
109 ecosystem based, marine food web interactions (Christensen and Walters, 2004; Christensen
110 et al., 2005). EwE works sequentially, where first an Ecopath model is populated and balanced
111 at a specified point in time, then Ecosim is used to simulate the model through time (Walters
112 et al., 1997). The Ecopath model is balanced by assuming that the energy removed from each
113 species group, through fishing or predation, for example, must be balanced with the energy

114 consumed by that group (Christensen and Pauly, 1992). Ecosim is then added to dynamically
115 simulate ecosystem-based changes over time. Ecosim uses foraging arena theory (Walters and
116 Juanes, 1993), which assumes only a portion of the prey biomass is available to the predators.
117 This partitioning of prey resources can be used as a proxy for spatial dynamics, and also has
118 a stabilizing effect on ecosystem dynamics through providing refuge to prey groups (Walters
119 et al., 1997). EwE models can be used for exploring impacts of fishing in conjunction with envi-
120 ronmental shifts or trends, and for exploring optimal fishing policies (Christensen and Walters,
121 2004). EwE models have more recently been used to produce time-series predation mortality
122 for use in single-species stock assessment (Bentley et al., 2019).

123
124 The multi-species size spectrum model specifies individual traits for each species group, and
125 also utilizes the size spectrum model for predator-prey interactions. Prey selection is a func-
126 tion of predator size, prey size, and the prey-species preference for a given predator. With this
127 model, we can predict species' size distributions, abundance, productivity and predator-prey
128 interactions. Hence, it is possible to evaluate trade-offs based on responses in community and
129 foodweb structure, population status, diversity, and fisheries yield (Blanchard et al., 2014).
130 The possible trade-offs that we can explore with this model are limited to fishing effects such
131 as focusing fishing effort on different parts of the system, and basic environmental effects such
132 as variations in primary productivity.

133
134 In this paper, we describe and evaluate TBGB_AM, which is the first end-to-end ecosystem
135 model for the Tasman and Golden Bays, New Zealand, as well as the two alternative ecosystem
136 models; TBGB_EwE and TBGB_SS. We present analyses of the models, comparing both state
137 and dynamics to each other and to current knowledge, and make recommendations on the
138 appropriate use of each model.

139

140 2 Methodological Approach

141 Model development primarily focused on the Atlantis model for the TBGB ecosystem. The
142 alternative models using the Ecopath with Ecosim (EwE) and multi-species size-structured
143 model frameworks were developed as simplifications of TBGB_AM, and have been assessed
144 with respect to TBGB_AM where it was possible to do so. TBGB_AM has been tested with
145 respect to initialisation uncertainty, realised growth and mortality rates, variability from the
146 assumed oceanographic variables, and connectivity analysis following the methods of McGregor
147 et al. (2019, 2020). All three models and associated R scripts are available on Github McGregor
148 (2019).

149

150 The process of developing these models was not linear, but rather iterative and incremen-
151 tal. There were six main stages to the development, each of which was re-visited until we were

152 satisfied with the performance of the models and our understanding of their dynamics. The
153 main stages can be summarised as:

- 154 1.) Model design: data and model inputs were collated and defined and the base TBGB_AM
155 developed.
- 156 2.) Alternative models: two alternative ecosystem models were developed; one size-structured
157 and one Ecopath with Ecosim.
- 158 3.) Calibration: the base historical TBGB_AM was calibrated without fishing such that this
159 model had stable biomass trajectories over the 1900–2016 model period, realistic diets, growth
160 rates, natural mortalities, with these compared to the alternative models where appropriate.
- 161 4.) Sensitivity analyses: TBGB_AM was tested for sensitivity to uncertainty in the initial
162 conditions and oceanographic variables. Simulations were explored aimed at understanding
163 connectivity and influence between the species groups.
- 164 5.) Fishing: historical fishing was included in all three models using forced catch removals.
- 165 6.) Skill assessment: comparisons to abundance indices and biomass estimates were carried
166 out for all models, including between-model comparisons.

167
168 Sections 3–8 cover each of these six main stages, followed by Section 9: Bringing it together,
169 compares the performance and dynamics as they relate to the three models.

171 3 Model design

172 An Atlantis model is developed as components relating to the physical, biological, ecological,
173 and fishing components of a marine ecosystem. It uses these components to simulate the ecosys-
174 tem through time, calculating each new state based on the previous state and the events of the
175 current timestep (McGregor et al., 2019). This section is structured similarly, and describes
176 the physical, biological, ecological, and fishing components of TBGB_AM. Further details on
177 Atlantis can be found in the Atlantis user manual (Audzijonyte et al., 2017).

179 3.1 Model area

180 The TBGB area comprises waters in Tasman and Golden Bays, at the northern end of South
181 Island, New Zealand (Figure 1). The area is bounded in the north by a line connecting the
182 eastern tip of Farewell Spit and Stephens Island at the northern extreme of the Marlborough
183 Sounds, and by the coastal margin within the bays (but excluding estuaries and Croisilles
184 Harbour). It equates to Statistical Area 038, one of many areas used to define the location of
185 commercial fish catches in the New Zealand EEZ (Mackay et al., 2005).

186
187 An Atlantis model is defined spatially using polygons and depth layers, with each poly-

188 gon/depth layer referred to as a cell. The intention of the splits is to capture important aspects
 189 of the region but at a simplified level such that modelling the region over many years becomes
 190 possible (i.e. balancing detail with computational efficiency). The modelled area was divided
 191 into 25 polygons (Figure 2), which represent the main physical and biochemical structure of
 192 the ecosystem (Handley et al., 2018) and the historical footprint of fishing activity (Figure
 193 2). There is one additional boundary polygon which flanks the northern boundary and allows
 194 for the exchange of water, nutrients and biota from the dynamic model domain. All model
 195 polygons were further divided into water column depth layers, ranging from one layer in some
 196 nearshore polygons to five layers for the deepest polygons. The defined depth layers are shown
 197 in Figure 2. In addition to the water column layers, each polygon contains one epibenthic and
 198 one sediment layer.

199

3.2 Time

201

202

203

204

205

206

207

An Atlantis model is run with a burn-in period followed by a model period. The purpose of the burn-in period is to allow initial fluctuations resulting from the initial state of the model to stabilise (McGregor et al., 2020). TBGB_AM consists of a 35-year burn-in period (1865–1899), followed by a model period from 1900 to 2014 (inclusive). All results presented here are from the model period 1900–2014. The model used 12 hour timesteps to allow for changes in temperature, light and feeding patterns between night and day.

3.3 Oceanography

Salinity, temperature and water exchange between cells were forced in TBGB_AM using outputs from a ROMS (Regional Oceanographic Modelling System) model that covered six years 2008–2013 (inclusive) (Chiswell et al., 2019). Water flows across each cell face cause the movement of nutrients (such as ammonia and nitrate) available to primary producers. The speed and direction of currents influence the spatial distribution of plankton groups. Water temperatures influence biological processes such as respiration (Hoegh-Guldberg and Bruno, 2010) (for more details, see Supplementary A). The base TBGB_AM presented here repeated the available ROMS variables as a six-year cycle. Averaging the ROMS variables across these years was not considered as this could result in implausible physical dynamics, especially with respect to water movement between cells. We ran sensitivities varying the order of ROMS years or repeating one ROMS year to help understand the effects of inter-annual oceanographic variability on this model, following the methods applied in McGregor et al. (2019).

3.4 Species groups

TBGB_AM uses 51 species groups to model the biological processes. Species groups were defined based on broadly similar form, habitat, and diet. Of these 51 groups, 12 vertebrates, two invertebrates, and one algae comprise single species; all other groups comprised two or more species. The single-species groups are either highly abundant (such as barracouta or seagrass), very distinctive (like fur seals), or for which there are key ecological questions that may require investigation on their own (like snapper and scallops). The main component species of the groups are shown in Tables 1–4. Species group names are intended to be informative but not necessarily restrictive. For example, an ‘invertivores’ species group would eat primarily invertebrates, but may also consume a small proportion of vertebrate prey. Species groups modelled with age-structure (all vertebrates and 5 invertebrate species groups) were modelled using 10 age-classes, with the average expected lifespan of each group split equally into these age-classes. Within each age class, numbers of animals and average weights were tracked. Weights of animal were tracked as mg N, which was split into structural (S_N) and reserve (R_N) components following the definition in Broekhuizen et al. (1994) where reserve weight is the part that can be used during periods of starvation, which includes flesh, fat, reproductive components and other soft tissue. Primary producers and remaining invertebrate groups were modelled as biomass pools (mg N m^{-3}) with no age-structure. Weights and biomass-pools were tracked in mg N as nitrogen is the currency used to track the transfer of energy in Atlantis models (Audzijonyte et al., 2017). Initial conditions for the species groups were estimated or inferred depending on data and information available. Details on the species groups initial conditions and biological parameters are in Supplementary B.

Table 1: List of vertebrate species groups for TBGB-AM. Names in bold at the start of each multispecies group indicates the most dominant species in that group, and it is the species from which productivity parameters for that group were derived. Lifespan is the assumed maximum number of years an individual in that group may live. Ben, benthic; invert, invertivore; lrg, large; mesopel, mesopelagic; pisc, piscivore; sml, small.

