Multiple lineages of birds have independently evolved foraging strategies that involve catching aquatic prey by striking at them through the water's surface. Diurnal, visual predators that hunt across the air-water interface encounter several visual challenges, including sun glint, or reflection of sunlight by the water surface. Intense sun glint is common at the air-water interface, and it obscures visual cues from submerged prey. Visually-hunting, cross-media predators must therefore solve the problem of glint to hunt effectively. One obvious solution is to turn away from the sun, which would result in reduction of glint effects. However, turning too far will cast shadows over prey, causing them to flee. Therefore, we hypothesized that foraging herons would orient away from, but not directly opposite to the sun. Our ability to understand how predators achieve a solution to glint is limited by our ability to quantify the amount of glint that free-living predators are actually exposed to under different light conditions. Herons (*Ardea* spp.) are a good model system for answering questions about cross-media hunting because they are conspicuous, widely distributed, and forage throughout a variety of aquatic habitats, on a variety of submerged prey. To test our hypothesis, we employed radiative transfer modeling of water surface reflectance, drawn from optical oceanography, in a novel context to estimate the visual exposure to glint of free-living, actively foraging herons. We found evidence that *Ardea* spp. do not use body orientation to compensate for sun glint while foraging and therefore they must have some other, not yet understood, means of compensation, either anatomical or behavioral. Instead of facing away from the sun, herons tended to adjust their position to face into the wind at higher wind speeds. We suggest that radiative transfer modeling is a promising tool for elucidating the ecology and evolution of air-to-water foraging systems.

19 **Abstract**

20 Multiple lineages of birds have independently evolved foraging strategies that involve catching
21 aquatic prey by striking at them through the water's surface. Diurnal, visual predators that hunt
22 across the air-water interface encounter several visual challenges, including sun glint, or
23 reflection of sunlight by the water surface. Intense sun glint is common at the air-water interface,
24 and it obscures visual cues from submerged prey. Visually-hunting, cross-media predators must
25 therefore solve the problem of glint to hunt effectively. One obvious solution is to turn away
26 from the sun, which would result in reduction of glint effects. However, turning too far will cast
27 shadows over prey, causing them to flee. Therefore, we hypothesized that foraging herons would
28 orient away from, but not directly opposite to the sun. Our ability to understand how predators
29 achieve a solution to glint is limited by our ability to quantify the amount of glint that free-living
30 predators are actually exposed to under different light conditions. Herons (*Ardea* spp.) are a
31 good model system for answering questions about cross-media hunting because they are
32 conspicuous, widely distributed, and forage throughout a variety of aquatic habitats, on a variety
33 of submerged prey. To test our hypothesis, we employed radiative transfer modeling of water
34 surface reflectance, drawn from optical oceanography, in a novel context to estimate the visual
35 exposure to glint of free-living, actively foraging herons. We found evidence that *Ardea* spp. do
36 not use body orientation to compensate for sun glint while foraging and therefore they must have
37 some other, not yet understood, means of compensation, either anatomical or behavioral. Instead
38 of facing away from the sun, herons tended to adjust their position to face into the wind at higher
39 wind speeds. We suggest that radiative transfer modeling is a promising tool for elucidating the
40 ecology and evolution of air-to-water foraging systems.

41

42 **Introduction**

43 Birds have repeatedly, and independently, evolved foraging strategies that involve detecting prey
44 in water, and striking at them through the air-water interface. To do so successfully, they must
45 contend with a number of visual challenges imposed by the optical properties of the water itself.
46 First, water surfaces can reflect light. Sun glint (hereafter, “glint”) refers to the reflection of
47 sunlight by a water surface, directly toward the viewer (Hochberg et al., 2011; Preisendorfer &
48 Mobley 1986). Glint obscures detection of upwelling light from beneath the surface of the water,
49 making it more difficult to see objects below the surface. Humans experience glint as visible
50 bright spots on the surface of the water. Glare is the visual discomfort from the direct reflection
51 of the sun light into their eyes (e.g., Signoroni et al., 2020).

52

53 Cross-media predators, by definition, are attempting to locate submerged prey, and therefore we
54 expect them to have evolved ways to compensate for the effect of glint. One obvious method of
55 reducing the effect of glint is to turn away: an animal that forages at the air-water interface
56 should orient itself generally away from the sun under clear sky conditions if it aims to reduce
57 visual exposure to glint. But by how much? The amount of glint exposure is a complex function
58 of the viewing direction, field of view of the detector or eye, topography of a wind-blown sea
59 surface, sun elevation and the spectral distribution of light.

60

61 Radiative transfer modeling, used in optical oceanography, has shown that glint is generally
62 reduced with an increasing difference in bearing from the sun (Mobley, 1999). For example,
63 assuming 5 m/s wind, a sun elevation of 60° , and a viewing angle looking 40° downward with
64 respect to the horizon, the sea surface would reflect only about 3% of the skylight incident upon

65 the sea surface for an animal viewing the sea surface facing directly opposite (180°) to the sun's
66 bearing. This percentage remains fairly similar until the viewer is facing perpendicular (90°) to
67 the sun's bearing, but begins to rise fairly quickly thereafter, to about 12% when facing directly
68 into the sun's bearing (Fig. 7 in Mobley, 1999). Under higher wind conditions and/or when the
69 sun is directly overhead (sun elevation 90°), orientation plays less of a role in reducing glint
70 (Zhang et al. 2017).

71

72 However, aquatic birds that hunt during the daytime must compensate for an additional
73 challenge: they must be within striking distance of their prey without causing prey to flee. Even
74 though glint is lowest at 180° to the sun's bearing, this is also the bearing that would cause a
75 predator to hunt directly into its own shadow. Several aquatic prey species are known to flee
76 when shadows pass overhead (e.g., Forward, 1977; Roberts, 1978; Yoshizawa & Jeffery 2008).
77 Therefore, a bird hunting across the air-water interface on a sunny day is likely trading off its
78 ability to see prey against the prey's ability to see them.

