

Feeding behaviour in a 'basal' tortoise provides insights on the transitional feeding mode at the dawn of modern land turtle evolution

Nikolay Natchev, Nikolay Tzankov, Ingmar Werneburg, Egon Heiss

Almost all extant testudinids are highly associated with terrestrial habitats and the few tortoises with high affinity to aquatic environments are found within the genus *Manouria*. *Manouria* belongs to a clade which forms a sister taxon to all remaining tortoises and is suitable as a model for studying evolutionary transitions within modern turtles. We analysed the feeding behaviour of *Manouria emys* and due to its phylogenetic position, we hypothesise that the species might have retained some ancestral features associated with an aquatic lifestyle. We tested whether *M. emys* is able to feed both in aquatic and terrestrial environments. In fact, *M. emys* repetitively tried to reach submerged food items in water, but always failed to grasp them - no suction feeding mechanism was applied. When feeding on land, *M. emys* showed another peculiar behaviour; it grasped food items by its jaws - a behaviour typical for aquatic or semiaquatic turtles - and not by the tongue as generally accepted as the typical feeding mode in all tortoises studied so far. In *M. emys*, the hyolingual complex remained retracted during all food uptake sequences, but the food transport was entirely lingual based. The kinematical profiles significantly differed from those described for other tortoises and from those proposed from the general models on the function of the feeding systems in lower tetrapods. We conclude that the feeding behaviour of *M. emys* might reflect a remnant of the primordial condition expected in the aquatic ancestor of the tortoises.

18 INTRODUCTION

19 Comprising more than 180 species, the cryptodiran taxon Testudinoidea represents the most
20 diverse group of extant turtles (e.g., Fritz and Havaš, 2007; Thomson and Shaffer, 2010).
21 Traditionally, it contains three major extant groups, including the emydids, the geoemydids and
22 the testudinids (tortoises) (Fig. 1). All molecular phylogenetic studies (Iverson et al., 2007;
23 Shaffer, 2009; Thomson and Shaffer, 2010; Barley et al., 2010) confirm a sister group
24 relationship of the testudinids and the geoemydids (Fig. 1). The relationship of Platysternidae to
25 other turtle groups remains unresolved (Parham et al. 2006), but most molecular studies support
26 a closer relationship to emydids (e.g., Thomson and Shaffer, 2010; Crawford et al., 2015).
27 Palaeontological studies have shown that all testudinoids share aquatic ancestors, from which
28 terrestrial species evolved (Danilov, 1999; Sukhanov, 2000; Joyce and Gauthier, 2004).

29 The majority of the Triassic stem turtles were terrestrial as indicated by the design and
30 proportions of the limbs, which were adapted for terrestrial locomotion (for a comprehensive
31 discussion see Joyce, 2015). With the emergence of modern turtles (Testudines) during the
32 Jurassic period (e.g., Danilov and Parham, 2006; Sterli, 2010; Sterli and de la Fuente, 2011), a
33 general transition of turtles into an aquatic environment occurred (Willis et al., 2013). The
34 invasion of aquatic environments induced diversification into several subgroups (see Joyce,
35 2007; Thomson and Shaffer, 2010). Due to the different physical properties (drag, viscosity, etc.)
36 of air and water, the new environment required morphological and functional adaptations of the
37 locomotion- and feeding system to enable efficient swimming behaviour and aquatic food uptake
38 (i.e. suction feeding) (Schumacher, 1973; Lemell et al., 2002).

39 The sister group of all remaining Testudinoidea is the diverse and possibly paraphyletic
40 extinct taxon †Lindholmemydidae (Fig. 1; Lourenço et al., 2012), which contains genera such as

41 †*Mongolemys* and †*Lindholmemyd* (Danilov, 1999; Joyce and Gauthier, 2004). Some poorly
42 documented aquatic taxa such as †Haichemydidae and the †Sinochelyidae may perhaps also
43 belong to †Lindholmemydidae. This group was recorded from aquatic sediments of the late Early
44 Cretaceous and apparently had an amphibious lifestyle (Sukhanov, 2000). Among recent
45 cryptodirans, semi-aquatic to semi-terrestrial lifestyle is typical for most emydids (plus
46 platysternids) and geoemydids, as well as for some kinosternids (see Depecker et al., 2006, but
47 also Nakajima et al., 2014). The remaining extant species are entirely terrestrial (tortoises), or
48 predominantly aquatic (see Joyce and Gauthier, 2004; Rasmussen et al., 2011).

49 Among modern turtles, a transition from an aquatic to a semi-terrestrial or fully terrestrial
50 habitat and the capacity to exploit terrestrial food sources has evolved independently within all
51 three major testudinoid lineages (for overview see Summers et al., 1998; Natchev et al., 2009).
52 At least eight emydid species are able to feed on land as well as under water (see Bels et al.,
53 1997, 2008; Summers et al., 1998; Stayton, 2011). During terrestrial feeding, such amphibious
54 emydids use their jaws to grasp food items (jaw prehension). Similarly, all amphibious
55 geoemydids studied to date also use jaw prehension in terrestrial food uptake (see Heiss et al.,
56 2008; Natchev et al., 2009). In contrast, all testudinids studied so far use the tongue to touch the
57 food items, a behaviour referred to as “lingual prehension” (see Wochesländer et al., 1999; Bels
58 et al., 2008). According to Bels et al. (2008), lingual prehension is obligatory for all tortoises.

59 The tortoises show a clear tendency towards herbivory and emancipation from water as
60 living and feeding medium (see Pritchard, 1979; Ernst and Barbour, 1989; Bonin et al., 2006). In
61 fact, testudinids seem to have lost their ancestral ability to feed under water and exclusively rely
62 on terrestrial trophic ecologies. Some predominantly terrestrial geoemydids are able to complete
63 the whole feeding process on land and under water (Natchev et al., 2010). Similarly, testudinids

64 with tendencies towards an amphibious lifestyle might have retained the ancestral skill to feed
65 underwater. Hence, information on bimodal feeding mechanisms in tortoises is of great
66 importance to understand the evolution of terrestrial feeding mechanisms and subsequent
67 evolution of the predominantly terrestrial lifestyle in tortoises.

68 The genus *Manouria*, being of the most 'basal' extant tortoises with a strong association to
69 aquatic environments (Høybye-Mortensen, 2004; Stanford et al., 2015), constitutes a suitable
70 model to study the feeding mechanisms in testudinids. Its partially aquatic feeding habit
71 purported to be associated with the observed morphological extension of the palatines onto the
72 triturating surface of the upper jaw (character 30 sensu Gerlach, 2001), a diagnostic feature
73 common to geoemydid turtles. Another geoemydid-like feature is the unique existence of class II
74 mental glands (Winokur and Legler, 1975).

75 The present study was conceived to provide a detailed analysis of the feeding behaviour in a
76 species of the genus *Manouria*. *Manouria emys* is found in close association with water. Hence, we
77 designed experiments to reveal whether this species is able to complete the entire feeding process
78 under both aquatic and terrestrial conditions as some geoemydids do (see Natchev et al., 2009,
79 2010).

80 Similar to all investigated testudinids, the Asian forest tortoise possesses a well developed
81 tongue. The hyoid complex is predominantly cartilaginous (Heiss et al., 2011). On the base of
82 the specific morphology of the feeding apparatus (elastic basis of the oropharynx and
83 voluminous lingual structures) we suggest a poor suction feeding performance in case *Manouria*
84 attempts to feed under water.

85 Wochesländer et al. (1999, 2000) and Bels et al. (2008) stated that the feeding kinematics in
86 all testudinids involve two common features: an obligatory lingual prehension and the split of the

87 gape cycle in four main phases: slow open phase I (SOI); slow open phase II (SOII); fast open
88 phase (FO); fast close phase (FC). In our experiments we test whether these kinematical
89 elements are present in the feeding behaviour of *M. emys*. On the base of our findings, we fine-
90 tune the kinematical feeding models proposed for tortoises. The gained new data require a re-
91 evaluation of the concept on the function of the tongue in the food uptake in tortoises. Having in
92 mind the phylogenetical position of *M. emys* and the specifics of its feeding behaviour, we
93 propose hypothesis on the evolution of the terrestrial feeding among testudinoids in particular
94 and turtles in general. We discuss also on the interrelationship between the diet and the feeding
95 media in the course of turtle's evolution.

96

97 **MATERIALS AND METHODS**

98

99 Ecological background

100 Both extant species of *Manouria*, the Asian forest tortoise *M. emys* and the impressed
101 tortoise *M. impressa*, have a restricted distribution in Southeast Asia. *M. emys* has a narrow
102 distribution in Bangladesh, India (Assam, Meghalaya, Mizoram, Nagaland), Myanmar, Thailand,
103 Malaysia (East and West), and Indonesia (Kalimantan, Sumatra). The nominate subspecies, *M.*
104 *emys emys* - the subject of this study, inhabits the southern part of the species range (Fritz and
105 Havaš, 2007; TTWG, 2014, Stanford et al., 2015).