| Species group | Main species | Lifespan (years) |
|---------------------|---|------------------|
| Barracouta | Barracouta | 10 |
| Carpet shark | Carpet shark | 20 |
| Demersal fish | Giant stargazer , Ling, Yellow-eyed mullet, Sea perch, Rattails, Grey mullet, Silver dory, Lookdown dory, Northern bastard cod, Goatfish, Scaly gurnard, Pigfish, Spotted stargazer, Two saddle rattail, Oblique banded rattail, Opalfish, Brown stargazer, Cucumber fish, Swollenhead conger, Giant boarfish, Capro dory, Silverside, Globefish | 20 |
| Elasmobranch invert | Rough skate , Skates undefined, Dark ghost shark, Smooth skate, Other sharks and dogfish, Elephant fish, Eagle ray, Stingray, Short-tailed black ray | 10 |
| Elasmobranch pisc | Thresher shark , Electric ray, Seal shark, Seven-gilled shark, Bronze whaler shark, Blue shark, Mako shark, Sharks undefined | 20 |
| Flatfish | Sand flounder , Greenback flounder, Lemon sole, New Zealand sole, Yellow-belly flounder, Witch, Black flounder, Turbot, Brill, Speckled sole | 5 |
| Kahawai | Kahawai | 30 |
| Leatherjacket | Leatherjacket | 5 |
| Mackerels | Jack mackerel (Yellow-tail) , Jack mackerel (Greenback), Jack mackerel (Peruvian), Blue mackerel | 20 |
| Mesopel fish invert | Blue warehou , Silver warehou, Bluenose | 20 |
| Pelagic fish lge | Trevally , Albacore, Hoki, Hake, Porcupine fish, Kingfish, Frostfish, Gemfish, Sunfish, Skipjack tuna, Oilfish, Southern boarfish, Ray's bream | 50 |
| Pelagic fish sml | Pilchard , Redbait, Anchovy, Garfish, Sprats, Whitebait, Ahuru | 10 |
| Pinniped | Fur seals | 20 |
| Red gurnard | Red gurnard | 20 |
| Red cod | Red cod | 5 |
| Reef fish invert | Butterfish , Blue moki, Marblefish, Trumpeter, Banded wrasse, Scarlet wrasse, Wrasse (undefined), Red moki, Copper moki, Seahorse, Spotty, Porae, Long-finned boarfish, Spiny seadragon, Southern bastard cod | 10 |
| Reef fish pisc | John dory , Blue cod, Conger eel, Hapuku, Hagfish | 10 |
| Rig | Rig | 20 |
| School shark | School shark | 50 |
| Seabird | Seabirds, shorebirds, & black swans | 20 |

| | | |
|------------------------|-------------------------------|----|
| Snapper | Snapper | 50 |
| Southern spiny dogfish | Southern spiny dogfish | 30 |
| Tarakihi | Tarakihi | 40 |

Table 2: List of invertebrate species groups for TBGB_AM. Description includes main species. Lifespan is the maximum number of years an individual in that group may live. Those groups with no value for lifespan are modelled as biomass pools and hence do not have a lifespan defined as this is only relevant when modelling numbers. Carniv, carivore; Invert comm, commercial invertebrates; herb, herbivore; scav, scavenger; Macro-benth, macrozoobenthos; Meiobenth, meiobenthos; Zoo, zooplankton.

| Species group | Description | Lifespan (years) |
|----------------------|---|-------------------------|
| Benthic Carniv | Some gastropod molluscs, polychaetes & crustaceans | |
| Benthic grazer | Benthic animals that consume diatoms and sea grass | |
| Carniv Zoo | Planktonic animals (size 2–20 cm) | |
| Cephalopod | Arrow squid , Octopus, Broad squid | 2 |
| Deposit feeder | Detritivores, e.g., some gastropod molluscs, polychaetes, echinoderms (including holothurians) & crustaceans | |
| Dredge oysters | Dredge oyster | 4 |
| Filter other | Non-commercial benthic filter feeders, e.g., sponges, bryozoans, ascidians, turbellarians, bivalves, hydroids | |
| Gelat Zoo | Salps, ctenophores, jellyfish | |
| Invert comm Herb | Paua , Kina | 6 |
| Invert comm Scav | Rock lobster , Paddle crab, Whelks, Sea cucumber | 8 |
| Macrobenth other | Non-commercial benthic organisms (size >1 mm), e.g., polychaetes, echinoderms, sea anemones, crustaceans | |
| Meiobenth | Benthic organisms (size 0.1–1 mm), e.g., nematodes, some small crustaceans | |
| MesoZoo | Planktonic animals (size 0.2–20 mm) | |
| MicroZoo | Heterotrophic plankton (size 20–200 μm) | |
| Mussels | Greenlip mussel , Horse mussel | 2 |
| Scallops | Scallop | 2 |
| Surf clams | Cockle , King clam, Pacific oyster, Pipi, Mactra | 2 |

Table 3: List of phytoplankton and algae species groups for TBGB_AM.

| Species group | Description |
|----------------------|-------------------------------|
| Diatoms | Diatoms (large phytoplankton) |
| Macroalgae | Macroalgae |
| Microphytobenthos | Unicellular benthic algae |
| Pico-phytoplankton | Small phytoplankton |

Table 4: List of bacteria and detritus species groups for TBGB_AM.

| Species groups | Description |
|-----------------------|-------------------------|
| Carrion | Dead and decaying flesh |

| | |
|---------------------|---|
| Labile detritus | Organic matter that decomposes at a fast rate |
| Pelagic bacteria | Pelagic bacteria |
| Refractory detritus | Organic matter that decomposes at a slow rate |
| Sediment bacteria | Sediment bacteria |

3.5 Predation

Simulated predation was a four step process which occurred within each cell and at each timestep. From the predator's perspective the steps modelled (as summarised in McGregor et al. (2019)) are: 1.) Am I allowed to eat it? 2.) Is it in the same place at the same time as me? 3.) Does it fit in my mouth? 4.) How much can I eat? Full details are in the Atlantis User's Guide (Audzijonyte et al., 2017). Holling Type II functional feeding response was applied in step 4, which is a function of prey abundance, and predator search rate and handling time.

Diets of each species group were summarised using the same prey categories as in McGregor et al. (2019): Algae, Bacteria, Bird, Cetacea, Coelenterate, Crustacean, Detritus, Echinoderm, Elasmobranch, Microzooplankton, Mollusc, Phytoplankton, Polychaete, Teleost, and Tunicate (Figure 3). While this summary misses the temporal, spatial, age and size components of the predator-prey interactions, it is useful to check overall diets. For example, warehou (mesopel fish Invert) eat mostly salps (tunicates) as expected; school shark eat mostly fish as expected; flatfish (mostly flounder and sole) eat mostly benthic invertebrates; and invert comm herb (paua and kina) eat mostly algae. Trophic levels were calculated for each species based on their diets at the prey species group level, summarised over model space, time and species age-classes. The resulting trophic levels ranged from 1 for the primary producers through to 5.49 for elasmobranch piscivores (Figure 4). The trophic levels are generally higher than they should be which is due to combining juvenile and adult diets in the trophic level calculation. For example, elasmobranch piscivores predate on juvenile barracouta, but the contribution of barracouta to the trophic level of elasmobranch piscivore uses the trophic level of barracouta averaged over all age-classes, which will be higher than the juvenile trophic level. The effect is confounded throughout the foodweb, as barracouta adults (to continue with this example) also predate on juvenile pelagic fish large, which will artificially increase the trophic level of barracouta.

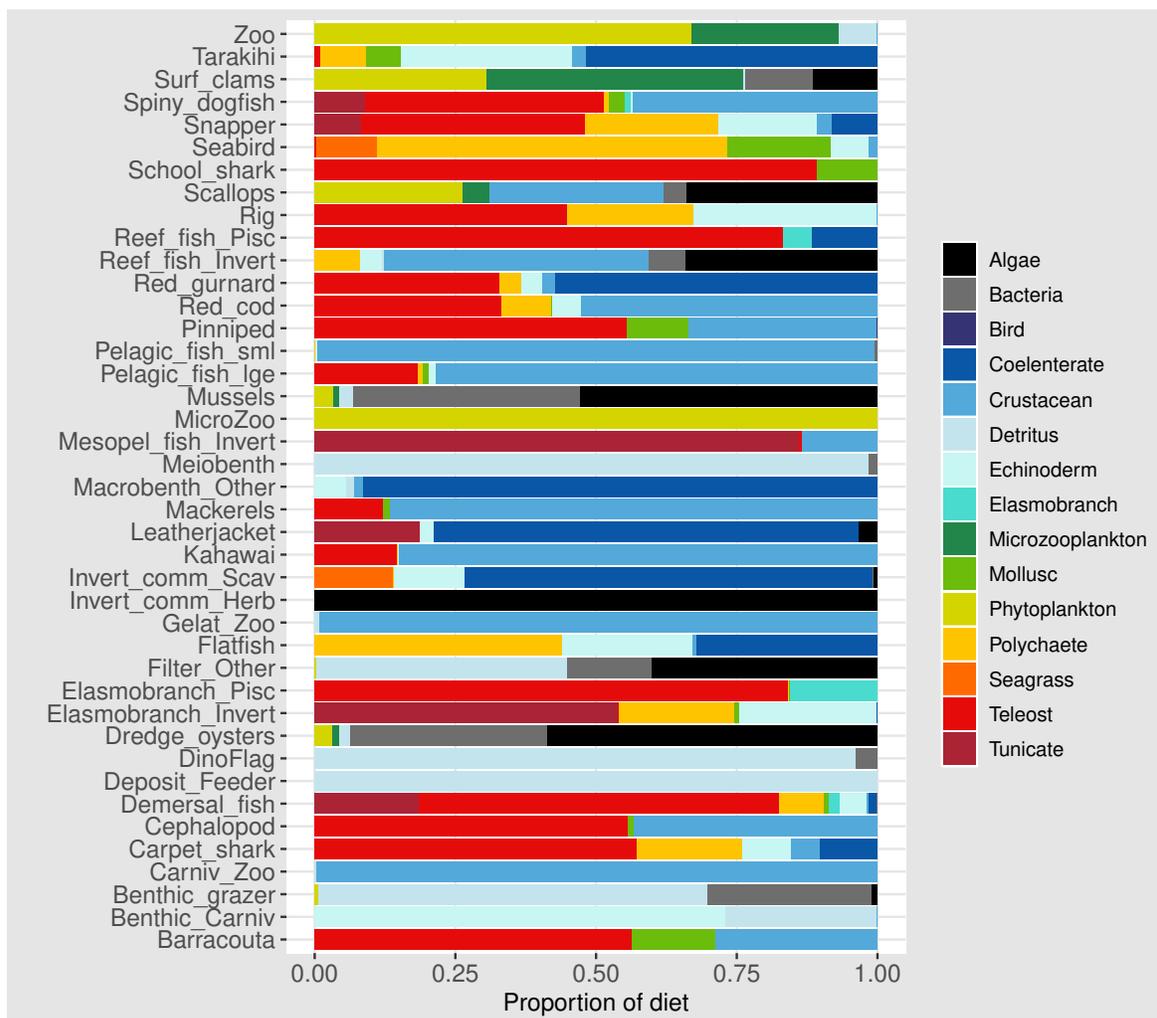

Figure 3: Summary of the proportion of prey groups in the diets of species groups (Tables 1 and 2) over model years 1900–2014 from the fished model where the proportion is by mg N consumed.