79

80 Mobley (1999) used radiative transfer modeling to show that when orienting a light detector at
81 about 135° away from the bearing of the sun while measuring remote sensing reflectance of
82 oceanic environments, the view of glint from the water surface is as low as possible over a wide
83 range of water surface and environmental conditions, without facing directly into self-shadow.
84 When the sun is overhead, however, orientation does not play a role in reducing glint. Mobley's
85 work, by extension, suggests that although there is a range of orientations at which birds could
86 reduce their exposure to glint, orienting at 135° to the bearing of the sun is the position in which

87 birds hunting across the air-water interface can best trade off reducing glint exposure, while also
88 avoiding casting shadows over potential prey. This logic assumes that birds see and perceive
89 glint as we do, an assumption that may not be justified, given the limitations on what we know
90 about avian vision. Nonetheless, there is some limited, and anecdotal evidence that they do and
91 that they may be trading off glint exposure against their own detectability as we predicted based
92 on Mobley's (1999) radiative transfer modeling. For example, Brown Pelicans (*Pelecanus*
93 *occidentalis*), were found to orient at an average of 135.6° to sun bearing (s.d. = 36.1°) as they
94 dove for fish (Carl, 1987). We have also documented that a tern diving for fish in a pond, did so
95 at about 140° to sun bearing, (documented on video three times in a row; it also did so several
96 times in a row before the lead author started recording the behavior; Supplemental Video 1).
97 Even the behavior of non-aquatic avian predators suggests that they experience challenges from
98 intense light conditions as we do. When the dark facial masks on Masked Shrikes (*Lanius*
99 *nubicus*) were painted white, they oriented away from the sun to a greater degree than shrikes
100 with black masks (Yosef, Zduniak & Tryjanowski, 2012.), suggesting that sunlight reflecting
101 from their facial feathers caused some visual discomfort.

102

103 Visual ecologists have demonstrated that orientation is important in visual function (e.g.,
104 Muheim, Phillips & Åkeesson, 2006; Penacchio et al., 2015), but there are only a handful of
105 studies that investigate orientation specifically with regard to hunting strategies (Carl, 1987;
106 King & LeBlanc, 1995; Yosef, Zduniak & Tryjanowski, 2012. ; Huveneers et al., 2015).
107 Orientation with respect to the sun may affect the ability to see prey, and therefore should be
108 explicitly considered when studying the foraging ecology of visual, cross-media predators. Here,
109 we examine the hypothesis that avian cross-media predators use body orientation to reduce glint

110 in their strike zones while hunting, and that they do so in a manner that trades off glint exposure
111 against self-shadow into their strike zones (Fig. 1). To test this hypothesis, we studied diurnal
112 herons of the genus *Ardea*, which belong to a clade of piscivorous birds that have been
113 specializing to hunt across the highly reflective air-water interface for over 50 million years
114 (Prum et al., 2015).

115

116 We studied, specifically, two daytime-active herons, Great Blue Herons (*Ardea herodias*) and
117 Great Egrets (*Ardea alba*; hereafter, “herons”). These species are good models for answering
118 questions about cross-media hunting because they are numerous, conspicuous, widely
119 distributed, and forage throughout a variety of aquatic habitats, on a variety of submerged prey.
120 If herons were using orientation to trade off glint and self-shadow, we predicted that they would:
121 a. orient in ways that minimize glint, and maximize the signal from upwelling light (i.e., the light
122 reflected by potential submerged prey items), as compared with what would be expected if heron
123 orientation were random, and b. specifically, we expect them to orient at an average of 135° to
124 the sun bearing. Great Blue Herons tend to be slightly more crepuscular than the more diurnal
125 Great Egrets (McNeil, Benoît & DesGranges, 1993). In gathering data from both, our intent was
126 to obtain generalizable information about how herons might compensate for glare while hunting
127 through the air-water interface, over a wide range of daylight conditions. We employed radiative
128 transfer modeling in a novel context to directly estimate the actual exposure of individual birds
129 to glint, on the basis of their orientation to the sun, the sun elevation, and light conditions.

130

131 We also considered the hypothesis that heron body orientation could be related to wind.
132 Orientation with respect to both sun position and wind direction have been widely recognized as
133 important physiological mechanisms by which animals regulate body and microhabitat
134 temperatures (e.g., Orr, 1970; Walsberg, 1993; Fortin Larochelle & Gauthier, 2000; and many
135 others). If herons were orienting to prevent loss of body heat, we predicted that heron orientation
136 would correlate with wind direction, particularly at higher wind speeds. In addition, because of
137 light reflecting from differently oriented wave facets, the advantages of orienting away from the
138 sun are also reduced under higher wind speeds compared to flat conditions. Hence, we predicted
139 that they would be more likely to face into the wind, regardless of sun position, as wind speed
140 increased.

141

142 **Materials & Methods**

143 In June 2013, January 2014, and January-February 2015, we opportunistically obtained 279
144 observations of 68 free-living, foraging herons in southern Florida (Fig. 2). As our study
145 involved focal animals in the field, it was not possible to record data blind. In areas where an
146 individual heron seemed to be actively guarding a foraging area (e.g., by chasing other
147 individuals away), we sampled the site only once. However, in areas where there were several
148 herons foraging, we were able to obtain observations of different individuals at the same
149 location. From a minimum distance of 20m, using binoculars (Nikon Monarch 3, 10x42), we
150 observed individual foraging herons, and recorded up to 6 instantaneous samples of their body
151 and head orientations, or fewer, if the individual flew away. In 2013, instantaneous samples were
152 spaced 5 minutes apart, while in 2014 and 2015 samples were taken every two minutes. At the
153 beginning of each observation, we noted the date, time, and the species. We noted sun visibility