106 *M. emys* inhabits tropical evergreen monsoon forests and exhibits high tolerance for soil
107 moisture. It is commonly found reposing in wet areas, buried in mud or under the leaf litter
108 where it may spend long periods of time. It is active even during rainy weather. Direct sun
109 exposure and basking are not required. Furthermore, this species has a mostly crepuscular and

110 nocturnal lifestyle (Ernst, Altenburg, and Barbour, 2000; Vetter and Daubner, 2000, Stanford et
111 al., 2015).

112 According to the available literature, the diet of *M. emys* includes plants, fungi,
113 invertebrates, and frogs (Nutphand, 1979; Das, 1995; Lambert and Howes, 1994, Høybye-
114 Mortensen, 2004). It has been reported to feed on plants in shallow mountain streams (Nutphand,
115 1979).

116

117 Experimental setting

118 Animal husbandry and experiments were in strict accordance with the Austrian Protection of
119 Animals Act. The animals used in the present study were obtained commercially and kept at 12 h
120 dark/light cycles in a large terrarium (150x100 cm ground area) with a permanently filtered
121 water basin and spacious terrestrial area. The turtles were fed different fruits, vegetables,
122 commercially obtained tortoise pellets, dead mice, as well as pieces of cattle heart and liver,
123 offered on the terrestrial part of the terrarium. Carapace lengths in the three subadult
124 experimental animals ranged between 109-135 mm with body masses between 234-236 g. For
125 filming terrestrial feeding, the specimens were put in a dry glass cuvette (24x60x30 cm). When
126 the food was offered on the floor of the cuvette, the tortoises often twisted their necks and rotated
127 their heads in attempt to grasp the food item. The side movements made the filming of the
128 animals in strict lateral view very difficult and the landmarks were not clearly visible during the
129 sequence. By the use of forceps for food display we completely eliminated these problems and
130 were able to shoot perfect lateral plans of the feeding turtles. The food in the feeding
131 experiments was offered at a position which was similar to the position on which we offered the
132 food in the terrarium where the tortoises were housed. The animals did not extend vastly their

133 necks to reach the food items (see Supplements). The position of the offered food was
134 completely “natural”. The tortoises needed to stretch their necks forwards rather than
135 downwards, which did not impacted other kinematic patterns of the feeding cycles.

136 As food items we used small pieces of cattle heart measuring approximately 5x5x5 mm.
137 The turtles were filmed from lateral aspect (with a reference grid 1x1 cm in the background) via
138 the digital high-speed camera system Photron Fastcam-X 1024 PCI (Photron limited; Tokyo,
139 Japan) at 500 fps with a highly light-sensitive objective AF Zoom - Nikkor 24-85 mm (f/2,8-4D
140 IF). Two “Dedocool Coolh” tungsten light heads with 2 x 250 W (ELC), supplied by a
141 “Dedocool COOLT3” transformer control unit (Dedo Weigert Film GmbH; München, Germany)
142 were used for illumination. We filmed and analysed the food uptake and the food transport
143 cycles in eight feeding sequences for each specimen.

144 The setting for filming aquatic feeding of submerged food comprised the experimental
145 aquarium filled with water to a level of 3 cm and presentation of food items in front of the
146 turtle’s snout. In order to reduce the light intensity and for optimisation of the digitising process,
147 the frame rate was reduced to 250 fps. As the tortoises were unable to grasp the food item in a
148 total of 36 trials, the kinematics of the feeding apparatus had been analysed (see below) in nine
149 selected representative feeding trials.

150 For both terrestrial and “aquatic feeding” sequences, horizontal (X-axis) and vertical (Y-
151 axis) coordinates of relevant landmarks (see Fig. 2) were digitised frame by frame using “SIMI-
152 MatchiX” (SIMI Reality Motion Systems; Unterschleißheim, Germany). Based on the
153 displacement of the markers, we were able to calculate the gape amplitude (distance between the
154 tip of the upper and lower beak), head movement (distance between the anterior tip of the
155 carapace and the point “P” on Fig. 2), tongue movements (distance between the most ventral

156 point on tympanum and the tip of the tongue when visible), and hyoid movements (distance
157 between the point “P” on Fig. 2 and the basis of the posterior ceratobranchial). To compare the
158 kinematic feeding pattern of *M. emys* to those of other studied turtles and to understand the
159 coordination between the elements of the feeding apparatus, these data were used for calculation
160 of the following kinematical variables: duration of Slow open phase (SO); duration of Slow open
161 phases I and II (SOI and SOII) when present; duration of fast open (FO); duration of maximum
162 gape phase (MG); duration of fast close (FC); time to peak gape (TPG); total cycle duration
163 (TCD); duration of hyoid protraction (HyDD); duration of hyoid retraction (HyVD); duration of
164 the total hyoid cycle (THC); hyoid retraction velocity (HyRV); duration of head protraction
165 (HP); duration of head retraction (HR); duration of tongue protraction (TP); tongue retraction
166 velocity; delay of the start of hyoid retraction relative to the tongue retraction start; delay of
167 reaching peak gape relative to start of the hyoid retraction; delay of reaching peak gape relative
168 to tongue retraction start (see Table 1).

169

170 Statistics

171 We tested for any differences among the frequency of occurrences of defined patterns both in
172 food uptake (FU) and food transport (T), i.e. sequences with: missing split of the jaw opening in
173 SO and FO; without detectable split of discrete SOI and SOII slow gape phase; lacking MG
174 phase. In order to provide the comparisons, Chi-square test with Yates’ correction was
175 performed. Then we tested for possible existence of differentiation in kinematical variables in
176 both feeding stages (FU and T). All variables were tested with the Shapiro-Wilk test for normal
177 distribution. When the p-value was less than the chosen alpha level ($p < 0.05$), the null hypothesis
178 was rejected and data were excluded from further analyses. In addition, all variables included in

179 Table 1 were tested with Levene's and Brown-Forsythe tests and then processed with Welch's
180 ANOVA for heteroscedastic data. Tukey's honest significant difference test (HSD) was
181 performed for post-hoc analyses when applicable.

182 Furthermore, in order to express the degree of individual differentiation among the studied
183 specimens, a Canonical discriminant analysis (CDA) was performed. Standard descriptive
184 statistics including mean, range, standard deviation [(SD) and confidential interval at 95% CI]
185 were presented.

186

187 **RESULTS**

188

189 When feeding on land, the Asian forest tortoises always grasped food by the jaws. After
190 food uptake, one to four transport cycles followed prior to oesophageal packing (see Schwenk,
191 2000). The tip of the tongue was barely visible during food uptake (see Fig. 3b-c) indicating that
192 the tongue was not protracted. By contrast, during transport cycles, the cyclic movements of the
193 tongue were well visible as it was rhythmically pro- and retracted to transport the food item
194 towards the oesophagus (Fig. 5).

195 When trying to feed under water (Fig. 4), *M. emys* submerged its head under the water level
196 and protruded the gaping jaws toward the food item. The gape cycle was newer split in slow and
197 fast jaw open phases. The tongue tip was not visible from the lateral aspect and the hyolingual
198 complex did not protract prior reaching peak gape. No retraction of the hyoid complex was
199 detected prior jaw closure. The gape cycle duration exceeded one and a half seconds and was
200 1.94 ± 0.36 s (mean \pm SD). Despite the unsuccessful attempts, the turtles repeatedly tried to catch

201 the submerged food. In several events, we were able to detect that the food item was carried
202 away by the bow wave induced by jaw closing.

203 The variables of the kinematical profiles are summarised in Table 1. In the statistic tests, we
204 found highly significant differences in sequences with and without both SO I and SO II when
205 food uptake and transport stages were compared ($\chi^2_{(1, N=98)}=25.05$, $p < 0.001$). Similarly
206 significant differences were observed when comparing food uptake and transport cycles in
207 respect to sequences with and without slow jaw open phases as well as with and without
208 maintaining jaw maximum gape - MG phase ($\chi^2_{(1, N=98)}=6.10$, $p=0.02$; $\chi^2_{(1, N=98)}=6.52$, $p=0.01$).

209 Nine of the variables which describe the food uptake process were detected to show
210 significant differences between individuals (Table 1). In transport cycles, six out of 18 variables
211 differed significantly amongst individuals (see Table 1)., Seven out of nine variables differed
212 significantly when testing for differences between grasping and transport cycles: fast jaw open
213 duration (FO; $F_{\text{Welch}(1,43)}=15.17$, $p=0.011$); maximum gape (MG; $F_{\text{Welch}(1,26)}=15.89$, $p=0.001$);
214 fast closing (FC; $F_{\text{Welch}(1,26)}=7.86$, $p=0.010$); time to peak gape (TPG; $F_{\text{Welch}(1,72)}=46.78$,
215 $p < 0.001$); total gape cycle duration (TCD; $F_{\text{Welch}(1,72)}=52.50$, $p < 0.001$); head protraction duration
216 (HP; $F_{\text{Welch}(1,67)}=52.23$, $p < 0.001$); and head retraction duration (HR; $F_{\text{Welch}(1,47)}=12.57$, $p=0.002$).

217 When comparing three further parameters among the transport cycles in all three specimens
218 (delay of HyVD start relative to TR start; delays of TPG relative to HyVD; delay of TPG relative
219 to TR starts), statistically significant differences were found among all compared pairs
220 ($F_{\text{Welch}(2,105)}=41.58$, $p < 0.001$).

