

Secondary nucleation overcomes seeding template in amyloid-like fibril formation

Katažyna Milto, Tomas Šneideris, Vytautas Smirnovas

Prions are infectious proteins where the same protein may express distinct strains. The strains are enciphered by different misfolded conformations. Strain-like phenomena have also been reported in a number of other amyloid-forming proteins. One of the features of amyloid strains is the ability to self-propagate, maintaining a constant set of physical properties despite being propagated under conditions different from those that allowed initial formation of the strain. Here we report a cross-seeding experiment using strains formed under different conditions. Using high concentrations of seeds results in rapid elongation and new fibrils preserve the properties of the seeding fibrils. At low seed concentrations secondary nucleation plays the major role and new fibrils gain properties predicted by the environment rather than the structure of the seeds. Our findings could explain conformational switching between amyloid strains observed in a wide variety of in vivo and in vitro experiments.

8 **Abstract**

9 Prions are infectious proteins where the same protein may express distinct strains. The strains are
10 enciphered by different misfolded conformations. Strain-like phenomena have also been reported
11 in a number of other amyloid-forming proteins. One of the features of amyloid strains is the
12 ability to self-propagate, maintaining a constant set of physical properties despite being
13 propagated under conditions different from those that allowed initial formation of the strain.

14 Here we report a cross-seeding experiment using strains formed under different conditions.
15 Using high concentrations of seeds results in rapid elongation and new fibrils preserve the
16 properties of the seeding fibrils. At low seed concentrations secondary nucleation plays the major
17 role and new fibrils gain properties predicted by the environment rather than the structure of the
18 seeds. Our findings could explain conformational switching between amyloid strains observed in
19 a wide variety of *in vivo* and *in vitro* experiments.

20

21 Introduction

22 Prions are infectious particles which play the main role in a group of fatal neurodegenerative
23 disorders, also known as the transmissible spongiform encephalopathies (TSE's). Prion diseases
24 propagate by self-replication of a pathogenic prion isoform (PrP^{Sc}) using cellular prion protein
25 (PrP^C) as a substrate (Prusiner, 1998; Collinge, 2001). Although structures of infectious forms of
26 PrP are still only partially defined, it is known that PrP^{Sc} is rich in beta-sheet structure and
27 demonstrates fibrillar morphology (Sim & Caughey, 2009; Colby & Prusiner, 2011). Different
28 conformations of PrP^{Sc} are responsible for variations in prion disease phenotypes and are usually
29 referred to as strains (Safar et al., 1998). For a long time prion protein was the only suspected
30 infective protein in humans, however recently there is growing evidence that proteins in other
31 amyloid-related diseases may spread via prion-like mechanisms (Lundmark et al., 2002; Soto,
32 Estrada & Castilla, 2006; Frost & Diamond, 2010; Brundin, Melki & Kopito, 2010; Eisele et al.,
33 2010; Angot et al., 2010; Westermark & Westermark, 2010; Masuda-Suzukake et al., 2013;
34 Eisele, 2013; Goedert et al., 2014). Moreover, the most recent data suggest that variants of
35 Alzheimer's disease are encoded by different strains (Stöhr et al., 2014; Watts et al., 2014;
36 Aguzzi, 2014).

37 A lot of information on possible mechanisms of amyloid-like fibril formation comes from *in*
38 *vitro* studies of the aggregation kinetics (Knowles et al., 2009; Arosio et al., 2014; Meisl et al.,
39 2014). It is thought that four major steps are involved in fibril formation (Meisl et al., 2014). In
40 the case of spontaneous aggregation, everything starts from primary nucleation. It takes time for
41 a group of soluble protein molecules to get together and misfold into an amyloid-like structure,
42 which serves as a nucleus for fibrillation. Once nuclei are formed, they start elongation into
43 fibrils by attaching soluble protein at the ends and refolding it into an amyloid-like structure.

44 Although nucleation and elongation could be sufficient for describing fibrillation, in many cases
45 secondary processes, such as fibril fragmentation and secondary nucleation are extremely
46 important (Knowles et al., 2009; Meisl et al., 2014). Fibril fragmentation increases the number of
47 fibril ends, which leads to faster elongation. The presence of fibrils can induce formation of new
48 nuclei with much shorter lag times compared to primary nucleation; this is referred to as
49 secondary nucleation (Meisl et al., 2014).