154 and cloud cover, as our predictions depended on the sun's being visible. We also noted wind
155 bearing and speed category: calm/virtually undetectable (approximately 0 m/s); leaves rustle
156 (approximately 5 m/s); branches sway (approximately 10 m/s); trees sway (approximately 15
157 m/s). If the wind speed and direction were noticeably variable, we updated this information
158 during every instantaneous sample. We also noted whether the bird's shadow was obstructed
159 (e.g., by emergent vegetation) during every instantaneous sample. The orientation of the birds'
160 bodies and heads, and the orientation of the wind were estimated in the field with a handheld
161 compass. Exact sun bearing and elevation were later retrieved from the National Oceanographic
162 and Atmospheric Administration's online sun position calculator, based on the time recorded for
163 each instantaneous sample in each observation. Also, the approximate latitude and longitude of
164 each location were obtained from Google Earth. We were then able to calculate the estimated
165 orientation differences between the birds and the sun, and between the birds and the wind, to use
166 in analyses. After the final field season, we quantified error associated with estimating heron
167 orientation. To do so, a field assistant placed a Great Blue Heron lawn ornament in 24 different
168 directions and recorded its real orientation while the lead author (who made all compass
169 measurements in the field) estimated each orientation from a distance of 20m, with the same
170 binoculars that were used in the field (Nikon Monarch 3, 10x42). Our estimations of body
171 orientations of a Great Blue Heron lawn ornament were within an average of 9.3° (s.d. = 7.5° , N
172 = 24). Therefore, we believe our estimates of heron body orientation are sufficiently accurate to
173 test the hypotheses of interest in this study.

174

175 Using the *HydroLight*[®] radiative transfer model (Mobley, 1998), we estimated absolute and
176 relative glint in the green spectrum (550 nm). We defined relative green glint as green glint

177 divided by the all incoming green light in the field of view (i.e., water-leaving radiance plus
178 radiance reflected by the sea surface). The relative measure is a type of signal-to-noise
179 measurement. We used green light exclusively, because we wanted our estimates of glint to be
180 conservative, in that they would maximize background brightness and minimize relative glint. In
181 general, green light penetrates furthest into coastal waters (Kirk, 2011), and is therefore the light
182 most available to be reflected by the seafloor, and exit the water as upwelling light. Therefore, in
183 comparison, the contribution of glint is lower relative to the upwelling light in the green
184 spectrum versus in other spectral regions.

185

186 We also used conservative but realistic values representing conditions in Florida, and conditions
187 for wild foraging herons, for all variables in *HydroLight*®, to obtain conservative estimates for
188 glint. We modeled reflectance for a light-colored sand (oid), which is both typical of many
189 Florida coasts, but also creates high reflectance off of the sea floor, thus increasing the relative
190 signal of upwelling light as compared with glint. We used a medium value for light attenuation
191 in the water by indicating that light would attenuate by half for every meter below the sea surface
192 (McPherson et al., 2011). We also used a water depth of 28 cm based on multiple records of the
193 water depths in which herons forage in Florida (Powell, 1987; Bancroft, Gawlik & Rutchey,
194 2002). We ran the model under two wind conditions: 5 m/s, and 10 m/s. We also ran each of
195 those models under two light conditions: where the sun was visible, and where it was obstructed
196 by clouds.

197

198 To continue in our effort to gain conservative absolute and relative estimates of green glint, we
199 also only retrieved outputs from a viewing direction of 40° to the nadir, because this viewing
200 direction minimizes the proportion of skylight reflected at the sea surface under multiple wind
201 speed scenarios (see Fig. 6 in Mobley, 1999).

202

203 We generated interpolated heat maps of absolute and relative glint in MATLAB (2015), using
204 estimates based on sun elevations of 0° , 15° , 30° , 45° , 60° , 75° and 90° from the horizon.
205 Finally, we used two-sample t-tests to compare estimates of visual exposure to glint for each
206 heron body orientation with estimates of glint exposure that we would expect if heron orientation
207 were random, using coordinates generated from random.org, to test the prediction that herons
208 would orient in a manner that reduced visual exposure to glint.

209

210 All other statistical analyses were performed in R (R Core Team, 2013). To examine heron
211 orientation relative to sun position, we used only instantaneous samples where herons' heads
212 were oriented in the same direction as their bodies, and where the herons' shadows were cast
213 over water (i.e., unobstructed by emergent vegetation, and not cast onto land), and the sun was at
214 least partially visible. To test the prediction that herons would orient 135° to the bearing of the
215 sun, we regressed the absolute difference between sun bearing and heron bearing (i.e. heron
216 orientation relative to sun bearing), against sun elevation, using generalized estimating equations
217 (Liang & Zeger, 1986) with the "geepack" package in R (Højsgaard, Halekoh & Yan, 2006). We
218 used sun elevation as the independent variable instead of time, so that we were comparing heron
219 orientations under consistent sun positions each day. To account for use of multiple observations

220 for some individual herons, which are likely correlated, we used generalized estimating
221 equations (GEE). GEE, an extension of generalized linear models, is a statistical approach for
222 estimating regression parameters with clustered data (Liang & Zeger, 1986). We used
223 “individuals” as grouping factors in our GEE model. We also used unstructured correlation
224 matrices because we were unsure of what, if any, kind of relationship there might be among
225 intra-individual data points. We then used the Wald-statistic to test the overall significance of the
226 regression. As there is no package to estimate power or effect size based on a Wald test, at
227 present, we estimated the effect size of our findings using a power analysis based on a
228 generalized least squares linear model of our data using the “pwr” package (Champely, 2015).
229 We similarly regressed the absolute value of the difference between wind and heron orientation
230 versus wind speed category; and the absolute value of the difference between sun and heron
231 orientation versus wind speed category as an ordered factor.

232

233 **Results**

234 Our prediction that herons would orient in a manner that suggested trading off reducing glint and
235 self-shadow in their strike zones was not supported. We detected no departures from random
236 orientation with respect to sun bearing in herons, across all sun elevations ($y = 89.37^\circ - 0.02x$;
237 $W = 0.003$; $p = 0.96$). This held true no matter whether we included the whole data set in the
238 analysis, or just the subset of the data from when both the sun and the heron’s shadows were
239 visible (Fig. 3a-b). The calculated effect size when regressing heron orientation relative to sun
240 bearing versus sun elevation was miniscule ($[r^2 / (1 - r^2)] = \sim 0.0002$).