221 The performed canonical discriminant analysis (CDA) revealed the existence of substantial
222 degree of individualism among the studied specimens (Fig. 7). However, only the first axis
223 eigenvalue exceeded the level of acceptance, i.e. 1. First axis explained 70% of the total

224 variance. Among the 18 studied variables only two (THC and HPR) showed higher correlation
225 scores than 0.75. On the base of the CDA and the detected degree of individualism mentioned
226 above, we can conclude that the patterns displayed by the studied specimens can be regarded as
227 similar but not as uniform.

228

229 **DISCUSSION**

230

231 The Asian forest tortoise repetitively tried to feed on dispersed food items under water,
232 which was an unexpected and hitherto unknown behaviour among tortoises. However, *M. emys*
233 always failed to consume the submerged food. On land, *M. emys* grasped food with the jaws, just
234 like all known aquatic or semiterrestrial turtles do, but not with the tongue as formerly predicted
235 for all tortoises. On the basis of our results we discuss several important evolutionary,
236 behavioural, and functional aspects.

237

238 **Evolution of food uptake among turtles**

239 In general, most aquatic turtles combine a fast acceleration of the head towards the food or
240 prey item and a suction feeding mechanism is induced by fast oropharyngeal volume expansion.
241 In some extant turtles, a strong suction flow can be generated and prey is directly sucked into the
242 oropharynx without contact with the jaws [e.g., *Chelus fimbriatus* (Lemell et al., 2002), *Apalone*
243 *spinifera* (Anderson, 2009), *Pelodiscus sinensis* (N.N. and I.W. unpublished data)]. However,
244 most extant turtles cannot generate such strong suction flows and only compensate (“gulp”) the
245 bow wave that otherwise would push small to moderately sized food items away from the fast
246 approaching head. Such species finally fix and grasp prey with the jaws (see Lauder and

247 Prendergrast, 1992; Lemell et al., 2000; Aerts et al., 2001, Natchev et al., 2009, 2011). We
248 consider the latter as plesiomorphic behaviour for extant turtles.

249 Among extant turtles, the ability to complete the whole feeding process (including food
250 uptake, food manipulation and transport, esophageal packing, and swallowing) on land has been
251 tested and documented for only six species so far. All of them were members of Testudinoidea
252 (Fig. 1; see also Summers et al., 1998; Bels et al., 2008; Natchev et al., 2009). The terrestrial
253 mode of food uptake differs dramatically among and within the three testudinoid subgroups (see
254 Bels et al., 1997, 2008; Summers et al., 1998; Wochesländer et al., 1999; Natchev et al., 2009,
255 present study). Correspondingly, it appears as if terrestrial feeding re-evolved several times
256 independently amongst turtles. Unfortunately, only limited experimental data are available on
257 feeding mechanisms in emydids and geoemydids. Further functional and palaeontological
258 investigations may help to sort out the issues on the evolution of the feeding behaviour and the
259 morphology of the feeding apparatus in testudinoids.

260 Very limited information is available on feeding mechanisms employed by amphibious non-
261 testudinoid turtles that occasionally exploit terrestrial food sources. Weisgram (1985 a,b)
262 documented a kinosternid (*Claudius angustatus*) that caught prey on land and dragged it into
263 water for transport and swallowing. Natchev et al. (2008) documented another kinosternid
264 (*Sternotherus odoratus*) catching food on land, but failing to transport it through the oropharynx.
265 Among extant turtles, successful food transport on land seems to be restricted to testudinoids.
266 The development of enlarged and muscular tongues within this group (von Bayern, 1884;
267 Werneburg, 2011) represents adaptation to improved terrestrial food manipulation.

268 Based on experimental data, Natchev et al. (2009) described and summarised three
269 categories of terrestrial food uptake modes among Testudinoidea: (A) Jaw prehension with

270 retracted hyolingual complex, as observed in the geoemydid genus *Cuora* (Natchev et al., 2009);
271 (B) Jaw prehension with slightly protracted hyolingual complex, as observed in emydids (Bels et
272 al., 1997; Stayton, 2011); (C) Lingual prehension - the tongue touches the food item prior to food
273 uptake, as documented in all tortoises studied so far (Wochesländer et al. 1999, Bels et al. 2008).
274 The food uptake mode of *M. emys*, however, differs substantially from that of all remaining
275 tortoises (category C). In fact, the hyolingual complex in *M. emys* remained fully retracted
276 during the food prehension on land, and the first contact with the food item was by the jaws.
277 Accordingly, the feeding mechanism of *M. emys* should be assigned to category A, along with
278 that of semi-aquatic geoemydids.

279 We now aim to construct a theoretical scenario on the evolution of terrestrial feeding
280 mechanisms in turtles. Given the aquatic origin of all living turtles, the functional transition from
281 aquatic to terrestrial feeding mechanisms could hypothetically have involved four stages,
282 beginning with an exclusively aquatic feeding ancestor. In different lineages and stages, turtles
283 may have left their aquatic environments for various reasons e.g. for exploiting new food niches.
284 The species that retained predominantly aquatic life styles may grasp food by the jaws on land,
285 but have to drag it into the water for further intraoral (hydrodynamic based) transport. In recent
286 turtles, such behaviour was documented in the kinosternids *C. angustatus* (Weisgram, 1985 a, b)
287 and *Sternotherus odoratus* (Natchev et al., 2011), as well as in the emydid *Trachemys scripta*
288 (Weisgram, 1985 b; Weisgram et al., 1989) and other emydids (see Stayton, 2011). Turtles of the
289 second hypothetical evolutionary stage grasped food by the jaws, while the tongue was used for
290 intraoral food transport on land. Such species would still have retained their underwater feeding
291 ability by using hydrodynamic mechanisms. When grasping food on land, the tongue remained
292 retracted or was protracted without however touching the food item. Among extant turtles, such a

293 feeding mode is found in the geoemydid genus *Cuora* (Heiss et al., 2008; Natchev et al., 2009,
294 Natchev et al., 2010) and in some emydids (Bels et al., 1997; Summers et al., 1998, Stayton,
295 2011). In the next theoretical evolutionary step (stage three), behavioural and morphological
296 adaptations for terrestrial feeding were further advanced, increasing the efficiency of terrestrial
297 food transport at the expense of the ability to use effective hydrodynamic mechanisms in water.
298 Such species still grasped food items with their jaws on land (as typical for aquatic or
299 semiaquatic turtles), but were no longer able to take up dispersed food if submerged, which
300 features prominently in the present case of *M. emys*. Finally, in a fourth stage, turtles became
301 fully terrestrial and their tongue was obligatorily involved in food uptake as documented in the
302 tortoises *Testudo (Eurotestudo) hermanni boettgeri* (Weisgram, 1985 b; Wochesländer et al.,
303 1999), *Kinixys belliana*, *Geochelone elephantopus* and *G. radiata* (Bels et al., 2008).

304 Our investigations demonstrate that the ‘basal’ tortoise *M. emys* does not contact food with
305 the tongue prior to jaw prehension on land. This shows that tongue to food contact is
306 characteristic of advanced tortoises only. We consider the terrestrial feeding behaviour of *M.*
307 *emys* as plesiomorphic and potentially inherited from its semiaquatic ancestors. On that base, *M.*
308 *emys* can be considered a transitional turtle in regard to secondary terrestriality.

309 We propose that hyolingual protrusion evolved in the lineage forming to advanced tortoises
310 (Fig. 1). *Manouria emys* has a large tongue with massive intrinsic and extrinsic musculature (see
311 Heiss et al., 2011). The advanced and complex lingual musculo-skeletal architecture allows the
312 turtle to protrude the tongue outside the margins of the rhamphothecae (see Fig. 2). However, *M.*
313 *emys* does not use lingual food prehension as typical for all other tortoises studied so far. In fact,
314 it seems that the *Manouria* [and perhaps *Gopherus* (N.N. personal observations)] “lineage” has
315 retained the jaw prehension mechanism inherited from earlier aquatic ancestors. It seems that the

316 tortoises, in general, evolved fleshy tongues which improve the food transport performance. The
317 advanced tortoises only refined the behaviour of food uptake on land via lingual food contact
318 prior to jaw closure (see Wochesländer et al., 1999; Bels et al., 2008).

319

320 **Function of the protruded tongue in the testudinid's food uptake**

321 What would be the potential advantage of the obligatory lingual protrusion, found in the
322 more derived tortoises? One possible explanation is that the tongue is used as a prehensile organ
323 for food ingestion analogous to that found in other tetrapod groups (for overview see Schwenk,
324 2000; Schwenk and Wagner, 2001). However, for tortoises such interpretation might be put into
325 question. By examining all published data available (Wochesländer et al., 1999; Bels et al.,
326 2008), we were not able to find any convincing evidence that tortoises collect food with their
327 tongues - they just touch it. In all published feeding sequences, the contact between the food and
328 the tongue is clearly demonstrated - yet, in all cases, after the initial contact of the tongue with
329 the food, the head moves forward and the food item is not dragged into the mouth by tongue
330 retraction, but is grasped by the jaws during the fast jaw closing (FC gape phase). Initial food
331 ingestion in tortoises might not be considered “lingual prehension” (see Schwenk, 2000; Bels et
332 al., 2008) in the strict sense, but should be regarded as “jaw prehension following lingual
333 contact”. This prompts the question: why is an obligatory contact of the tongue to the food
334 present in extant tortoises (except in *Manouria* and also conceivably in *Gopherus*) during food
335 uptake? In other words: why do tortoises apply a more complex and presumably more
336 energetically expensive food uptake mechanism by including movements of the hyolingual
337 complex in addition to the movements of the neck and jaws alone?