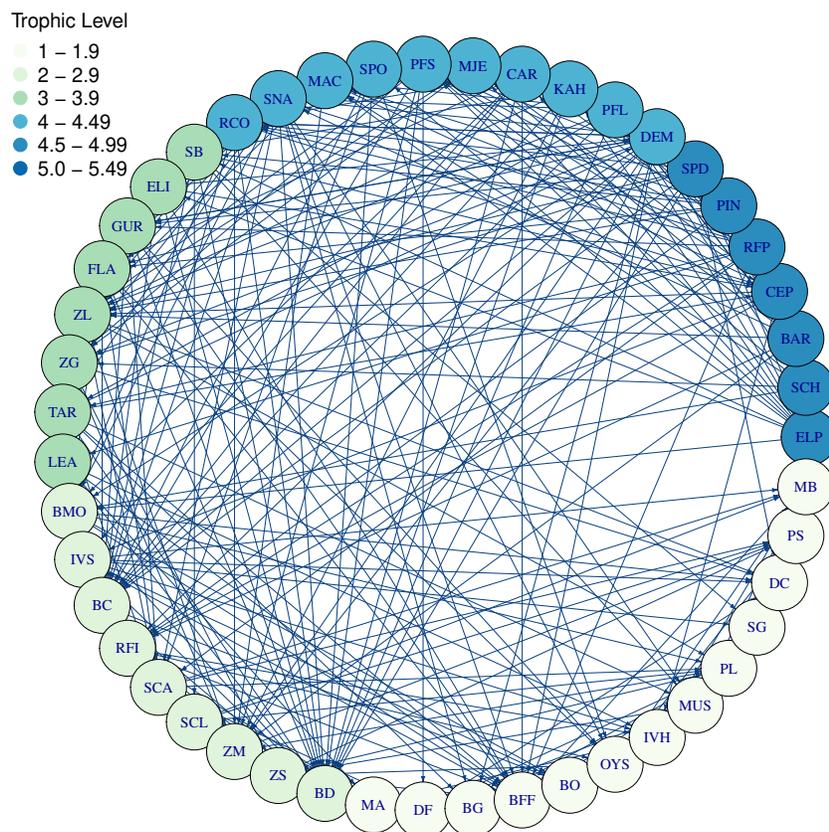

Figure 4: Foodweb coloured by trophic level from TBGB_AM diets summarised from the model simulation over years 1900–2014, from all model polygons and depth layers, and all species' age-classes. Species codes (3 or 2 letter) within the shaded circles identify the species functional groups (Tables 1–4). Lines connecting the shaded circles indicate predator/prey interactions. The colour of the shaded circle indicates the trophic level of each species group, with dark blue corresponding to the highest trophic level band (5–5.49), through to light cream corresponding to the lowest trophic level band (1–1.9).

4 Alternative models

The alternative models were developed as simplifications of TBGB_AM, although there are additional differences due to the structure of the respective frameworks.

4.1 TBGB_SS

The multi-species size spectrum model was constructed in R (R Core Team, 2020). The foundation for the work is the modelling framework *mizer* version 2.0.3, see Scott et al. (2014). This is available freely as an R package (Delius et al., 2020). For instructions on installing *mizer* and running models, see the *mizer* vignette (Delius et al., 2020). The earliest example of using *mizer* to model a multi-species system was by Blanchard et al. (2014), focusing on twelve common pelagic fish species in the North Sea.

As the first step of setting up the size spectrum model for TBGB, the species list was reduced to those for which a consensus was reached that they fed in a size-based way, and hence it was appropriate to use the size spectrum modelling framework to simulate their life processes. This meant not including the following species in the TBGB_SS model: fur seals, seabirds, benthic carnivores, benthic grazers, carnivorous zooplankton, detritivores, dredge oysters, benthic filter feeders, paua, rock lobster, benthic organisms, planktonic animals, heterotrophic plankton, greenlip mussels, scallops and cockles.

Seven parameters are needed as inputs to the size-structured model for each species. These include:

- the von Bertalanffy growth parameter k ;
- the allometric length-weight scaling multiplier a ;
- the allometric length-weight scaling exponent b ;
- the asymptotic body weight w_{inf} ;
- the maturity weight w_{mat} ;
- the preferred predator : prey mass ratio β ;
- the width of the feeding kernel σ .

The first five of these parameters are available directly from the Atlantis model. For the feeding parameters (β and σ) information was taken from the Atlantis model about the prey species of both adults and juveniles for each species. For the mass of the species doing the feeding, we used asymptotic mass for adults and maturity weight for juveniles. We then approximated the weight of the prey as half of the asymptotic mass

307 for the prey of adults, and half of the maturity weight for the prey of juveniles. We
308 then calculated the predator : prey mass ratio β by dividing the former by the latter
309 and taking the average over both juveniles and adults, and calculated the width of the
310 feeding kernel σ by taking the \log_{10} of the standard deviation of all the mass ratios.

311
312 Following this, we calculated the species interaction matrix. We used the spatial
313 overlap of species from the TBGB_AM to estimate the likelihood of interaction be-
314 tween three size combinations of predators and preys (adult predators - adult prey,
315 adult predators - juvenile prey and juvenile predators - juvenile prey), with the juvenile
316 predator - adult prey combination ignored. We then calculated the normalised (0 to
317 1) overall interaction for each species predator-prey pair using the average of the three
318 predator-prey size combinations.

319
320 Using the above parameters and interaction matrix with the software package *mizer*,
321 the following parameters were calculated for each species:

- 322 • $h_i(w)$, the maximum intake rate of an individual of species i and weight w ;
- 323 • γ_i , the search volume for species i at 1g weight;
- 324 • ks_i , a constant multiplier for metabolic rate.

325
326 Also, an extensive description of the default parameter values (where are challenging
327 to calculate empirically) is provided in (Delius et al., 2020). As part of the model set
328 up, the carrying capacity of the resource spectrum was reduced to 70% of that of the
329 North Sea model (Blanchard et al., 2014), as it was observed that feeding levels (even
330 for large individuals) in the TBGB model were too dependent upon the resource rather
331 than other species.

332
333 The final step for the model was to tune free parameters related to reproduction
334 (e_{repro} and R_{max}) to fit the unfished (virgin) biomasses of species to those generated in
335 the Atlantis model. The decision was taken to fix e_{repro} to 1 for all species, and modify
336 R_{max} for each species until a good fit was observed for all species biomasses. Pearson's
337 coefficient was used to measure closeness of fit between model biomasses and those of
338 the Atlantis model.

4.2 TBGB_EwE

TBGB_EwE was developed in two parts, a mass balanced model (Ecopath) and a simulation model (Ecosim). TBGB_EwE included the same 51 species functional groups used in TBGB_AM and were modelled as biomass pools (in t/km²). Diet and prey preferences, fishing mortality and initial conditions were all based on those used in TBGB_AM.

TBGB_EwE used a simpler spatial structure than that used for TBGB_AM, where all functional groups were assumed to inhabit the entire study area. The vulnerability of prey groups to predation and predatory searching rates was used as a proxy for the variability of preys and the different levels of interaction between species (predators and prey). Diet was also used as a proxy for spatial dynamics in terms of migration, where a proportion of the total diet could be apportioned to being outside the study area.

Realised diets in EwE rely on the assumption that what is consumption for one group is mortality for another. Ecotrophic efficiency is used as indication of how heavily a group is being preyed upon and whether enough individuals are available to die of old age. Diet must be input as the proportion of each prey group in a predator's diet. These proportions can be varied to allow for successful mass balance but builds basis of consumption rates and system dynamics. The relative proportion of prey groups in predator diets was different to those used in TBGB_AM, but since the dietary components remained the same, realised diets were comparable. The single biggest difference between the two diets related to modelling bacterial groups which affected the diets of those groups that consume bacteria.

Although it is possible to model age structure in EwE, this functionality was not used for TBGB_EwE, since interactions between adults and juveniles are not well simulated. For example, if there is less food for juveniles or more mortality (both resulting in less juvenile biomass) the adult population remains unaffected.

4.3 Comparison of alternative models

Table 5 presents key aspects of the alternative models as they compare to TBGB_AM. Neither of the alternative models developed have space explicitly defined. They do, however, both use an availability term which acts as a proxy for some spatial dynamics such as providing refuge from predators or fishing that might be expected from spatial separation. TBGB_SS sets an availability term for each pair of species groups that defines how much they are expected to spatially overlap. These were estimated using the

374 spatial overlap from the base TBGB_AM, averaged over the model years 1900–2014.
 375 These availabilities were not age- or size- structured, whereas the spatial distributions
 376 are in TBGB_AM.

377
 378 Species groups were another key difference. TBGB_EwE modelled the same 51
 379 species groups used in TBGB_AM, although as biomass pools (in t/km²) with no
 380 age structure. TBGB_SS modelled all 21 of the vertebrate species groups defined for
 381 TBGB_AM, as well as cephalopods. For these groups, the size-structured nature of this
 382 framework allows for variation in growth rates, diet and predation vulnerability through-
 383 out each groups' life span, from egg to adult. However, the size-structured model does
 384 not explicitly define or capture the dynamics of benthic invertebrate functional groups.

385
 386 Historical catches were forced in all three models, but in slightly different ways due
 387 to the structure of the models. TBGB_AM removed numbers of fish to match historical
 388 tonnes caught, and these were calculated within TBGB_AM based on the weights of
 389 individuals at each age class, with the total catch removed apportioned to age-classes
 390 based on selectivities defined by age-class. TBGB_EwE removed catches as biomass,
 391 and there was no age-structure, so no selectivities with respect to age or size were re-
 392 quired. TBGB_SS removed catches using an F time-series for each species group, which
 393 was based on estimates from TBGB_AM. TBGB_SS had knife-edge selectivity such that
 394 fish were only caught at or above the size at maturity.

395
 396 During model calibration, each of the models focused on different aspects of the
 397 model. TBGB_SS focused mostly on adjusting reproductive outputs for each species,
 398 and the planktonic primary production to achieve virgin biomasses matching those in
 399 the TBGB_AM model. TBGB_AM focused mostly on prey availabilities, and also ad-
 400 ditional (non predation) mortality for higher trophic levels. TBGB_EwE focused on
 401 balancing energy inputs (production) with outputs (consumption).