241

242 Overlaying our orientation data onto our heat maps displaying absolute and relative estimates of
243 green glint added further evidence that herons are not using body orientation to reduce visual
244 exposure to glint (Fig. 4). We decided to use only the heat maps we generated for 5 m/s wind
245 speed for analyses because the heat maps generated for 10 m/s wind appeared nearly identical.
246 There was no difference between the glint estimated at each heron orientation to the sun and glint
247 that would be experienced at random, either in absolute ($t = 1.76$, $p = 0.08$) or relative estimates
248 of green glint ($t = 1.55$, $p = 0.12$) with a visible sun. With a completely obstructed sun, glint was
249 still no different from random for absolute ($t = 0.14$, $p = 0.89$), or relative estimates of green glint
250 ($t = 1.10$, $p = 0.27$).

251

252 In support of our last hypothesis, herons tended to face more into the wind with increasing wind
253 speed. With each increase in ordered categorical wind speed, herons faced about 31.70° ($SE =$
254 9.39°) further toward the sun ($W = 114$, $p = 0.0007$) (Fig. 5).

255

256 **Discussion**

257 Our data provide strong evidence that herons are not using body orientation with respect to sun
258 position as a behavioral mechanism for reducing glint in their strike zone. Herons, when foraging
259 through the highly reflective air-water interface, are not avoiding orienting in directions with the
260 highest estimated exposure to glint, whether in absolute terms, or relative to incoming light, and
261 they are not trading off glint and shadow in their strike zones.

262

263 Our data also showed that as wind speed increased, herons tended to face more head-on into the
264 wind. In retrospect, this is not surprising. One likely explanation for orienting to the wind is that
265 herons are orienting for thermoregulatory purposes. Facing into the wind has been shown to
266 decrease heat loss in birds (e.g., Fortin Larochelle & Gauthier, 2000).

267

268 Herons, and other cross-media hunters, may compensate for glint in other ways. Krebs &
269 Partridge (1973) hypothesized that Great Blue Herons tilt their heads and long necks toward the
270 sun – in a foraging behavior known as “head-tilting” (Meyerriecks 1962) – to effectively shift a
271 perceived area of glare out of their intended strike path. However, their idea was not fully tested,
272 and further research is required to assess whether herons are head-tilting to compensate for glint
273 effects, or has a different function. Relatedly, differences in head placement during foraging
274 might account for some variability in heron body orientation with respect to sun elevation.
275 Future research could investigate the direction of viewing, and eye movement in relationship to
276 glint.

277

278 Because light that is reflected from water surfaces is polarized, some form of polarization vision
279 could be useful to cross-media hunters. Theoretically, there are at least two ways to filter
280 polarized light: before the image is projected onto the retina, or after. For polarized light to be
281 filtered prior to reaching the retina, herons would need an anatomical feature capable of
282 excluding it (as polarized sunglasses would). However, we are unaware of any evidence for such
283 anatomical features in any natural visual systems. For polarized light to be filtered after reaching
284 the retina, we would suggest some neurological capability that allows herons to detect, and

285 subsequently ignore the polarized light as “noise”, similar to how we would filter out a din of
286 many voices while conversing with a friend in a crowded restaurant. This possibility seems much
287 more likely. There is considerable evidence that animals across many taxa can see patterns of
288 light polarization, including some behavioral evidence in birds (reviewed in Muheim, 2011). We
289 suggest that behavioral studies designed to detect whether avian cross-media predators exhibit
290 polarized light sensitivity would be fruitful for understanding the ability of these birds to hunt
291 successfully in the face of intense glint.

292

293 Herons may be a good system in which to look for a mechanism for polarization vision in birds
294 because they do not seem to be behaviorally compensating for glint. To date, we only have some
295 very basic details about herons’ visual anatomy. In Great Blue Herons, fine structures of the
296 pecten (Braekevelt, 1991), rods and cones (Braekevelt, 1994) and cone pigments (Braekevelt &
297 Young, 1994) have been studied. Their rod to cone ratio is also documented; it is 0.6:1, which
298 puts them in between the diurnal herons (e.g., the Tricolored Heron, *Egretta tricolor*, has a rod to
299 cone ratio of 0.3:1) and the nocturnal herons (e.g., the Yellow-crowned Night Herons,
300 *Nycticorax violaceus*, has a 2.3:1 rod to cone ratio; Rojas et al., 1999). Generally, higher rod to
301 cone ratios produce better night vision than lower rod to con ratios (Rojas et al., 1999). In Great
302 Egrets the only scholarly reference we found regarding their eye anatomy dates back to a 1917
303 book, in which the basic macrostructure of the pecten, and the “dominant color” of the fundus
304 were described (Wood, 1917).

305

306 Although we have suggested some avenues of study to investigate other potential behavioral or
307 anatomical mechanisms for reducing glint exposure in herons, it is possible that there are cross-
308 media predators that do use body orientation to mitigate effects of glint. There is some anecdotal
309 evidence for this behavior in Brown Pelicans (*Pelecanus occidentalis*) and terns (Carl, 1987;
310 Supporting Information). Therefore, we suggest further study of body orientation relative to sun
311 bearing in these, and other, plunge-diving birds.

312

313 Lastly, we suggest continuing to use radiative transfer modeling to better understand the light
314 conditions that air-to-water cross-media predators face while foraging. This new tool might also
315 be useful for re-examining work from previous studies, for example on the physical conditions
316 that affect foraging success in piscivorous birds (e.g., Grubb, 1977; Bovino & Burt, 1979; Carl,
317 1987). Understanding the conditions under which birds view their prey will lead to deeper
318 understanding of their visual and behavioral ecology.

319

320 **Conclusions**

321 In this study, we tested the hypothesis that foraging herons would orient away from the sun to
322 avoid experiencing glare due to sunlight reflecting from surfaces of the water bodies in which
323 they hunt. Field observations of heron body orientation, along with our estimations of sun glint
324 via radiative transfer modeling provided evidence against our hypothesis; herons did not tend to
325 orient in a manner that reduced their exposure to glint, but rather oriented to face the wind at
326 higher wind speeds. Radiative transfer modeling, a tool from optical oceanography, was useful

327 for investigating visual and behavioral ecology in this air-to-water foraging system, and should
328 be considered in similar studies.