338 We propose that the lingual contact provides tactile information on the position of the food
339 item and helps the advanced tortoises to compensate the “information gap” which occurs when
340 the food is approached to a distance where it is out of sight. The eyes of tortoises are positioned
341 laterally on the head (Pritchard, 1979) and the turtles are not able to permanently observe the
342 position of the food item when the neck is protracted and the gape is positioned around it. The
343 prolonged maximum gape (MG) phase found in most ingestion cycles of *M. emys* (see Table 1,
344 Figure 3 and Figure 6) might be the result of lack of lingual contact with the food surface. In all
345 published sequences and kinematical profiles on food uptake in tortoises, there is a clear
346 tendency toward a split of the gape cycle into slow open (SO) and fast open (FO) gape phases
347 (see Wocheisländer, 1999; Bels et al., 2008). The lack of tongue protrusion might explain the lack
348 of slow open (SO) and fast open (FO) split in the gape cycle of food uptake in the geoemydid
349 *Cuora* (see Natchev et al., 2009). In most food uptakes analysed in *M. emys*, SO phases are not
350 present and the gape increases gradually (see Table 1 and Figure 6). Similar as in *Cuora*, the lack
351 of SO phases might be explained by the lack of tongue protrusion in food uptake (see Natchev et
352 al., 2009).

353

354 **Intraoral food transport on land**

355 The execution of the transport cycles require coordination of the activities of contractile
356 elements such as the jaw opening and closing muscles, head protracting and retracting muscles,
357 intrinsic and extrinsic lingual muscles, as well as muscles that protract and retract the hyolingual
358 complex as a whole unit (Jones et al., 2012; Werneburg, 2011, 2013). In contrast to this
359 complicated choreography, the mode of food prehension in *M. emys* suggests less complex
360 neuromotoric coordination between neck and jaw movements. Yet, the execution of the transport

361 cycles is often more than twice shorter in duration (see Table 1). A possible explanation for the
362 longer duration of food uptake cycles relative to transport cycles might be that during transport,
363 the coordination centres of the muscle activities execution are permanently supplied with
364 information concerning the position of the food item within the oropharynx and the proper
365 movements can be executed precisely in a shorter time.

366 In his work on the feeding mechanisms in domestic animals, Bels (2006) established that a
367 pre-programmed Generalise Cyclic Model (GCM) – very similar to those proposed from
368 Bramble and Wake (1985) – is universally valid among the different groups of tetrapods,. The
369 feeding kinematics of the Asian forest tortoise differs in some aspects from those proposed by
370 the GCM. The kinematics of the feeding system in *M. emys* seems to be pre-programmed, but
371 under permanent feed-back control. The values of the gape and hyoid/hyolingual cycle patterns
372 in the three specimens studied here show high degrees of variation, both concerning food uptake
373 and food transport (see Table 1 and Figures 5-7). The slow open phases (SO) are not obligatory.
374 The gape cycle often includes a phase of retaining maximum gape (see Table 1, Figure 3, 5). In
375 turtles, the maximum gape phase (MG) was described for the gape cycle in *Cuora sp.* (Natchev
376 et al., 2009, 2010) and was confirmed for kinostrnids (Natchev et al., 2011). The presence of a
377 prolonged maximum gape phase (MG) can be easily overlooked when the frame rate of the film
378 sequence is not high enough (i.e., step between successive frames over 10 milliseconds). Thus, it
379 may be present in other turtles but was not taken into account by the calculations of the
380 kinematical profile (see Stayton, 2011; Nischizawa et al., 2014).

381 The GCM presupposes that the start of hyoid retraction coincides with the start of fast open
382 phase (FO). However, our calculations (see Table 1 and Figure 5) demonstrate that in *M. emys*
383 the hyoid retraction in the food transport cycle starts shortly prior reaching peak gape. The same

384 pattern was detected by the investigation of aquatic, semi-aquatic, but also predominantly
385 terrestrial cryptodirans (Natchev et al., 2008, 2009, 2010, 2011).

386

387 **Relations between the habitat preferences and the diet in turtles**

388 In the evolution of the testudinids there is a clear shift not only in the habitat preferences
389 (from aquatic to terrestrial), but corresponding shifts are also seen in dietary preferences. In that
390 taxon it manifests in a tendency toward herbivory. Most of the recent tortoises rely on diets
391 mainly composed of plant material (for overview see Pritchard, 1979; Ernst et al., 2000; Bonin et
392 al., 2006). The partly carnivorous lifestyle of *Manouria sp.* (Bonin et al., 2006) may be a relic of
393 the carnivorous diet of the ancestor of the tortoises and supports the transitional status of the
394 genus.

395 Apparently the feeding media (air vs. water) and the dietary shift had a large influence on
396 the overall feeding behaviour of the testudinids (see Bels et al., 2008). The suction mechanism
397 was lost and replaced by a jaw food prehension system (this study) or by “lingual prehension”
398 (Wochesländer et al., 1999; Bels et al., 2008). Probably, the switch to herbivory determined the
399 reorganisations in the morphology of the jaw muscle system and the proportions of the skull in
400 tortoises (see Werneburg 2011, 2012, 2013). By feeding predominantly on plants (immobile
401 items), the tortoises may prolong the duration of the food uptake cycles and have more time to
402 adjust their prehension kinematics to every single feeding situation.

403 We propose that the habitat preferences and the diet change in turtles are firmly correlated
404 (e.g. Bels et al., 2008; Werneburg, 2014). The overall rigid design of the turtle ‘body plan’
405 hinder the animals to actively hunt for agile prey in terrestrial environments (King, 1996). We
406 hypothesise that this statement is also valid for the terrestrial stem turtles and that these animals

407 were predominantly herbivorous (sensu King, 1996). In aquatic turtles, in contrast, the buoyancy
408 of the water overrides the shell-caused restrictions of mobility and also suction feeding can be
409 applied for carnivorous feeding. Those advantages might have been the key factor for the turtles
410 to become aquatic (and carnivorous) in the Jurassic. There may be several reasons for the
411 secondary terrestriality in tortoises and presumably one of the main was the inter- and
412 intraspecific concurrence for food resources.

413

414 CONCLUSIONS

415

416 We propose that the ancestral food uptake mode in tortoises was jaw based when feeding on
417 land. During the shift from aquatic to terrestrial lifestyle, including a shift from aquatic to
418 terrestrial feeding biology, the *Manouria* (and most likely also *Gopherus*) “lineage” had retained
419 pure jaw prehension in food uptake. The hyolingual complex in that lineage exhibits the typical
420 morphological features of tortoises that feed exclusively on land (see Bramble, 1973; Winokur,
421 1988; Heiss et al., 2011), such as an enlarged fleshy tongue with abundant papillae, a complex
422 tongue musculature, a relatively small and mainly cartilaginous hyoid and hypoglossum. The
423 evolutionary shift in the morphology of the hyolingual complex was apparently primed by the
424 optimisation of the food transport behaviour and not for food uptake. We suggest that the
425 involvement of the tongue during food uptake found in the derived extant tortoises serves as a
426 tactile sensory tool for the localisation of the food item prior to jaw prehension. Thus, the tongue
427 is not used as the main food collecting organ in modern tortoises and the food uptake mode
428 represents a derived jaw prehension system.

429

430 **ACKNOWLEDGEMENTS**

431

432 We would like to thank Josef Weisgram, Andreas Wanninger, Patrick Lemell, Christian
433 Beisser and Thomas Schwaha (Department for Integrative Zoology, University of Vienna) for
434 providing material and suggestions for the executions of our experiments. Alexander
435 Westerström contributed sorely to the revision of our manuscript. Stefan Kummer, Katherina
436 Singer, Monika Lintner and Marion Hüffel are acknowledged for the careful housing of the
437 animals. The reviewers provided helpful comments and suggestions to improve our paper. The
438 study was funded by the FWF Austrian Science Fund, Project no. P20094-B17 on which E.H.
439 and N.N. were employed and the Advanced Postdoc Mobility fund P300P3_158526 of the Swiss
440 National Science Foundation granted to I.W.

Figure 1 (on next page)

Figure 1

Phylogeny of turtle clades with a focus on Testudinoidea. Interrelationship following Thomson and Shaffer (2010). Major evolutionary changes are listed; for details see text. Three modes of terrestrial food uptake are illustrated. A) Jaw prehension; the tongue is not protruded and is only used for food transport (Geoemydida, Manouria). B) Jaw prehension; the elongated tongue is protruded during prehension but does not contact the food and is only used for food transport (Emydidae). C) Prior to jaw prehension, the tongue contacts the food (advanced tortoises).