402

Table 5: Overview comparison of model structure for TBGB_AM (At-
 lantis model), TBGB_EwE (Ecopath with ecosim model) and TBGB_SS
 (size spectrum model).

| | TBGB_AM | TBGB_EwE | TBGB_SS |
|---------|--|--|---|
| Species | 51 groups; age-structured; individuals and biomass pools | 51 groups; no age-structure; biomass pools | 22 groups + primary producer; size-structure; individuals |
| Spatial | 25 dynamic polygons, 5 water column depth bins | Not spatial, availability term acts as proxy | Not spatial, availability term acts as proxy |

| | | | |
|---------------|--|---|---|
| Temporal | 12-hour time steps; adaptive time steps for high rate-of-change components such as nutrients; burn-in 1865–1900; model hindcast 1900–2014 | Annual timesteps; model hindcast 1959–2014 | 10 time steps per year; model hindcast; 1900–2014 |
| Predation | Prey availability matrix; spatial/temporal overlap; gape size; feeding dynamics (handling time, searching time, maximum growth, prey abundance); assimilation efficiency; habitat refuge | Prey availability matrix; habitat refuge | Prey availability matrix; size-based (similar to gape size) |
| Environmental | Forcing of sea temperature, salinity and flux; potential to force light, sediments, nutrients, and habitat | Potential to force as time-series e.g. changes in sea temperature or primary production | Potential to force changes in primary production |
| Fishing | Currently forced removals, defined by fleet, month, polygon, species functional group, and age-class; potential for effort-based; potential to link economic component | Forces using a time-series of fishing mortality F ; values from TBGB_AM outputs; defined by fleet and species group | Forces using a time-series of fishing mortality F ; values from TBGB_AM outputs; defined by species group |

5 Calibration

Calibration of TBGB_AM included ensuring stable biomass trajectories when applying no fishing; realistic realised diets; realistic growth and mortality (size-at-age and proportions-at-age), following the methods and recommendations of Pethybridge et al. (2019), and McGregor et al. (2019). Parameters tuned during calibration are listed in Supplementary J, and generally consisted of growth, mortality and predation parameters.

Biomass trajectories should reach a quasi-equilibrium when modelled with constant oceanography and no fishing (Kaplan and Marshall, 2016). While oceanography is not constant in our non-fishing model as it changes by year (Section 3.3), most of the age-structured groups should maintain their dynamic stability. For the TBGB_AM base model, all biomass trajectories remained within 20% of their coefficients of variation (CVs) over the simulated 1900–2014 model period. Biomass trajectories for all age-structured groups from the un-fished model are in Supplementary C.

Atlantis simulates growth rates of age-structured groups as a function of consumption. If growth is too slow, there may be insufficient food available, the feeding search rate could be too low or handling time too high, and the reverse of these when growth is too fast. In the TBGB_SS model growth is also a function of consumed prey, taking into account metabolism and movement (Scott et al., 2018). Allocation of consumed prey to reproduction is set such that growth approximates the von Bertalanffy curve at a constant feeding level (Hartvig et al., 2011). Simulated growth rates of age-structured species groups were assessed by comparing the simulated size-at-age with those expected based on growth curve estimates from the literature (Supplementary B), and those resulting from the size-spectrum model. The full growth curves are in Supplementary D, and summary figures of the maximum expected size for each species functional group (L_∞) are in Figure 5. We used the upper 90th percentile for weight, converted to length using the length-to-weight conversion parameters (Supplementary B), from TBGB_AM outputs from 1900–2014 as L_∞ , and the maximum size from the base un-fished model at equilibrium for TBGB_SS. While many were in line with the literature, both models generally produced smaller maximum sizes than what the literature suggests for the larger species such as elasmobranch piscivores and school sharks, and TBGB_AM generally produced larger than expected maximum sizes for smaller species groups such as pelagic fish small, cephalopods and mackerels.

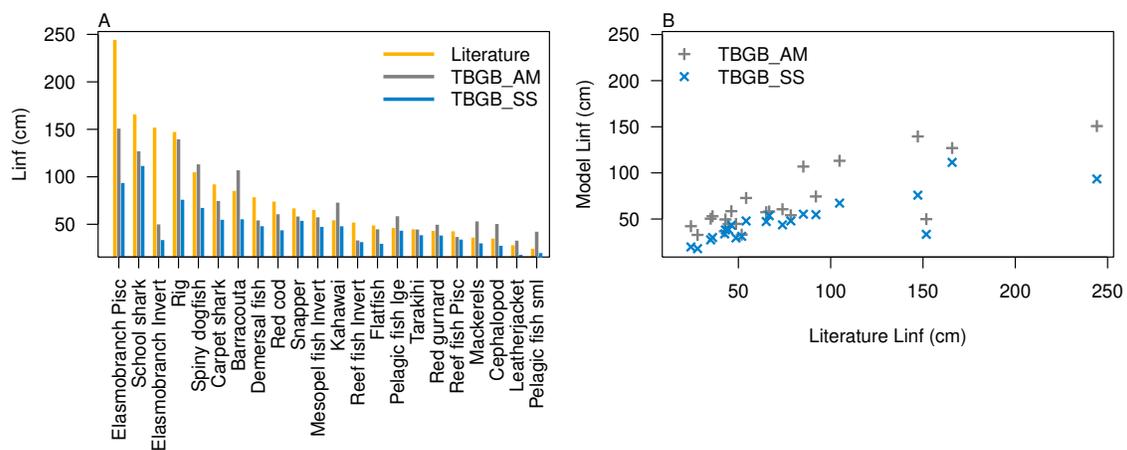

Figure 5: L_∞ from the literature (orange bars), TBGB_AM (grey bars) and TBGB_SS (blue bars) (A), and TBGB_AM L_∞ plotted against literature L_∞ (grey pluses) and TBGB_SS L_∞ plotted against literature L_∞ (blue crosses) (B).

438

439

In a closed system, natural mortality should ideally be entirely intrinsic within the

440 model (e.g. from predation, starvation, and light, oxygen or nutrient deprivation). As
441 this was not the case in TBGB_AM, additional mortality was applied for some species
442 groups to allow for natural mortality suffered either outside of the model domain, or not
443 captured by the model dynamics. Following the approach of McGregor et al. (2019), age-
444 structured simulated natural mortality rates from the stable base model were compared
445 to estimates of M from the literature where available (Supplementary B) by comparing
446 the proportions-at-age with the corresponding exponential decay curve. The overlaid
447 simulated and ‘observed’ were generally very similar (Supplementary E), although ka-
448 hawaii stood out as having less natural mortality in the model than the literature would
449 suggest, as did (although to a lesser extent) mesopelagic fish invertivores.

451 6 Sensitivity analyses

452 A sensitivity analysis of the TBGB_AM was carried out to assess the uncertainty of the
453 model inputs, the propagation of this uncertainty to the outputs and therefore its effects
454 on model performance. This analysis was performed on the following components of the
455 TBGB_AM

457 6.1 Initial conditions

458 Initial conditions were perturbed for TBGB_AM following the methods of McGregor
459 et al. (2020). The resulting simulations were then used for assessing responses of
460 TBGB_AM to historical fishing, thus allowing us to present these results as envelopes of
461 plausibility rather than single trajectories. The species groups with the largest between-
462 run CVs by the end of the simulation period (2000–2014) were generally lower in the
463 foodweb, such as zooplankton, deposit feeders and picophytobenthos (Figure 6). In
464 addition to these, scallops and flatfish also featured among those with high CVs, and
465 for both of these it was due to an apparently fine line between the stock crashing under
466 fishing pressure, or persisting (Figure 7).

468 6.2 Oceanographic variability

469 The effect of recycling oceanographic variable was assessed following the methods of
470 McGregor et al. (2019), which has two parts: 1.) establishing confidence intervals for
471 our model simulations with respect to oceanographic variability; 2.) assessing the effect

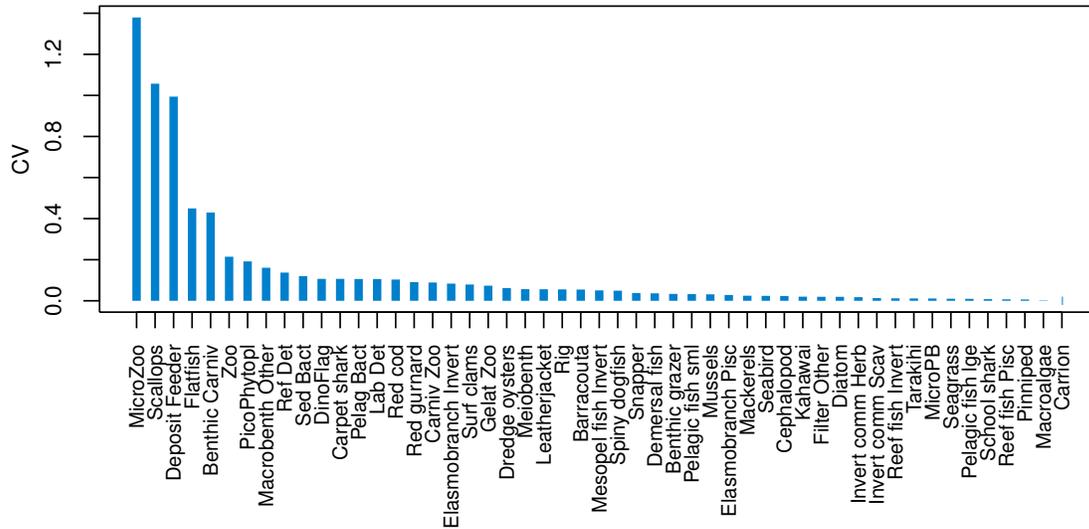

Figure 6: Between-run CVs from 2000–2014 that resulted from perturbing the initial conditions of TBGB_AM.

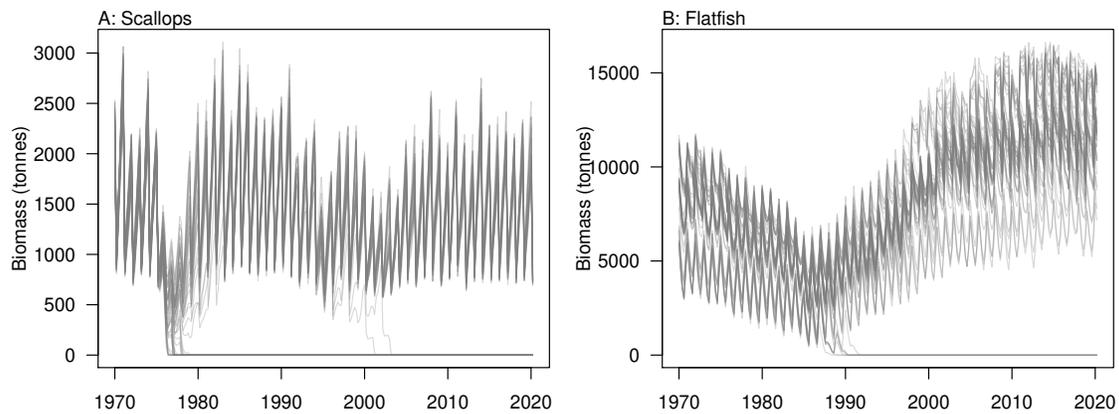

Figure 7: Simulated biomass trajectories from TBGB_AM under perturbed initial conditions for A: scallops and B: flatfish.