331 We are grateful to the Smithsonian Marine Station, where a portion of these data was collected
332 while HMB was working under the advisement of C.S. McKeon. For edits and helpful
333 commentary, we are also grateful to T.W. Cronin, the entire Ornithology Group at the University
334 of Connecticut, Andrew Moiseff, Eric Schultz, the late Eldridge Adams, and reviewers.

Figure 1

Schematic representation of an overhead view of a foraging heron.

We predicted that herons would orient generally away from the sun to minimize visual exposure to glint; if they also avoid casting shadows over prey (which alert prey to their presence), we predict that they will orient at about 135° away from the bearing of the sun.

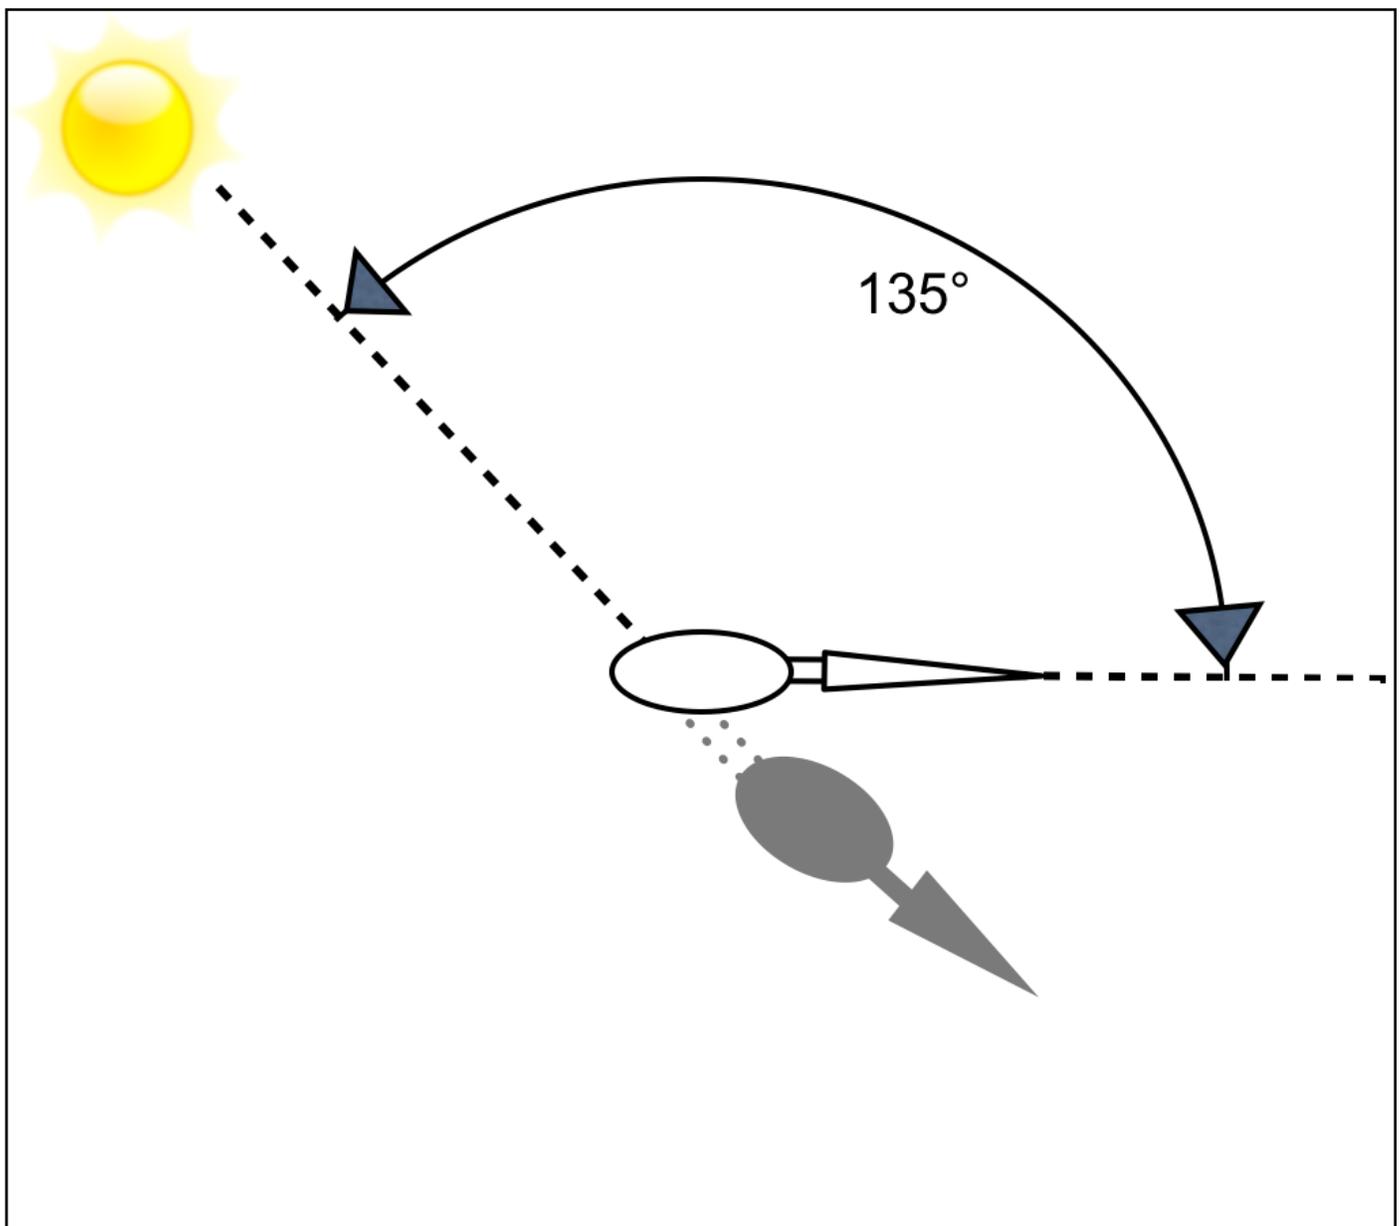

Figure 2

Locations at which herons were observed in southern Florida, USA.