2

Figure 2

Selected frame from a high-speed video sequence (500 frs) of food transport in *Manouria emys*, showing the landmarks used for kinematic analyses: C, rostral tip of sagittal line of the carapace, Hy, hyoid at the basis of ceratbranchial I; LJ, tip of the lower jaw; P, posterior most point of crista supraoccipitale; TT, tip of the tongue; Tv, ventral most point of the tympanum at the position of the jaw joint; UJ, tip of the upper jaw; grid 10x10 mm. Abbreviations in Appendix 1.

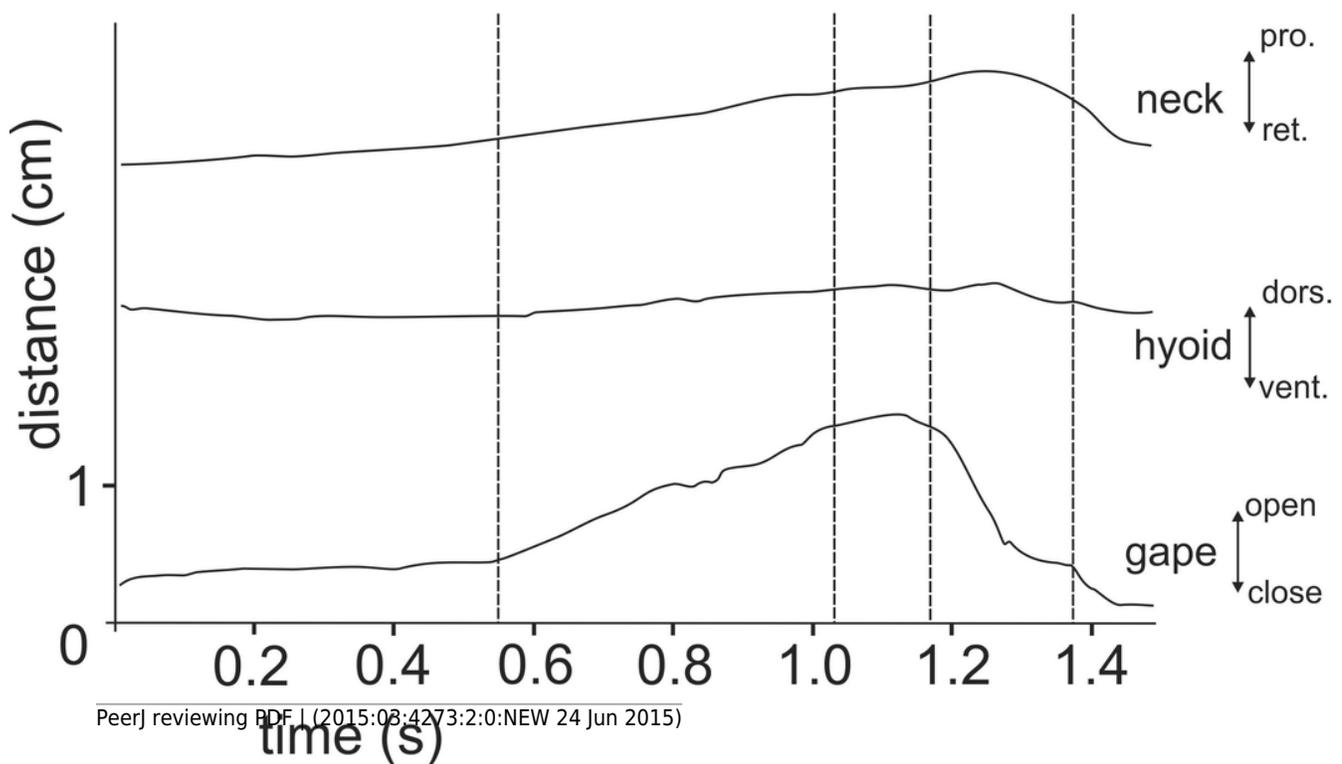

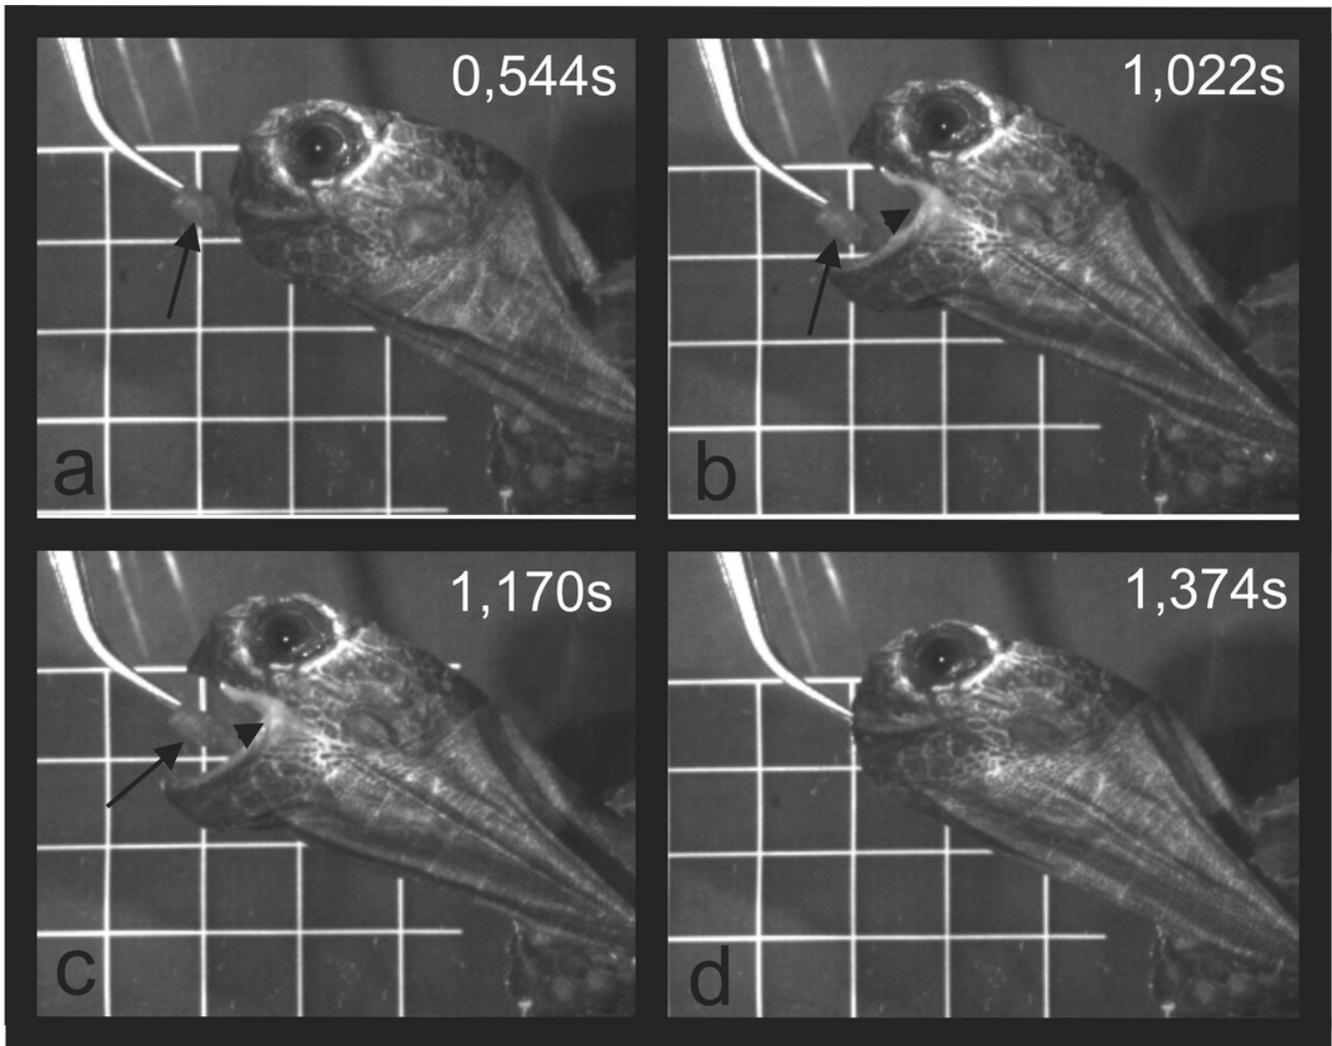

3

Figure 3

Selected frames and graphics (based on a high-speed video with 500 frs) represent the movements of jaws, hyoid and t head during terrestrial food uptake in *Manouria emys* when feeding on pieces of beef heart; a, slow open phase end (lacking discrete SOI and SOII); b, fast open end; c, fast close start; d, fast close end; arrows indicate the position of the food item; arrowheads represent the position of the tip of the tongue; grid 10x10 mm.