472 of repeating oceanographic variables from any one year, and whether these take the
 473 model outside of the established confidence intervals.

474

475 Part one sampled ROMS years at random with replacement for each model year
 476 simulated (bootstrapped the ROMS years) and repeated this for 50 model runs; part
 477 two repeated one ROMS year for all model years simulated and did a separate model
 478 run for each of the six ROMS years. In both cases, the 2008 ROMS was repeated for
 479 a 35-year burn-in period, followed by a 115 year simulation. The 2008 ROMS year was

480 chosen for the burn-in period as this year seemed to be representative of the means
 481 from all ROMS years for sea temperature and salinity when averaged over the model
 482 area. The full set of figures with temperature and salinity from each ROMS year,
 483 overlaid with averages from all ROMS years are in Supplementary A. Figure 8 shows
 484 the sum-of-squares between the values for each ROMS year and the average for salinity
 485 and temperature as well as the Pearson's correlations. The 2008 ROMS year had the
 486 lowest combined sum-of-squares, although correlation for salinity was not as high as the
 487 other years. Bootstrapping the ROMS years was used to establish confidence intervals
 488 with respect to between-year oceanographic variability. Repeating each ROMS year in
 489 turn was testing the effect of multiple years being different to the other years in some
 490 consistent way, such as cooler or warmer.

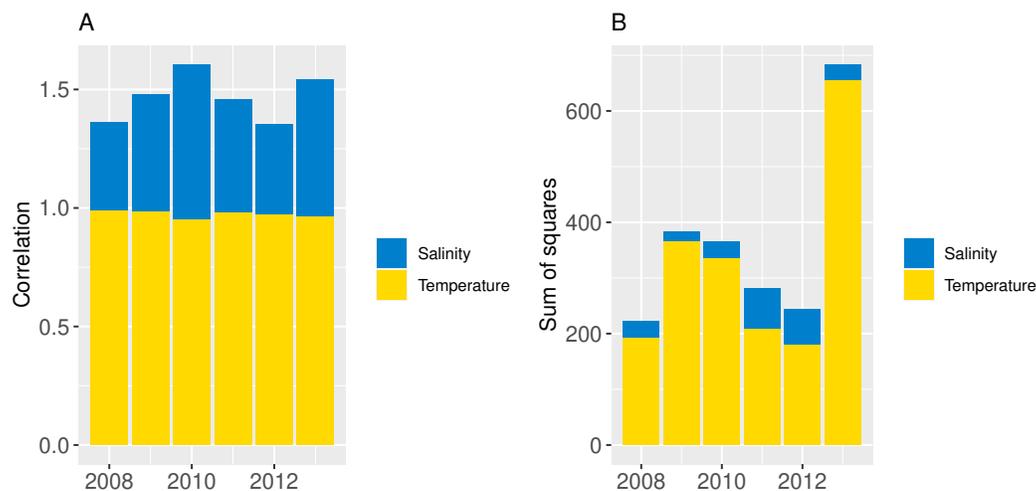

Figure 8: Correlation (A) and sum-of-squares (B) for salinity (blue) and sea temperature (yellow) variables for each ROMS year with respect to the relative averages from all ROMS years.

491
 492 The established biomass confidence intervals established from varying the oceanographic
 493 variables were fairly narrow for most species groups, with CVs < 10% (Figure
 494 9). Of the exceptions, micro-zooplankton had the highest CVs extending up to almost
 495 250%, followed by deposit feeders, benthic carnivores, meso-zooplankto, dinoflagelettes,
 496 and pico-phytoplanton. That these groups were found to be most sensitive to oceanographic
 497 variability in the model is a plausible and sensible result. When we compared
 498 the between-run CVs, we found these varied more than when sampling ROMS years
 499 randomly (Figure 9), suggesting strong effects from repeating the ROMS variables from
 500 any one year. Dinoflagelettes, seagrass and meiobenthos all had greater between-run

501 CVs from repeating ROMS years than from sampling ROMS years.

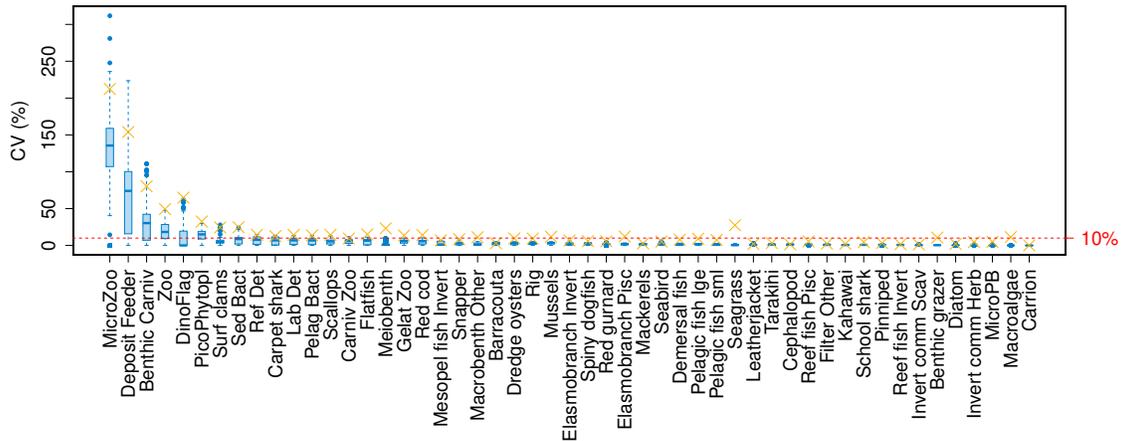

Figure 9: Between-run CVs for biomass output trajectories for each species group in TBGB_AM, from 50 model runs with ROMS years (2008–2013) sampled at random with replacement for each model year 1900–2014 (blue boxes) and upper 90% CIs for between-run CVs from repeating each ROMS year for the 1900–2014 model years (gold crosses).

502

503 6.3 Connectivity and influence

504

505 Understanding which species groups are most influential in the model is another test
 506 for realistic dynamics, and is another way we can compare the dynamics of the models.
 507 EwE models output several measures of keystoneity, with KS_3 recommended to be
 508 ‘best’ by Valls et al. (2015) following analyses of many variations on keystone ranking
 509 calculations. For TBGB_AM, we followed the simulation method applied in McGregor
 510 et al. (2019), but modified the keystoneity calculation to match that recommended in
 511 Valls et al. (2015) and applied in EwE (Equation 1). For the TBGB_AM simulations,
 512 we perturbed each species group in turn by adding additional natural mortality, then
 513 analysed the responses of the other groups in the system after a 50-year simulation pe-
 514 riod. Two levels of additional mortality were applied: $M(\text{per year}) + (0.1, 0.005)$, and
 515 the resulting biomasses analysed with respect to the Base Model to calculate keystone
 516 rankings, which were then compared to those produced for TBGB_EwE.

516

$$KS_i = \log \left(\sqrt{\sum_{i \neq j} m_{ij}^2} \times drank_i \right) \quad (1)$$

517 m_{ij} is the impact of species i on species j ,
 518 $drank_i$ is the rank of species i in descending order of biomass

519

520 The top species for keystoneity are not the same for TBGB_AM which has mus-
 521 sels, demersal fish, seabirds, and dredge oysters, and TBGB_EwE which has reef fish
 522 piscivores, elasmobranch piscivores, pelagic fish large and snapper (Figure 10). The
 523 Pearson's correlation between the two sets of rankings is 0.19, suggesting a weak and
 524 likely insignificant correlation. If we lower the benchmark to within the same third for
 525 keystone ranking (e.g. top, middle, or bottom third for both models), 11 out of the 30
 526 age-structured species groups are within the same third; and seven are in the opposite
 527 third.

528

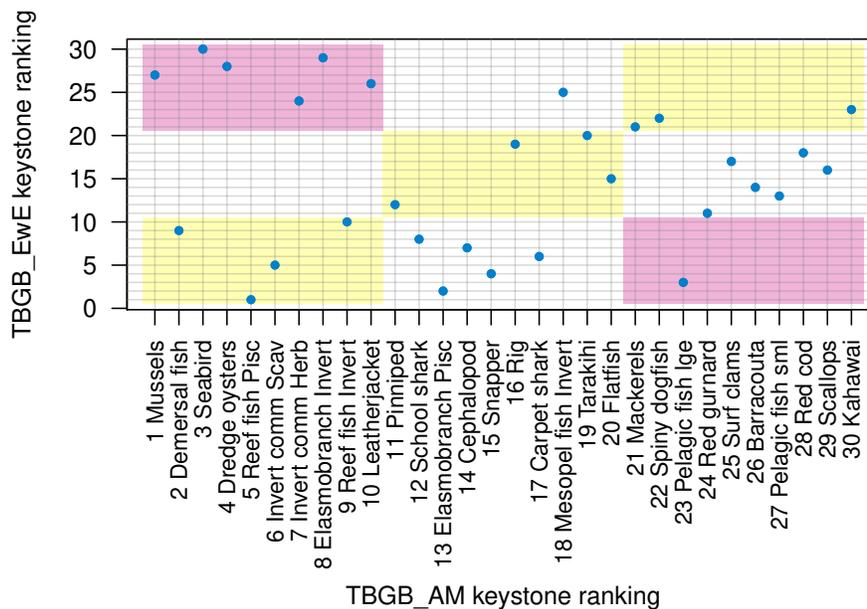

Figure 10: Keystone ranking from TBGB_AM (x-axis) and TBGB_EwE (y-axis) for all age-structured species groups, with numbers giving keystoneity ranking (1 is the most influential using Equation 1). Shading indicates species groups that are at least within the same third of keystone ranking in both models (e.g. top third, middle third, bottom third) (yellow), and those that are in opposite thirds (e.g. top third in TBGB_AM and bottom third in TBGB_EwE or top third in TBGB_EwE and bottom third in TBGB_AM) (red).

7 Fishing

Catch histories from 1900 to 2013 were estimated for all of the species groups that have been commercially exploited. Catches required partitioning to provide catch by species group, by month, by fleet, and by cell. The available catch data seldom provided this level of detail, so numerous assumptions were necessary to develop catch histories (more details in Supplementary Materials). The model operated on a one-day cycle, so catches were actually required for this time interval. However, it was considered that an estimation of catches by month (subsequently split into daily amounts) would be sufficient to describe the patterns of seasonal variation in commercial catch apparent for most of the species groups.