50 How would such a mechanism of fibril formation work in the case of different amyloid strains?
51 Strain-like structural polymorphism was observed in a number of different amyloid-forming
52 proteins (Tanaka et al., 2004, 2005; Yamaguchi et al., 2004; Dzwolak et al., 2004; Petkova et al.,
53 2005; Jones & Surewicz, 2005; Heise et al., 2005; Paravastu et al., 2008; Makarava et al., 2009;
54 Colby et al., 2009; Dinkel et al., 2011; Jones et al., 2011; Chatani et al., 2012; Bousset et al.,
55 2013; Ghaemmaghami et al., 2013; Cobb et al., 2014; Tycko, 2014; Surmacz-Chwedoruk,
56 Babenko & Dzwolak, 2014). To form different amyloid strains *de novo* using the same protein,
57 different environmental conditions, such as temperature (Tanaka et al., 2005), shear forces
58 (Makarava et al., 2009), concentration of denaturants (Cobb et al., 2014) or co-solvents
59 (Dzwolak et al., 2004) are involved. Once nuclei are formed, they are able to carry strain-specific
60 properties even in unfavorable environments (Dzwolak et al., 2004; Petkova et al., 2005;
61 Makarava et al., 2009; Cobb et al., 2014; Surmacz-Chwedoruk, Babenko & Dzwolak, 2014).
62 This indicates that environment defines different strains during primary nucleation, but affects
63 only kinetics, not the structure, of fibrils formed via elongation. In the case of secondary
64 nucleation, formation of new nuclei is induced by existing fibrils, but there is no experimental
65 evidence if the structure of these nuclei is determined by the environment conditions, or by

66 structure of the fibrils. Or in other words, can secondary nucleation be responsible for
67 conformational switching in amyloid-like fibril strains?

68 **Materials and Methods**

69 Recombinant mouse prion protein fragment (rMoPrP(89-230)) used in this study was purified
70 and stored as described previously (Milto, Michailova & Smirnovas, 2014). Protein grade
71 guanidine hydrochloride (GuHCl) was purchased from Carl Roth GmbH, guanidine thiocyanate
72 (GuSCN) and other chemicals were purchased from Fisher Scientific UK.

73 To prepare different fibril strains, monomeric protein from a stock solution was diluted to a
74 concentration of 0.5 mg/ml in 50 mM phosphate buffer (pH 6) containing 2 M or 4 M GuHCl,
75 and incubated for one week at 37°C with 220 rpm shaking (in shaker incubator IKA KS 4000i).
76 For seeding experiments rPrP-A^{4M} fibrils were treated for 10 minutes using Bandelin Sonopuls
77 3100 ultrasonic homogenizer equipped with MS72 tip (using 20% power, cycles of 30 s/30 s
78 sonication/rest, total energy applied to the sample per cycle – 0.36 kJ). The sample was kept on
79 ice during the sonication. Right after the treatment, fibrils were mixed with 0.5 mg/ml of mouse
80 prion solution in 2 M GuHCl in 50 mM phosphate buffer, pH 6, containing 50 mM ThT.
81 Elongation kinetics at 60°C temperature was monitored by ThT fluorescence assay (excitation at
82 470 nm, emission at 510 nm) using Qiagen Rotor-Gene Q real-time analyzer (Milto, Michailova
83 & Smirnovas, 2014). ThT fluorescence curves were normalized by dividing each point by the
84 maximum intensity of the curve.

85 For denaturation assays, amyloid fibrils were resuspended to a concentration of 25 mM in 50
86 mM phosphate buffer, pH 6, containing 0.5 M GuSCN and homogenized by sonication. These
87 solutions were diluted 1:4 in a buffer containing varying concentrations of GuSCN, and

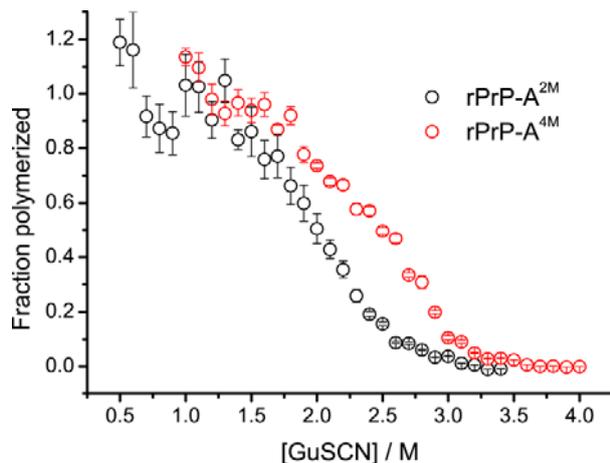

88 incubated for 60 min at 25°C. Samples were then mixed 1:20 with 50 mM ThT, and fluorescence
89 was measured at 480 nm using the excitation wavelength of 440 nm. Denaturation curves were
90 normalized by dividing each point by the average intensity of the points in the plateau region.