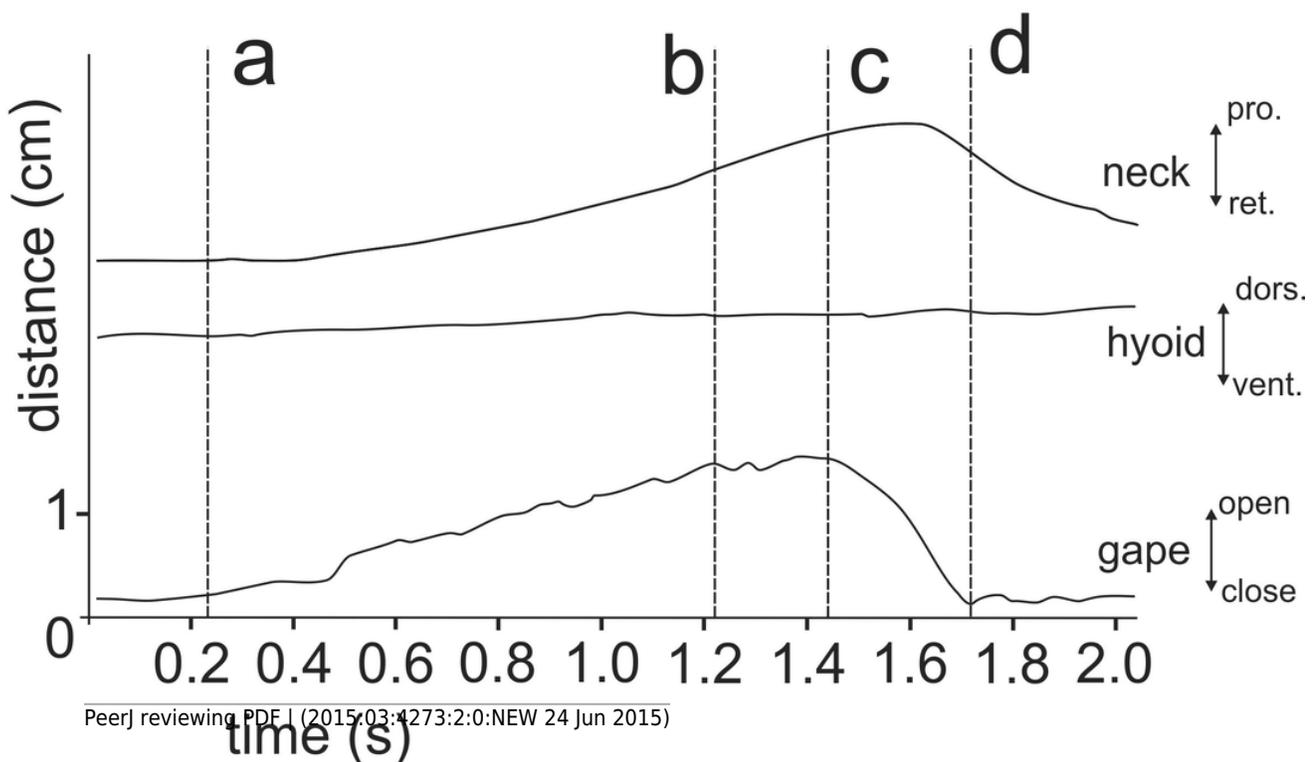

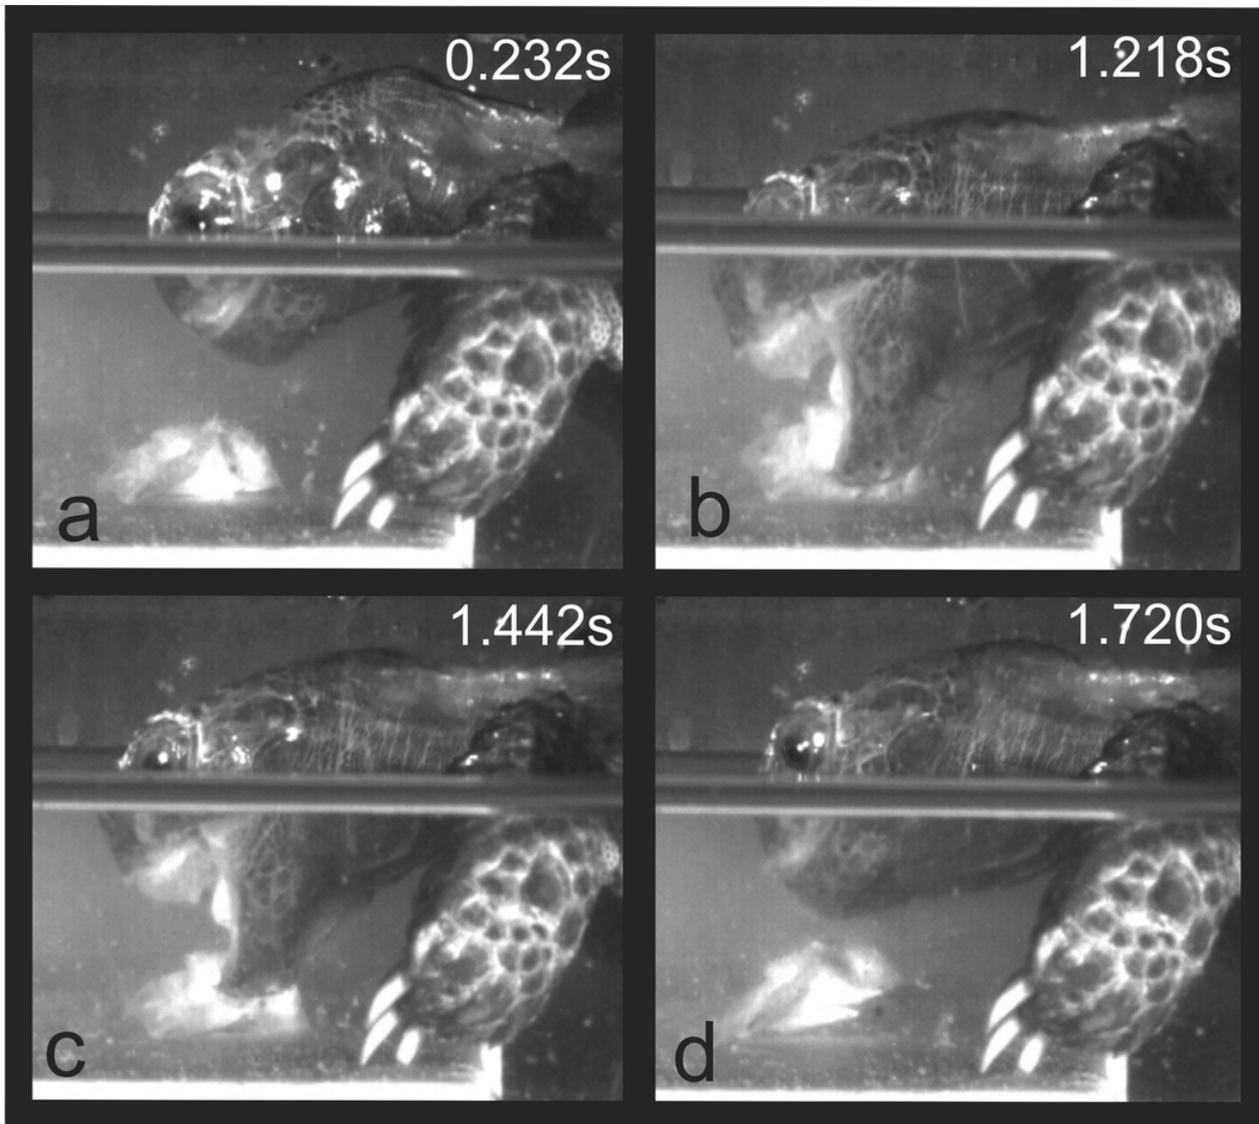

Abbreviations in Appendix 1.