Catch histories for the commercially exploited bivalve species (scallops, oysters, mussels and surf clams) were developed using the units tonnes meatweight (rather than greenweight (unshucked shellfish)). Meatweight landings of scallops have been recorded, and the derivation of the catch history for this group is given below. Landings of the other three bivalve groups are recorded as greenweight. Catch histories for these were derived (in tonnes) for polygon and month as described above for wetfish from the FSU and QMS databases. The greenweights were then adjusted to meatweight using the following conversion factors: dredge oysters, 0.12; mussels, 0.25; surf clams, 0.18.

The commercial catch history for scallops was developed using data from Williams et al. (2014). Data from 1978 onwards were reported by scallop reporting sector (see figure 3 of Williams et al. (2014)), and these were allocated to polygon and to month. Catch was allocated amongst months in each polygon using the proportions used to derive figure 10 of Williams et al. (2014). Catches from 1959 to 1977 were not available by area, so were allocated to polygons based on the mean distribution of catches after 1977.

Reliable estimates of recreational catch from the TBGB region are sparse; Cole et al. (2006) estimated shellfish harvest in 2003–04, Davey et al. (2008) estimated harvest of snapper and blue cod in 2005–06, and a National Research Bureau survey estimated catches of all species in 2011–12 (B. Hartill, NIWA, pers. comm.). Other estimates are available (see Ministry for Primary Industries (2017)), but they are generally not considered reliable (B. Hartill, NIWA, pers. comm.). It is acknowledged that the recreational catch in this area is very dynamic, with factors like weather and localised abundance of species driving harvest levels.

8 Skill assessment

A research trawl survey series conducted in 11 years between 1992 and 2013 has sampled in Tasman and Golden Bays (Stevenson and Hanchet, 2000; Stevens et al., 2017). Biomass estimates from strata 17, 18, and 19 (approximating Statistical Area 038 which is the TBGB_AM model area) were compared to the biomass outputs from TBGB_AM. Three of the species groups (red gurnard (Starr and Kendrick, 2017a), snapper (Langley, 2018) and rig (Starr and Kendrick, 2017b)) have CPUE (catch per unit effort) that we have also compared to the corresponding TBGB_AM biomass outputs. There is a dredge survey for scallops in Tasman and Golden Bays, conducted annually in May–June (Williams et al., 2014, 2015) for which the dredge efficiency was revised in (Tuck et al., 2018). It is the revised biomass index we have used to compare with the TBGB_AM scallop biomass. The full set of figures with survey biomass estimates overlaid on TBGB_AM biomass outputs are in Supplementary G. The three species groups with corresponding CPUE and survey biomass estimates are presented in Figure 11. As a quantitative measure of comparison, we calculated Pearson’s correlations (Table 6). We used Pearson’s which is one of the metrics used for other Atlantis model skill assessments (McGregor et al., 2019; Sturludottir et al., 2018; Olsen et al., 2016). The correlations between the model and survey range from 79% for school shark, down to -79% for rig. Rig were also negatively correlated with the CPUE index at -37% (Table 6). The rig survey biomass suggests the population was very low from 2000–2011, whereas TBGB_AM was stable with a slight increase in biomass for these years. The CPUE for rig also suggested a decline in the early 2000’s, followed by an increase which is not apparent in the survey or TBGB_AM. The other negatively correlated species were cephalopods (-15%), and tarakihi (-20%), neither of which had an apparent trend in the survey biomass or the TBGB_AM biomass. Nine out of the 19 species groups with survey biomass estimates had positive correlations of greater than 20%. Only snapper was positively correlated with CPUE (66%).

Table 6: Pearson’s correlation between TBGB_AM spawning stock biomass (SSB) and survey biomass estimates (Survey) and fishery catch per unit effort (CPUE) (rounded to 2 significant figures). Invert, invertivore; mesopel, mesopelagic; pisc, piscivore.

| Species group | Survey | CPUE |
|---------------|--------|------|

| Reef fish Pisc | -0.084 | NA |
| Rig | -0.79 | -0.37 |
| Scallops | 0.36 | NA |
| School shark | 0.79 | NA |
| Snapper | 0.13 | 0.66 |
| Spiny dogfish | 0.27 | NA |
| Tarakihi | -0.2 | NA |

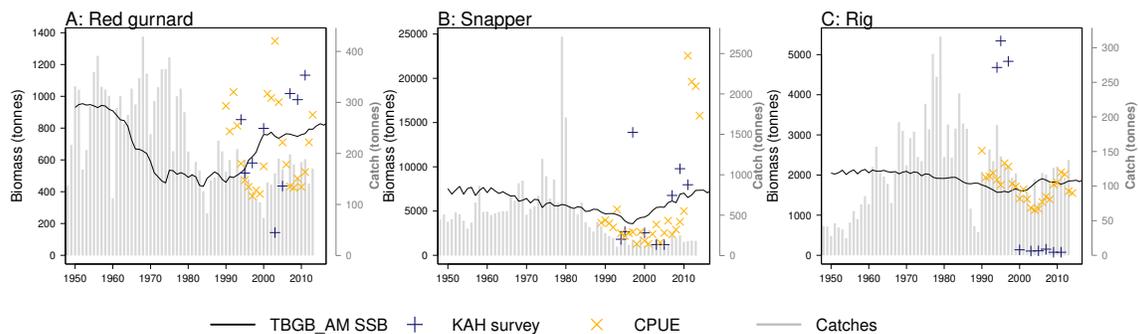

Figure 11: TBGB-AM estimated spawning stock biomass (SSB) (black solid), survey estimated biomass (midnight blue pluses), and CPUE (orange crosses) where available for the red gurnard (A), snapper (B), and rig (C). CPUE and survey biomass estimates were rescaled to match the mean of the TBGB-AM estimated SSB. Grey bars are estimated catches that were forced removals in TBGB-AM.

9 Bringing it together: comparing modelled ecosystem dynamics

9.1 Realised diets

We compared realised diets from the three models, using the base un-fished version, at equilibrium for TBGB-SS, and summarised over 1900–2014 and 1959–2014 for TBGB-AM and TBGB-EwE respectively. The full set of figures showing proportion of weight consumed prey species group for each of the three models are in Supplementary H. We

600 dropped plankton diet proportions for TBGB_SS as they swamped the diets due to
601 large amounts of this being eaten when the animals are very small, as is the nature of
602 a size-spectrum model. Having done this, the next smallest prey group (pelagic fish
603 small) then dominated all diets. They were even the largest prey group for predators
604 that don't generally consume small pelagic fish, such as reef fish invertivores, elasmobranch
605 invertivores, carpet sharks and flatfish. As a result, the diets can only be similar
606 between the size-structured model and the other two models for predators that eat a
607 lot of small pelagic fish. The realised diets from TBGB_EwE don't seem to show any
608 changes from the input diets, so these do not reflect anything of the model dynamics,
609 but rather how the diets were specified for the model. The TBGB_AM realised diets are
610 the most complex, and achieving realistic realised diets was one of the goals of model
611 calibration. The results presented for the model comparison have been summarised over
612 model space, time and species age, which loses a lot of the detail, but is a necessary
613 abstraction for the purpose of comparison. We calculated Spearman's rank correlation
614 of the diets as direction and monotonicity between diets seemed more appropriate than
615 to test for a linear relationship. We assigned a value of -1 to any compared diets with
616 zero overlap. There were five species groups where the size-structured model had zero
617 overlap with the other two models due to these predators only eating pelagic fish small
618 in the size-structured model, and not eating 'pelagic fish small' in the other two models.
619 These were leatherjacket, rig, flatfish, reef fish invertivores and pelagic fish small.
620 Between the Atlantis and EwE models, the invertebrates were more likely to have negatively
621 correlated diets, with the exception being carpet shark, found to be eating more
622 red cod in TBGB_AM and less demersal fish and invert commercial scavengers than in
623 TBGB_EwE (Figure 12).

624

625 9.2 Trophic level

626 We compared trophic levels calculated from realised diets for TBGB_AM and TBGB_EwE.
627 We did not calculate trophic levels for TBGB_SS due to the differences in diets, the limited
628 number of species groups modelled, and the focus of the size-structured model on
629 animals progressing through the trophic levels as they grow. While the latter is somewhat
630 applicable to the Atlantis model as prey preferences are separately defined for juveniles
631 and adults, and spatial, temporal, habitat and gape sizes allow for further differences
632 in diet between age-classes, the coarse scale of up to 10 age-classes for each species
633 group makes the realised diets and hence trophic levels more comparable with the
634 EwE model. Nonetheless, there were some systemic differences in trophic level between

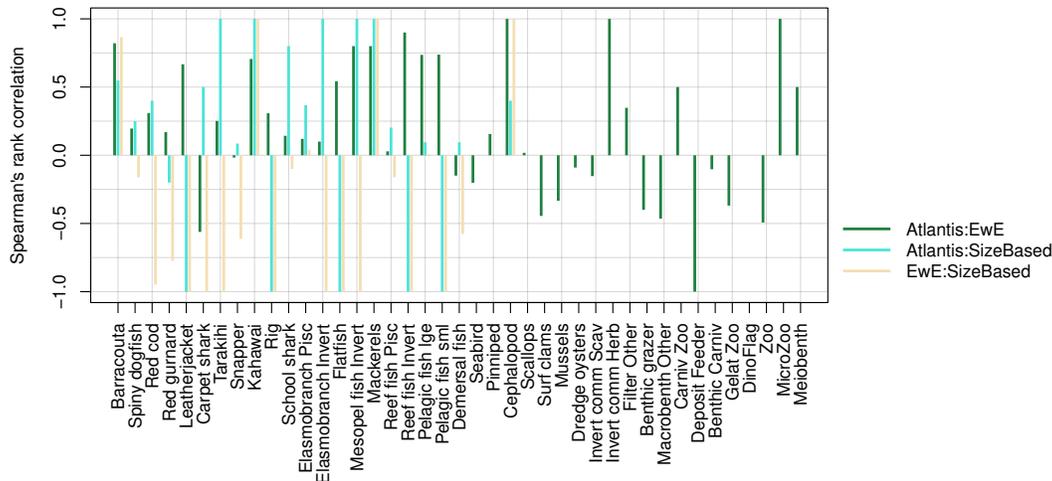

Figure 12: Spearman's rank correlation comparing realised diets from TBGB_AM with TBGB_EwE (dark green bars); TBGB_AM with TBGB_SS (aqua bars) and TBGB_EwE with TBGB_SS (beige bars). Diets with zero overlap were assigned a value of -1.