Circles indicate where data were collected. Some circles overlap more than one sampling location. Image Credit: The map was cropped from the original, "Administrative Map of Florida," created by Eric Gaba, via Wikimedia Commons (c) 2008 (user ID: Sting, CC BY 3.0).

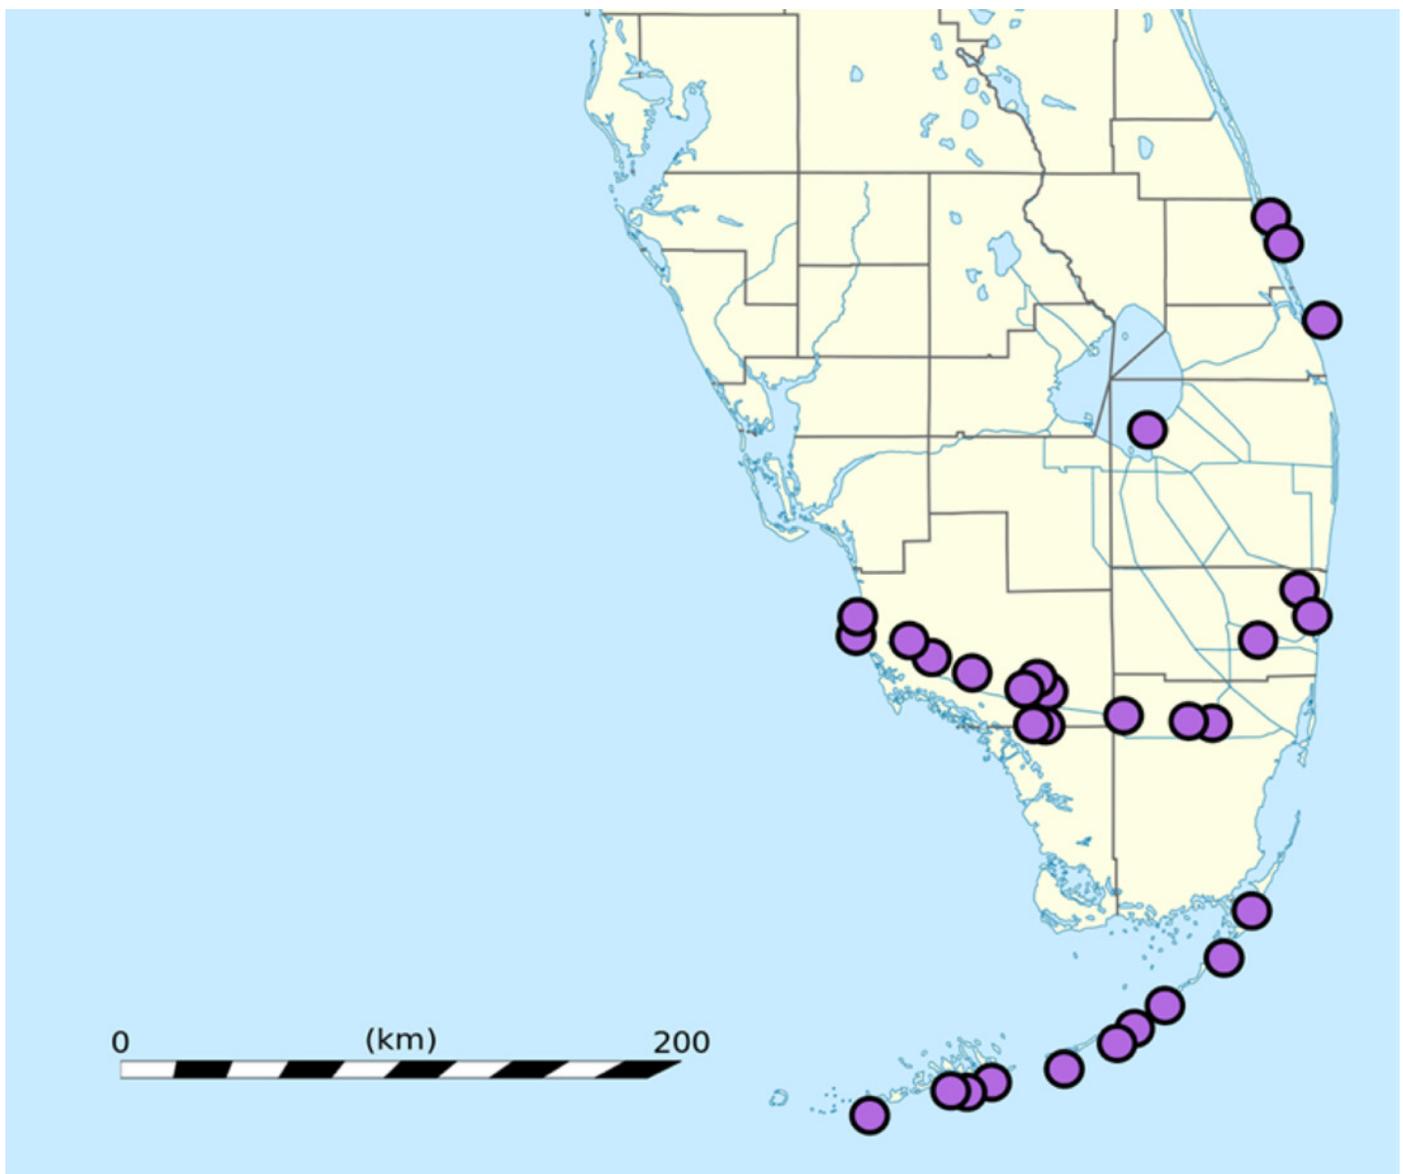

Figure 3

Scatterplots of our data, using points where heron's head and body orientations were in parallel.