91

92 **Results**

93 Conformational stability of PrP^{Sc} as defined by resistance to chemical denaturation has been one
94 of the key parameters used to define differences between strains (Colby et al., 2009). Different
95 strains of recombinant mammalian prion protein amyloid-like fibrils made in 2 and 4 M
96 guanidine hydrochloride (rPrP-A^{2M} and rPrP-A^{4M}, respectively) were thoroughly characterized
97 by Surewicz group (Cobb et al., 2014). We used recombinant N-terminally truncated mouse
98 prion protein (rMoPrP(89-230)) to create rPrP-A^{2M} and rPrP-A^{4M} strains of amyloid-like fibrils.
99 Similar to recent data on recombinant human PrP (Cobb et al., 2014), rMoPrP fibrils formed in 2
100 and 4 M guanidine hydrochloride (GuHCl) have different conformational stability (Fig.1). Due
101 to the fact that rPrP-A^{4M} fibrils could not be fully denatured using even 7.5 M GuHCl (Cobb et
102 al., 2014), a denaturation assay using a more strongly chaotropic salt, guanidine thiocyanate
103 (GuSCN) was performed. Midpoint of denaturation of rPrP-A^{2M} is at ~2 M GuSCN and rPrP-
104 A^{4M} is at ~2.5 M GuSCN, respectively. This difference served as a simple, unbiased marker of
105 different strains in further experiments.

106

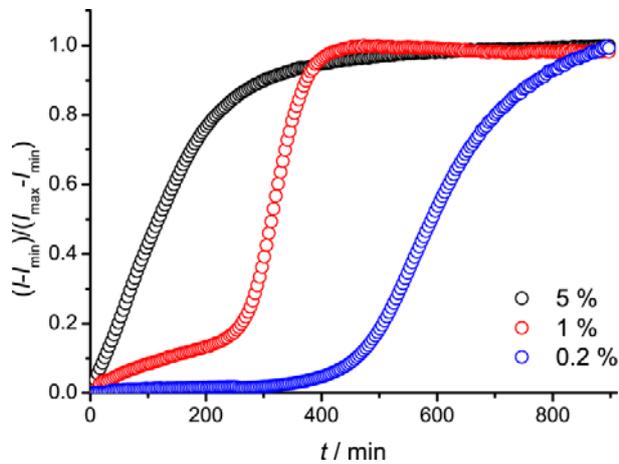

107

108 **Figure 1.** Denaturation profiles of rPrP-A^{2M} and rPrP-A^{4M} fibrils in GuSCN reveal different conformational
 109 stabilities. Standard errors calculated from 12 measurements using Student's t-distribution at P=0.05.

110

111 In our previous work we have described elongation kinetics at different temperatures and
 112 guanidine hydrochloride (GuHCl) concentrations, using rPrP-A^{2M} as a seed (Milto, Michailova
 113 & Smirnovas, 2014). It was not possible to get reliable data above 2.5 M GuHCl due to
 114 depolymerization of rPrP-A^{2M}. Thus only one way cross-seeding is possible for rPrP-A^{2M} and
 115 rPrP-A^{4M} strains. We followed cross-seeding kinetics using different concentrations of seeds. As
 116 seen in figure 2, five percent seeds led to fast growth of amyloid-like fibrils from the very
 117 beginning, suggesting fast fibril elongation. At 1% seed volume elongation is slower, but after
 118 some time the rate of aggregation explodes. At a lower concentration of seeds elongation is very
 119 slow and the curve looks sigmoidal, as usually seen in case of spontaneous fibrillation. However
 120 in absence of seeds no aggregation was detected within the experimental timeframe, which
 121 means the observed process, is fibril-induced secondary nucleation (see Supplementary
 122 information for the fitting data).