635 TBGB_AM and TBGB_EwE, such as the higher trophic levels generally presenting with
 636 inflated trophic levels in the Atlantis model (Figure 13). For example, elasmobranch pisci-
 637 vores have trophic level 5.5 in TBGB_AM and 4.8 in TBGB_EwE. The difference seems
 638 to be largely due to the fairly high presence of macrobenth other in the TBGB_EwE
 639 diet that is not apparent in TBGB_AM. School shark also have a higher trophic level
 640 in TBGB_AM at 5.5 compared to 5.1 in TBGB_EwE, and this is likely due to larger
 641 proportions of cephalopods and gelatenous zooplankton in the TBGB_EwE diet,
 642 and the higher proportions of barracouta and mackerels in the TBGB_AM school shark
 643 diet. There is also a difference for bacteria as it was categorised as a predator in TBGB_EwE,
 644 but not in TBGB_AM in which we have given it a nominal close-to-zero trophic level
 645 of 0.01. Bacteria are consumed in TBGB_AM, but not in TBGB_EwE, so the bacteria
 646 trophic level affected other trophic levels in TBGB_AM but not in TBGB_EwE.

647

648 9.3 Responses to fishing

649 We forced historical fishing in all three models, then compared the resulting biomass
 650 trajectories. The overlaid figures are in Supplementary I, and we have summarised the
 651 comparisons using Pearson's correlation (Figure 14). Some of the species groups have
 652 very high (> 70%) correlation between all three models. These are elasmobranch inverte-
 653 vores, mackerels, mesopelagic fish invertivores, schools sharks, and spiny dogfish. There

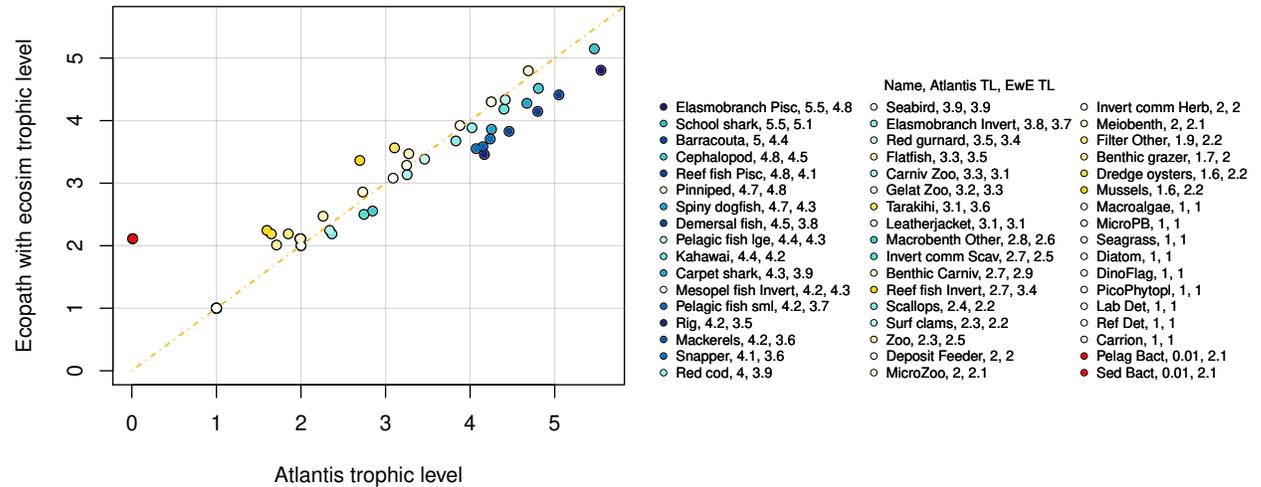

Figure 13: Trophic levels (TL) calculated from TBGB_AM (x-axis) and from TBGB_EwE (y-axis).

654 were no strong negative correlations between TBGB_EwE and TBGB_SS, but seven of
 655 the species groups had negative correlations of more than 50% between TBGB_AM and
 656 either TBGB_EwE or TBGB_SS. These were barracouta, carpet shark, elasmobranch
 657 piscivores, red gurnard, invert comm herbivores, leatherjacket and tarakihi. The ways
 658 in which they were different varied. For example, barracouta decreased under fishing
 659 for both TBGB_EwE and TBGB_SS, but gave no response for TBGB_AM, which could
 660 be due to migration in the Atlantis model buffering the effects of fishing. Carpet shark
 661 had fluctuations in biomass from 1980 in TBGB_SS that don't correspond to the time
 662 of direct fishing, and were not present for TBGB_AM or TBGB_EwE. There was a simi-
 663 lar situation for elasmobranch piscivores, with more variation with respect to time in
 664 TBGB_SS than would be expected as direct fishing effects, and that were not present in
 665 TBGB_AM or TBGB_EwE. Red gurnard increased during the period of heaviest fishing
 666 in TBGB_AM, then declined under lighter fishing that followed, whereas the responses
 667 in TBGB_AM and TBGB_SS were more indicative of direct fishing effects as the biomass
 668 declined under heavy fishing then recovered under light fishing. Invert comm herbivores
 669 decreased briefly in years with higher catches in TBGB_AM, with quick recoveries,
 670 but gave no response to fishing in TBGB_EwE, and were not included in TBGB_SS.
 671 Leatherjacket had a slightly decreasing biomass trend in TBGB_SS and TBGB_EwE, but
 672 remained flat for TBGB_AM. Tarakihi declined under the heaviest fishing in TBGB_SS
 673 and TBGB_EwE and recovered under lighter fishing, while in TBGB_AM the biomass
 674 signal was almost opposite.

675

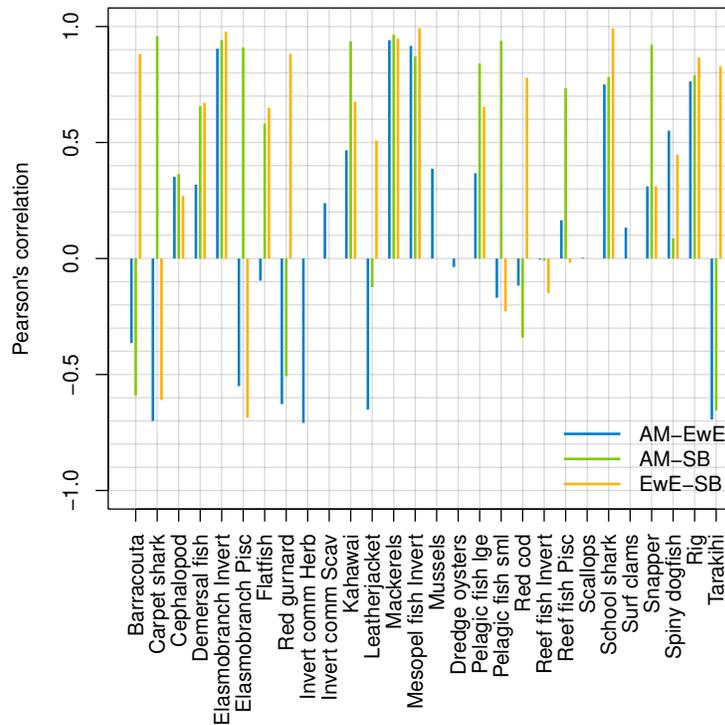

Figure 14: Pearson's correlation between model simulations in response to forced historical fishing.

9.4 Diversity

We calculated the modified version of Kempton's Q diversity index, as available in EwE (Christensen, 2009) to all three models. The response to historical fishing at the diversity level was very similar between TBGBG_AM and TBGB_EwE, but different in TBGB_SS (Figure 15). All three models signal a decline in diversity under fishing, but whereas there is only a decline in TBGB_SS, both TBGB_AM and TBGB_EwE show an initial increase in diversity under fishing which was then followed by a decline from the mid-late 1980s.

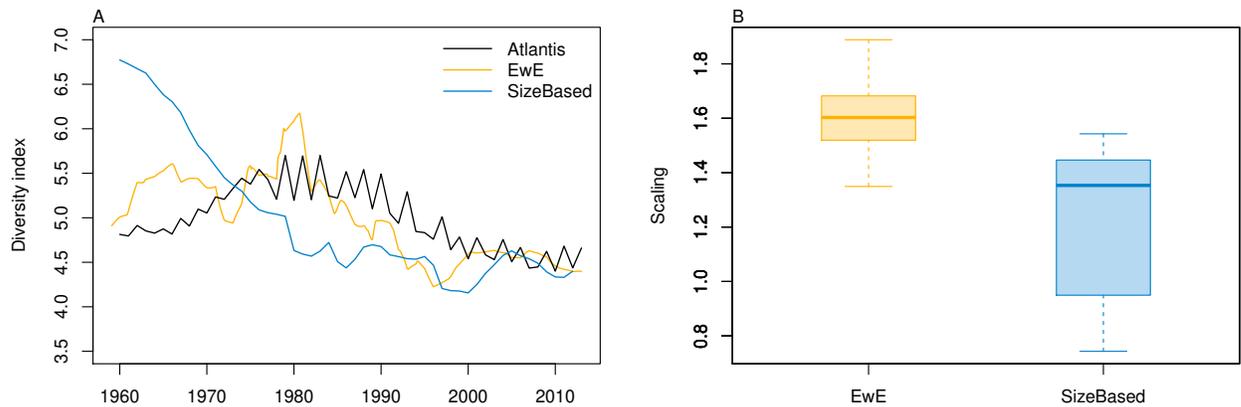

Figure 15: Diversity index for TBGB_AM (black line), TBGB_EwE (gold line) and TBGB_SS (blue line), scaled to the same mean (A) and scaling ranges given by TBGB_EwE diversity/TBGB_AM diversity (gold) and TBGB_SS diversity/TBGB_AM diversity (blue) (B).

10 Discussion

Key to this work, is to what degree the three developed ecosystem models of the TBGB ecosystem agree, and to what end they might be useful. Both of the terms ‘agree’ and ‘useful’ are open to interpretation. Testing for agreement between the models has been carried out in this study with respect to dynamics at the species group level, such as diets and growth rates, and with respect to dynamics at the system level such as trophic level and diversity. We will discuss model usefulness based on limitations due to model structure, intended purpose of the respective modelling frameworks, and concerns that have arisen through model validation and comparison carried out here.