4

Figure 4

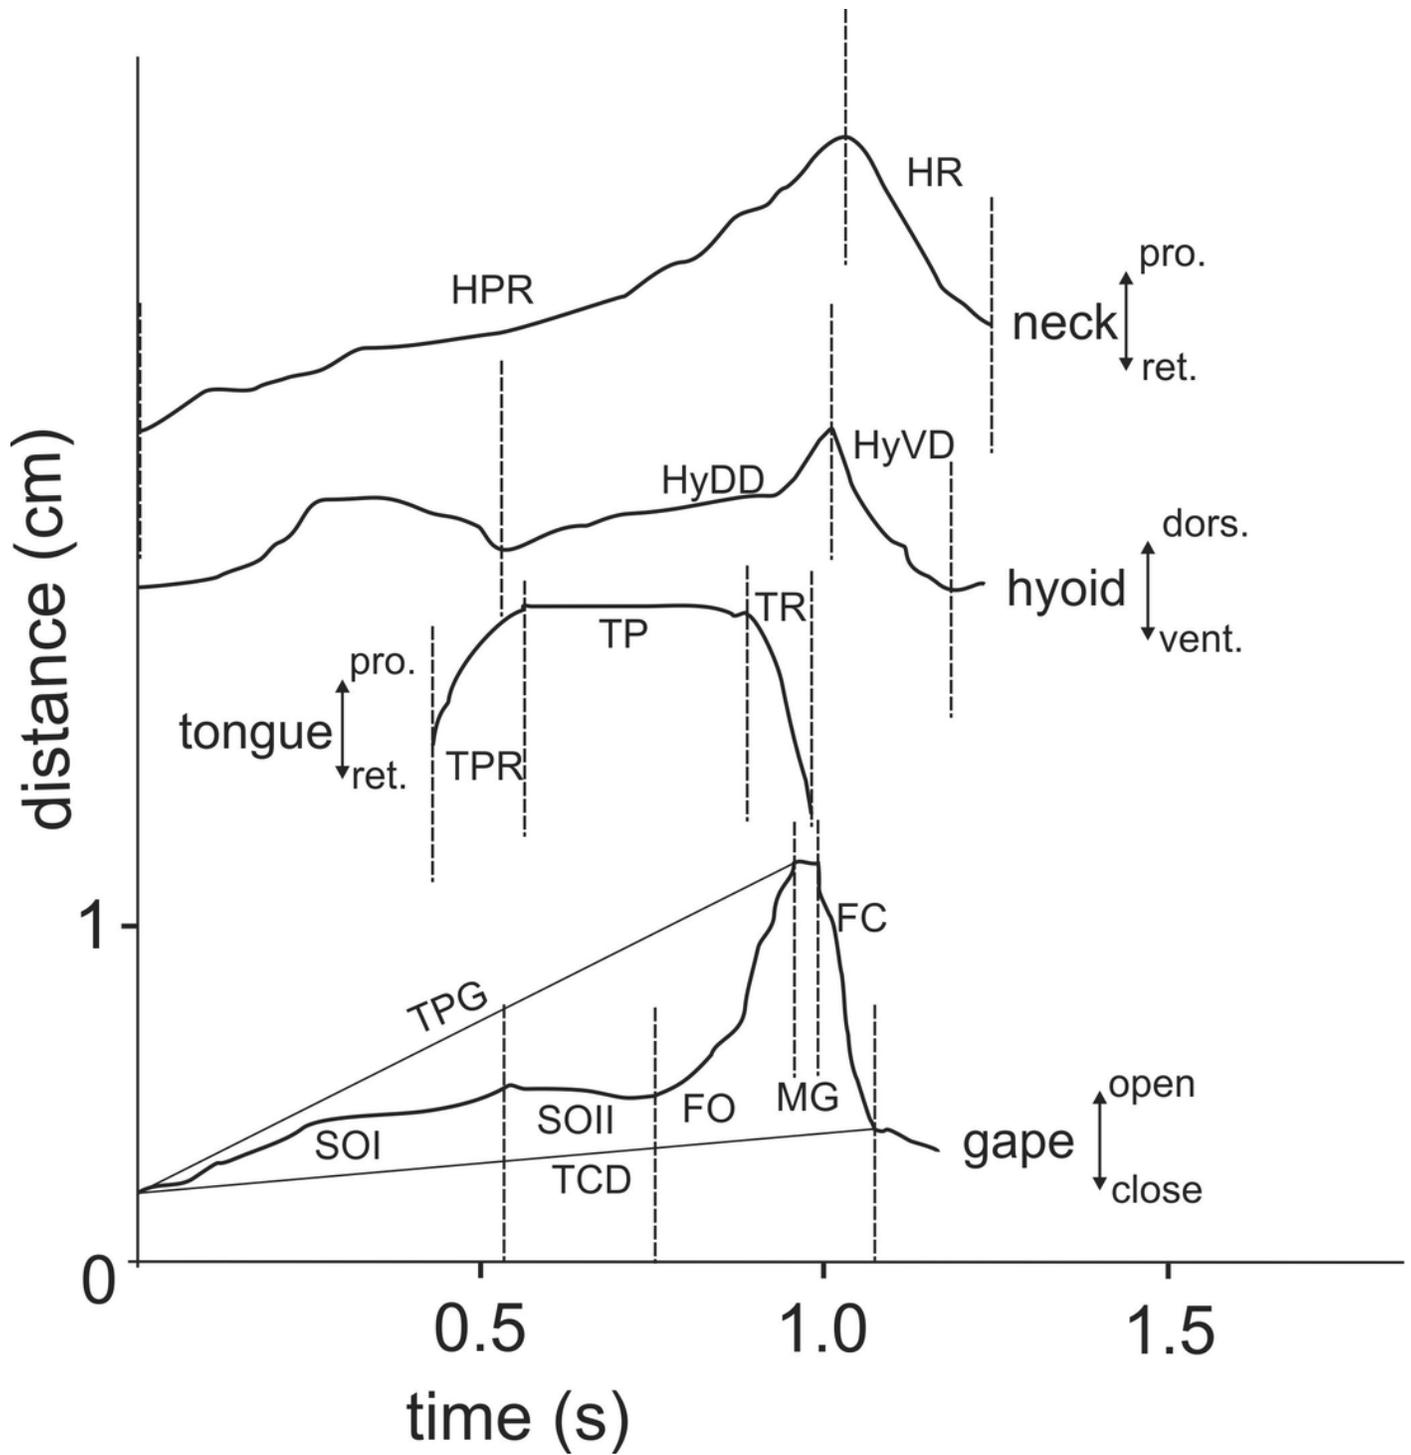

Selected frames and graphics (based on high-speed video with 250 frs) showing the movements of jaws, hyoid, and head during attempts of aquatic food uptake in *Manouria emys*; a, start of the gape cycle; b, end of jaw opening; c, maximum gape end; d, fast closure end; note the lack of movement of the hyoid complex during the whole cycle; grid 10x10 mm. Abbreviations in Appendix 1.