123

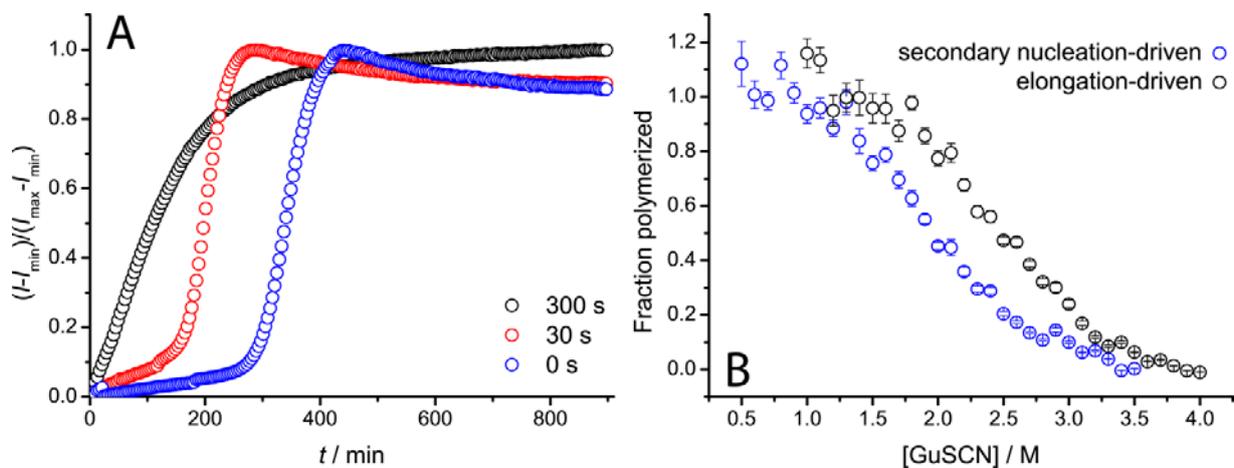

124

125 **Figure 2.** Concentration of seeds determines the mechanism of aggregation. Different amounts of rPrP-A^{4M} fibrils
126 (sonicated for 300 s) were added to the solution of rMoPrP, prepared in 2 M GuHCl, 50 mM phosphate buffer, pH6.
127 The kinetics was followed at 60°C using Thioflavin T (ThT) fluorescence assay. No change of ThT fluorescence
128 was observed in samples without seeds.

129

130 Similar change from elongation-driven to secondary nucleation-driven processes can be observed
131 using sonicated versus unsonicated fibrils as seeds (Fig. 3A). The fibril denaturation assay (Fig.
132 3B) revealed that stability of fibrils formed in elongation-driven process is the same as of the
133 rPrP-A^{4M} strain, which was used as a seed. However for the secondary nucleation-driven
134 process, stability of fibrils is the same as the rPrP-A^{2M} strain, which is favored by the
135 environment. This leads to the conclusion that fibril formation from secondary nucleation does
136 not follow the seeding template, despite using template fibrils as nucleation sites.

137

138 **Figure 3.** Amount of fibril ends determines the mechanism of aggregation and conformation of the final strain. (A)
 139 Different times of sonication were used to prepare rPrP-A^{4M} seeds. Sonication breaks fibrils into shorter pieces
 140 increasing number of fibril ends. The same amount of seeds (5%) was used in all experiments. (B) Denaturation
 141 profiles of fibrils obtained using unsonicated (secondary nucleation pathway) or highly sonicated (elongation
 142 pathway) rPrP-A^{4M} fibrils as seeds.

143

144 Discussion

145 Amyloid strain switching has been observed in animal studies (Bartz et al., 2000; Asante et al.,
 146 2002; Lloyd et al., 2004; Ghaemmaghami et al., 2013), cell culture (Li et al., 2010), and
 147 experiments in vitro (Castilla et al., 2008; Makarava et al., 2009; Surmacz-Chwedoruk, Babenko
 148 & Dzwolak, 2014). Two possibilities are suggested to explain this phenomenon (Collinge &
 149 Clarke, 2007; Cobb & Surewicz, 2009). The first one describes coexistence of multiple structures
 150 in the infective material, when only the dominant type would be recognized experimentally;
 151 however upon transmission to different host, the minor population may self-propagate much
 152 better and become dominant, reflected in the change of strain properties. Recently this way of
 153 amyloid strain switching was demonstrated for insulin fibrils *in vitro* (Surmacz-Chwedoruk,

8

154 Babenko & Dzwolak, 2014). The second possibility suggested that sometimes host protein can
155 adopt amyloid conformations distinct from the heterologous template. The Baskakov group
156 demonstrated adaptive conformational switching within individual fibrils as a possible
157 mechanism for such change (Makarava et al., 2009). Our data suggests a possibility of strain
158 switching via secondary nucleation pathways. Moreover, secondary nucleation can explain
159 switching of strains in absence of species barrier, for example in case of recently described
160 Darwinian evolution of prions in cell culture, which showed strain mutations within a single host
161 protein (Li et al., 2010) or in case of protein misfolding cyclic amplification (PMCA) of
162 recombinant PrP (Smirnovas et al., 2009). In summary, continuous propagation or switching
163 between amyloid strains may be determined by the mechanism of replication in addition to the
164 environment. In cases when a species barrier or environmental barrier stops or slows down fibril
165 elongation, there is the possibility of secondary nucleation events to seed the formation of
166 different strains. The mechanism is dependent on the concentration of fibril ends, which opens
167 up a new dimension in cross-species and cross-environment seeding/infection experiments.
168 Assuming the same mechanisms of prion propagation *in vivo*, there is a possibility of one strain
169 of PrP^{Sc} causing different disease variants. For example a hypothesis of both variant Creutzfeldt-
170 Jakob disease (CJD) and sporadic CJD to be caused by different amounts of the same PrP^{Sc} could
171 be valid.

172

173 **Acknowledgments**

174 The authors thank Prof. Witold Surewicz for sharing MoPrP(89-230) plasmid and Dr. Jonathan
175 G. Cannon for critical reading of the manuscript.