The ecosystem models developed in this work are all useful tools for helping us learn about and understand the TBGB ecosystem. We can use these models to explore scenarios designed to understand the flow-on effects of different pressures on the ecosystem. As the models vary in structure and complexity, they are not equally suited for all scenarios (Table 7). Where more than one model is suited to explore a scenario, these models may highlight different aspects of the ecosystem’s response due to differences in structure and how these follow through to affect dynamics. When presented with different outcomes, the question should not be ‘which model is more right’, but rather ‘what can we learn from the outcomes of each model, and how do they relate to each other’. Using multiple models can give us a more extensive understanding of the ecosystem responses, hence it is ideal to use more than one model to explore a scenario where it is possible to do so. Proxies can be used to explore scenarios in TBGB_AM and TBGB_SS that they are not directly suited for. For example, coastal erosion could be explored through reduced habitat, and increased sedimentation could use additional mortality for animals that are expected to be vulnerable to this change.

Table 7: Overview of model use suitability for TBGB_AM (Atlantis model), TBGB_EwE (Ecopath with ecosim model) and TBGB_SS (size spectrum model). ✓: the model is suited for the scenario; ✗: the model is not directly suited for the scenario, although in some cases a proxy may be used. An extension to the *mizer* package used for TBGB_SS has been developed to include temperature effects (Woodworth-Jefcoats et al., 2019), and this could be applied to extend the uses of TBGB_SS.

711 The alternative models used parameter values from the Atlantis model, such that
 712 comparisons between the three models would relate to model structure rather than
 713 parameterisation. For some parameters these were inputs to the Atlantis model from
 714 available data or the literature, e.g. lifespan or age at maturity, and these should be
 715 the same if the alternative models were developed independently to the Atlantis model.
 716 Some parameter values were informed using outputs from the Atlantis model, such as F
 717 values, and predator:prey spatial overlap, and using these likely increased the similar-
 718 ities in model dynamics from what we might have seen had the models been developed
 719 independently. The comparison between model structure still remains useful, but it is
 720 worth noting that without having first developed the Atlantis model, these alternative
 721 models would need different means of specifying some of the parameter values and thus
 722 could produce different model dynamics.

723
 724 At the species group level, diets could be compared across all three models, although
 725 they reflect slightly different aspects of the modelled dynamics. The TBGB_EwE diets
 726 were relatively unchanged from the input diets; although they underwent some adjust-
 727 ments during calibration, they cannot really be considered an output of the model.
 728 The size-structured model has far greater emphasis on diets of species when they are
 729 very small and only eat phyto- or zoo-plankton, or slightly bigger and eating small
 730 pelagic fishes, and these aspects of life history are not included in the other two models.
 731 TBGB_AM has species recruited to the model as juveniles into the youngest age-class,
 732 but they could be several years old upon entering the model depending on the lifespan
 733 of the species, due to the equal sized age-classes. TBGB_EwE doesn't model indi-
 734 viduals, and has no age-structure, but diets have been defined to assume the species
 735 group biomass pools resemble those corresponding to adult and juveniles combined in
 736 the TBGB_AM. TBGB_AM diets are perhaps the most reflective of model dynamics,
 737 as they are the result of spatial, temporal, growth, gape-size, life-stage, competition,
 738 prey availability dynamics as well as prey preferences. The vertebrate species groups
 739 generally had good diet correlation between TBGB_EwE and TBGB_AM.

Despite the good diet correlation between TBGB_EwE and TBGB_AM, the keystone analyses produced rather different rankings. This is interesting as we would expect connectivity and influence to be linked with diets. Some of the vertebrate species groups had almost reverse keystone rankings in the two models. For example, pelagic fish large and elasmobranch invertivores both had high keystone rankings in one model and low in the other, despite positively correlated diets and very similar trophic levels. It's possible these differences came from modelling species groups as biomass pools with no age or size structure compared to modelling individuals with both age and size structure. It is difficult to predict whether this will influence results when exploring scenarios, but it is worth considering that it could.

The emergent growth curves in the base TBGB_AM and TBGB_SS models need to be considered when using these models. While they are within the correct ballpark of the literature curves (the calibration goal for size-at-age outputs (Pethybridge et al., 2019)), the differences could still affect model results, and hence need to be considered. A species group which has larger fish for a given age-class in the model than suggested in the literature will suffer less mortality for a given biomass extraction (e.g. from fishing or predation) and for a given number of these fish, we can expect greater predation pressure on their prey. Conversely, smaller than expected fish will suffer a greater mortality in numbers for a given biomass extraction, and for a given number of these fish, we can expect less predation pressure on their prey. Size-at-age may also affect diets and prey selectivities through gape size limitations.

The tuning of model parameters during calibration focused on parameters relating to growth, mortality and predation. This process did not change parameters from known values in the literature, but rather tuned parameters such that the resulting dynamics came in line with those expected based on the literature. For example, calibrating TBGB_AM to achieve realistic growth curves involved checking prey availability, gape size limitation, competition from other predators, and feeding parameters such as handling time and clearance rates. Similarly, to achieve natural mortality in line with expected M values involved ensuring appropriate predation mortality at each age-class. Appropriate predation mortality involves availability to their predators (including spatial and temporal overlap), gape size limitation, other available prey for the predators, and feeding dynamics of the predators.

776 Having calibrated the model to produce realistic dynamics that are stable in the
777 absence of pressure such as fishing, perturbing the initial conditions then tested the
778 persistence of these dynamics. The lower trophic level species groups were generally
779 more sensitive to perturbations of the initial conditions. While this corresponds well
780 with higher variability expected at lower trophic levels in nature (Molinero et al., 2008),
781 it was more likely caused by how we modelled the lower trophic levels (McGregor et al.,
782 2020), as these were biomass pools with growth effectively instantaneous, and hence
783 could be more responsive. Scallops and flatfish were exceptions as they were both mod-
784 elled with age structure, and yet displayed high variability under historical fishing. These
785 species groups crashed under historical fishing in some simulations, and rebounded in
786 others, making the range of possible biomasses very wide. Further exploration into
787 which simulations led to which outcomes could help understand when these fisheries
788 might be under threat of collapse. It could also be interesting to test if there was a
789 connection between the two such that they crashed in the same simulations, or perhaps
790 when one crashed the other survived.

791
792 Varying the oceanographic variables through sampling ROMS years or repeating
793 a single ROMS year introduced greater variability in the model results than perturb-
794 ing the initial conditions. This suggests careful consideration needs to be made into
795 the forcing of the oceanographic variables for this Atlantis model. It may be helpful
796 to extend the ROMS model so a longer timeseries of forcing oceanographic variables
797 can be used. It also raises the question of possible effects from varying temperature
798 and perhaps productivity in TBGB_EwE to compare responses and flow-on effects. All
799 of these aspects will be important to consider for climate change scenarios. Climate
800 change scenarios are often driven through the oceanography, and how we apply this
801 is likely to be influential on results. While environmental effects can be simulated in
802 TBGB_EwE, changes in environmental variables would need to use proxies, such as
803 changes in primary productivity (e.g. Niiranen et al. (2013), Hoover et al. (2013)).
804 Climate change scenarios are less likely to be explored using TBGB_SS due to limited
805 scope for including oceanographic changes in this model, and the limited species groups.

806
807 The skill assessment of TBGB_AM with respect to CPUE and survey indices spanned
808 from very negatively correlated in the case of rig, to very positively correlated for school
809 shark. In the case of rig, the sudden drop in survey biomass does not seem to relate to
810 a shift in fishing pressure, so it is possible there is a recruitment driver at play that the
811 model isn't picking up on. It is possible in Atlantis to include recruitment variability

812 as a time series, which could help fit this trend in the hindcast, and could be used to
813 introduce variability when exploring scenarios into the future. Scenarios should explore
814 sensitivities on the species groups with low skill to assess the effect of these groups on
815 the scenario outcomes. This may be especially important for a species that also has a
816 high keystone ranking, as this would suggest they are more influential on the rest of the
817 species groups.

818
819 That the diversity responses to historical fishing pressure were similar in TBGB_EwE
820 and TBGB_AM suggests these models have captured similar system-level dynamics. It
821 would be interesting to explore this further by projecting both models into the future
822 with varying catch levels, perhaps focused on subsets of the system. This activity might
823 also help us understand the difference in diversity under fishing for TBGB_SS. The end
824 result of reduced diversity was consistent across all three models, but the absence of an
825 initial increase in diversity in the size-structured model remains a mystery. Typically,
826 size-spectrum indicators relate to size (e.g. mean length, maximum length, proportion
827 of large fish) (Shin et al., 2005; Blanchard et al., 2014). There do not appear to be ex-
828 amples of calculating a diversity index such as Kempton's Q from size-spectrum models.

829
830 As TBGB_AM is the most complete representation of the system out of the three
831 models developed here, there are unlikely to be scenarios that can be explored in one of
832 the alternative models but not in TBGB_AM. There may, however, be scenarios where it
833 makes more sense to explore them in one of the simpler models due to shorter run-times
834 and ease of use, especially if we were to transfer the EwE model to an R version using
835 *Rpath*. We could then load many simulations exploring fishing and climate change into
836 the future, and evaluate system-wide responses. We could use these results to define a
837 suitable subset of the scenarios to run in Atlantis.

838

839 11 Conclusions

840 The analyses presented in this paper describe the development and assessment of three
841 ecosystem models of the Tasman and Golden Bays. The most complex of these models
842 is an end-to-end ecosystem model using the Atlantis framework, that is spatially and
843 temporally resolved, and has the most complete representation of the system, including
844 oceanographic dynamics, light, nutrients, primary production, the foodweb consisting of
845 51 species groups, fisheries, and feedback loops within these components. The Atlantis

846 model was based on accepted standards in the literature, then assessed for initialisation
847 uncertainty, sensitivity to oceanographic variables, and realistic dynamics and responses
848 to historical fishing. The alternative models were both simplifications of the Atlantis
849 model, and were assessed through comparison with the Atlantis model. As parameters
850 were shared between the models, the models differed in structure rather than parameter-
851 isation. The models compared generally well for diets, growth and response to historical
852 fishing. Keystone analyses were not consistent between models, and this should be con-
853 sidered when using these models in parallel. We have shown the Atlantis model to be
854 robust under initialisation uncertainty, except for scallops and flatfish which presented
855 varied responses to historical fishing pressure. The Atlantis model was most sensitive
856 to varying the oceanographic variables, suggesting these sensitivities are important to
857 include when using this model. The alternative models produced similar dynamics to
858 the Atlantis model, and we recommend running these models in parallel where they are
859 suited for exploring scenarios. We recommend the use of proxies to extend the range of
860 possible scenarios for these simpler models. In using these models to explore scenarios
861 into the future, we recommend analysing how each model produces a result before trying
862 to understand what the result can teach us about the ecosystem, and we recommend to
863 always include sensitivities.