5

Figure 5

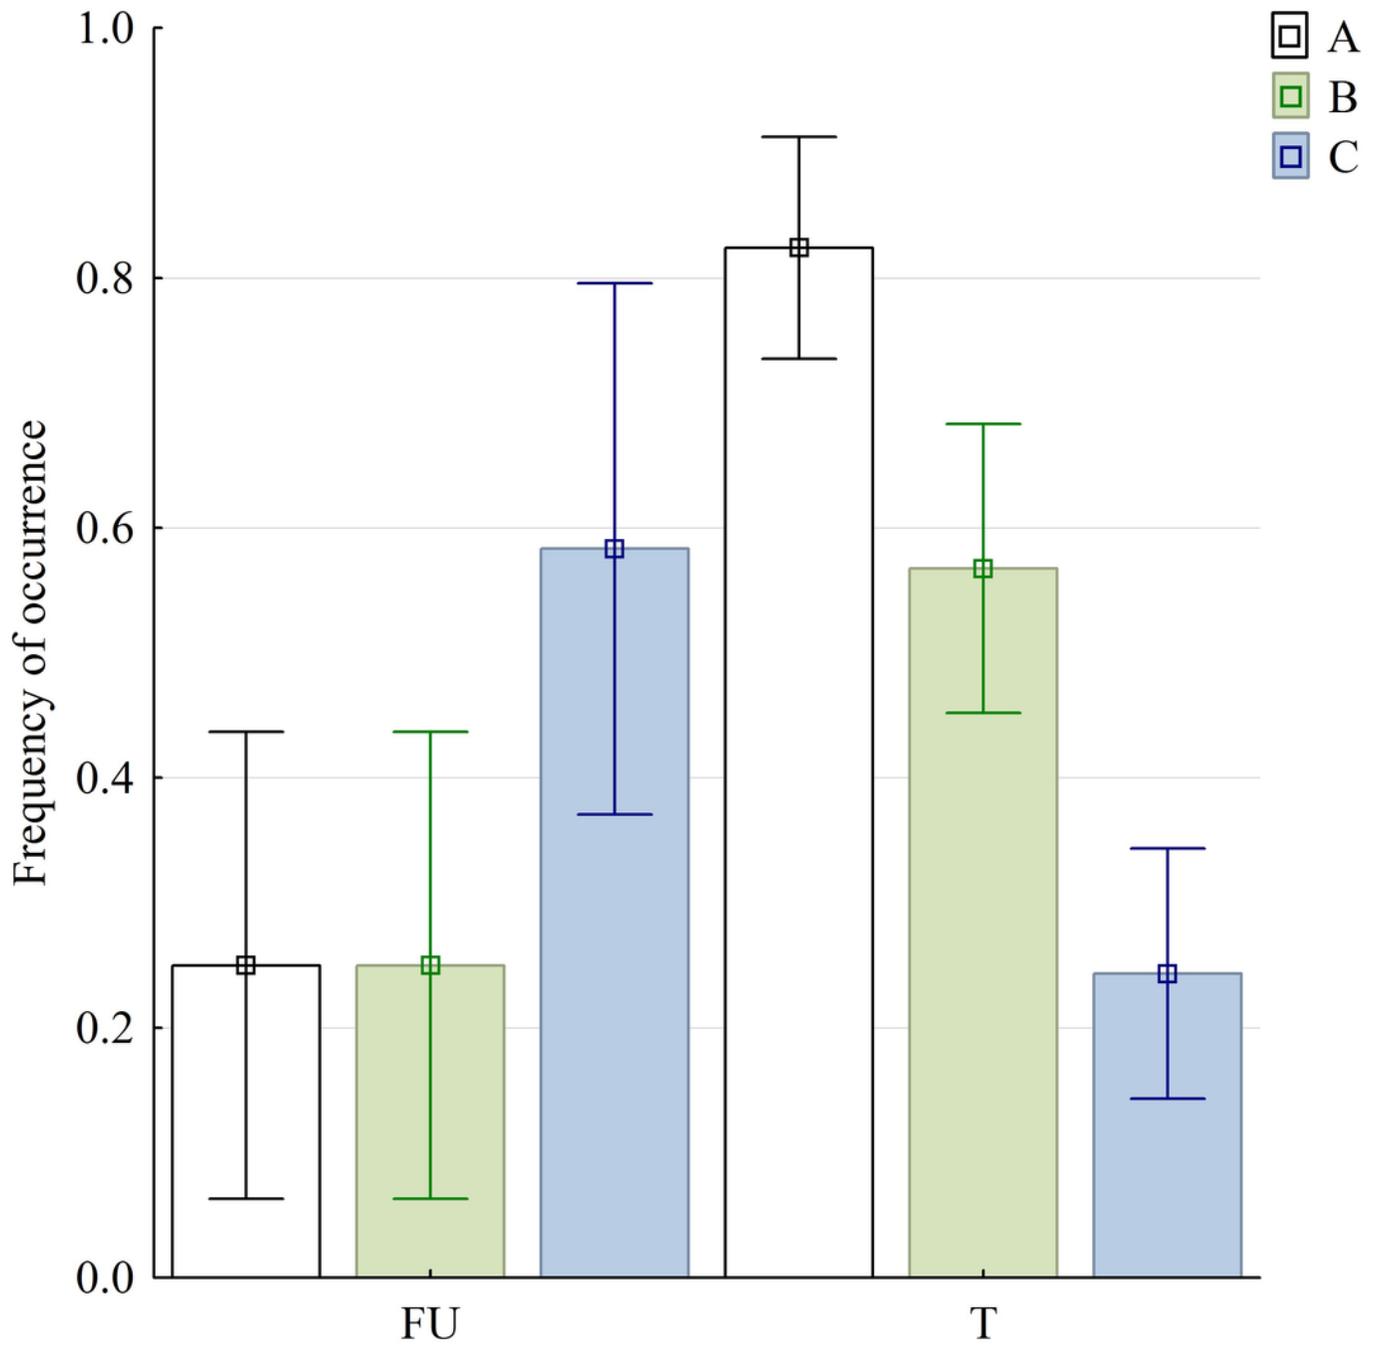

Selected graphics (based on a high-speed video with 500 fr/s) showing the movement patterns of jaws, hyoid, tongue and head during terrestrial food transport in *M. emys*; note the delay in hyoid ventral displacement relative to the start the retraction of the tongue tip, as well as the delay of both the tongue retraction and hyoid retraction relative to the start of the FO phase. Abbreviations in Appendix 1.

6

Figure 6

Graphical representation of three selected variables in food uptake (FU) and food transport (T) phases. Bars are denoted by their mean values and whiskers present the 95% CI; A, sequences with discrete SO and FO phases; B, sequences with no detectable split of discrete slow gape phase (SOI and SOII were inseparable); C - sequences with lacking MG phase. Abbreviations in Appendix 1.

7

Figure 7

Canonical centroid plots of three *Manouria emys* specimens (T1-T3), centroid scores for each individual and measurement repetition in food transport phase.

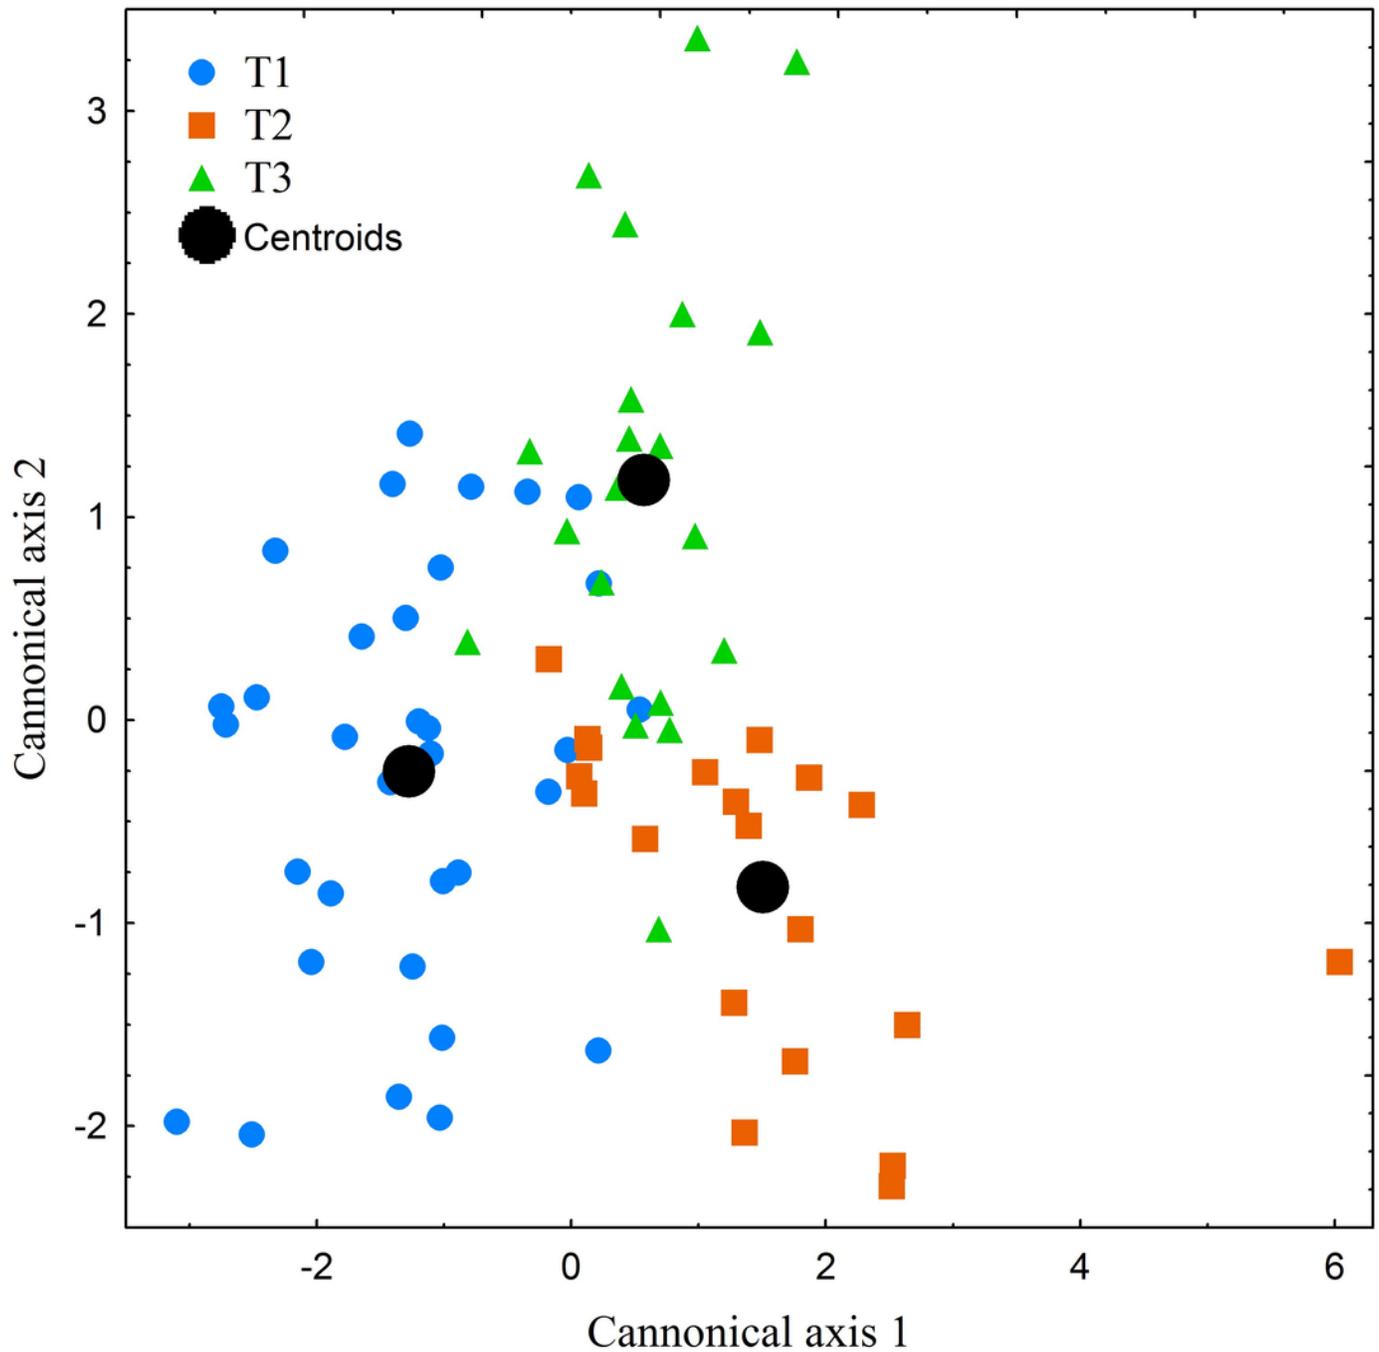

Table 1 (on next page)

Table 1

Variables describing the feeding process in *Manouria emys*, present as means \pm SD; n, sample size; *, significant differences ($\alpha=0.05$) among individuals in the ingestion phase (P1), in the transport phase (P2), and between both mode (P3); n.c., p value not calculated.

Abbreviations in appendix 1.

1