In both graphs, 0° on the x-axis indicates that the sun is on the horizon, and 90° indicates that the sun is overhead. On the y-axis, 0° indicates that the heron was facing directly into the sun, and 180° indicates that the heron was facing opposite to the sun. **a.** Using the whole data set, note that heron orientation with respect to sun position does not support our predictions, but rather appears random ($p = 0.95$). **b.** Using only data points where the sun was unobstructed (e.g., by clouds) and the heron's shadow was unobstructed (e.g., by emergent vegetation) thins the data substantially, but does not change the overall lack of pattern ($p = 0.96$).

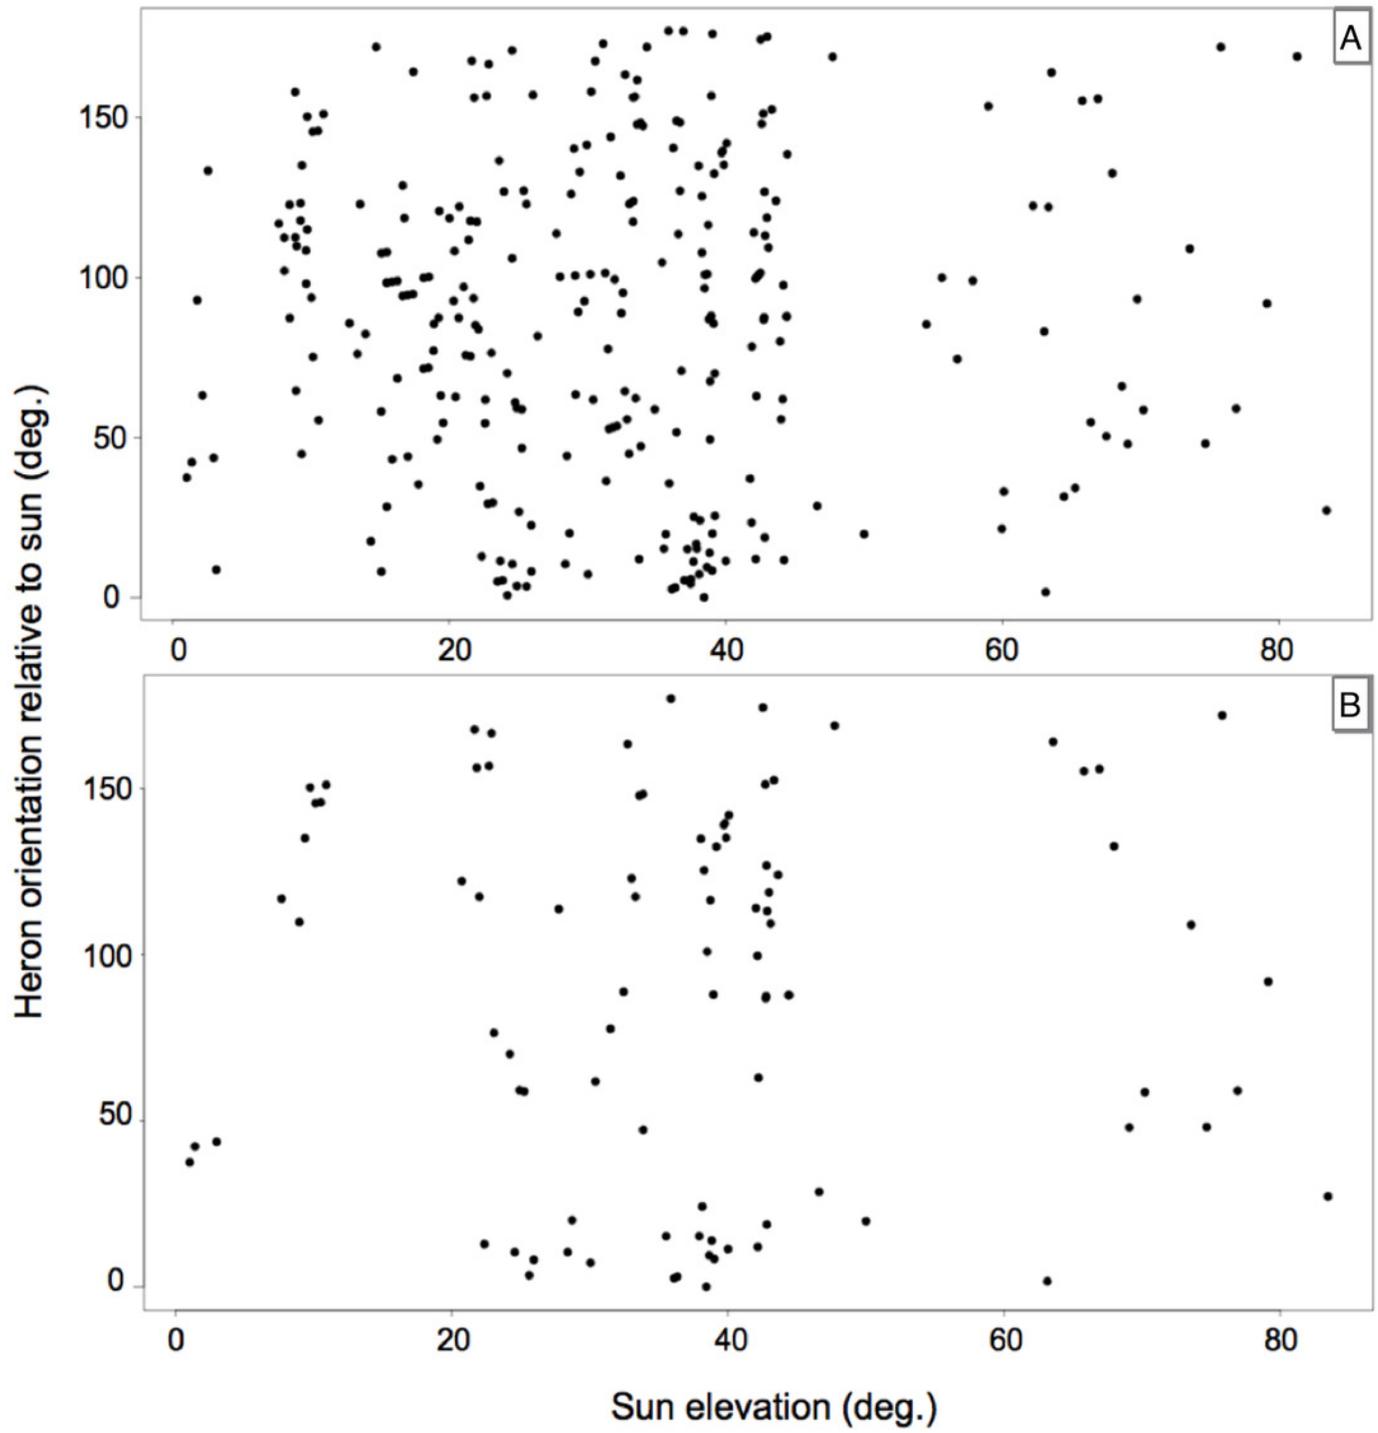

Figure 4

Heat maps that indicate measures of green sun glint (550 nm) directed at the viewer when wind is 5 m/s, by absolute (a, b) and relative (c, d) measures.

Our orientation data from Fig. 3b are superimposed on these heat maps by sun visibility: sun visible (left) and sun obstructed (right). Note that herons are orienting randomly, *and* they are foraging in “hot spots” where glint is maximized. (Heat maps for wind speeds of 10 m/s were nearly identical, and are not shown here.)

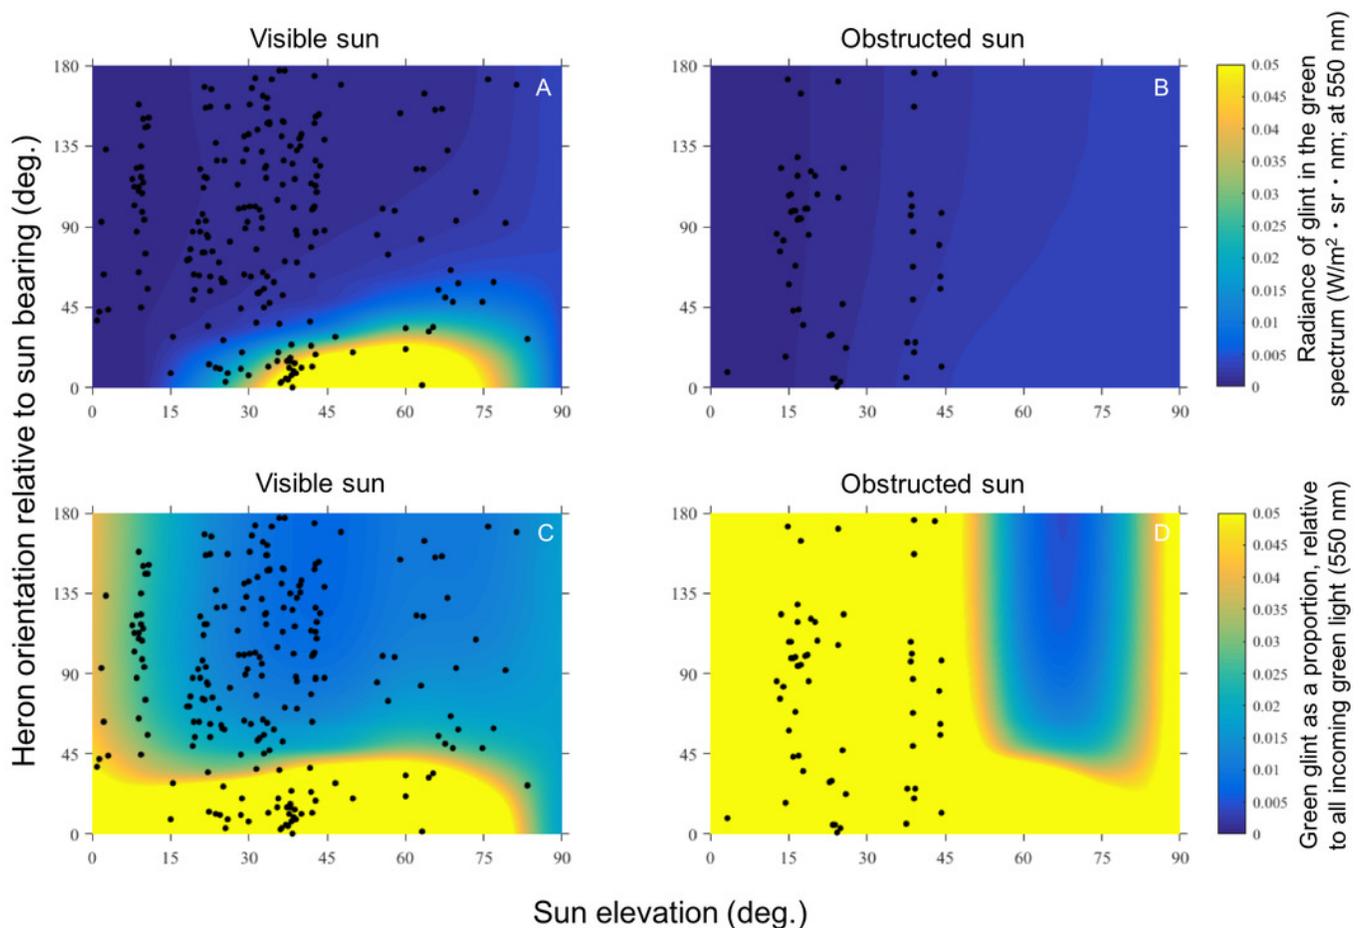

Figure 5

Box plot of heron orientation with respect to the bearing of the wind by wind speed category (0 = calm or ~0 m/s; 1 = leaves rustle or ~5 m/s; 2 = branches sway or ~10 m/s; 3 = trees sway or ~15 m/s).

On the y-axis, 0° indicates that the heron was facing directly into the wind, and 180° indicates that it was facing opposite to the wind. With each increase in ordered categorical wind speed, herons faced about 31.70° (SE = 9.39°) further toward the sun ($W = 114$, $p = 0.0007$).
