As in past pandemics, co-circulating pathogens may play a role in the epidemiology of coronavirus disease 2019 (COVID-19), caused by the novel severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2). In particular, experimental evidence indicates that influenza infection can up-regulate the expression of ACE2—the receptor of SARS-CoV-2 in human cells—and facilitate SARS-CoV-2 infection. Here we hypothesized that influenza impacted the epidemiology of SARS-CoV-2 during the early 2020 epidemic of COVID-19 in Europe. To test this hypothesis, we developed a population-based model of SARS-CoV-2 transmission and of COVID-19 mortality, which simultaneously incorporated the impact of non-pharmaceutical control measures and of influenza on the epidemiological dynamics of SARS-CoV-2. Using statistical inference methods based on iterated filtering, we confronted this model with mortality incidence data in four European countries (Belgium, Italy, Norway, and Spain) to systematically test a range of assumptions about the impact of influenza. We found consistent evidence for a 1.8–3.4-fold (uncertainty range across countries: 1.1 to 5.0) average population-level increase in SARS-CoV-2 transmission associated with influenza during the period of co-circulation. These estimates remained robust to a variety of alternative assumptions regarding the epidemiological traits of SARS-CoV-2 and the modeled impact of control measures. Although further confirmatory evidence is required, our results suggest that influenza could facilitate the spread and hamper effective control of SARS-CoV-2. More generally, our results highlight the possible role of co-circulating pathogens in the epidemiology of COVID-19.

20 Abstract

21 As in past pandemics, co-circulating pathogens may play a role in the epidemiology of
 22 coronavirus disease 2019 (COVID-19), caused by the novel severe acute respiratory syndrome
 23 coronavirus 2 (SARS-CoV-2). In particular, experimental evidence indicates that influenza
 24 infection can up-regulate the expression of ACE2—the receptor of SARS-CoV-2 in human
 25 cells—and facilitate SARS-CoV-2 infection. Here we hypothesized that influenza impacted the
 26 epidemiology of SARS-CoV-2 during the early 2020 epidemic of COVID-19 in Europe. To test
 27 this hypothesis, we developed a population-based model of SARS-CoV-2 transmission and of
 28 COVID-19 mortality, which simultaneously incorporated the impact of non-pharmaceutical
 29 control measures and of influenza on the epidemiological dynamics of SARS-CoV-2. Using
 30 statistical inference methods based on iterated filtering, we confronted this model with mortality
 31 incidence data in four European countries (Belgium, Italy, Norway, and Spain) to systematically
 32 test a range of assumptions about the impact of influenza. We found consistent evidence for a
 33 1.8–3.4-fold (uncertainty range across countries: 1.1 to 5.0) average population-level increase in
 34 SARS-CoV-2 transmission associated with influenza during the period of co-circulation. These
 35 estimates remained robust to a variety of alternative assumptions regarding the epidemiological
 36 traits of SARS-CoV-2 and the modeled impact of control measures. Although further
 37 confirmatory evidence is required, our results suggest that influenza could facilitate the spread
 38 and hamper effective control of SARS-CoV-2. More generally, our results highlight the possible
 39 role of co-circulating pathogens in the epidemiology of COVID-19.

40 Introduction

41 The current pandemic of coronavirus disease 2019 (COVID-19), caused by the novel severe
 42 acute respiratory syndrome coronavirus 2 (SARS-CoV-2), has led to global alarm. Following the
 43 first case reports in December 2019 in Wuhan, China [1], SARS-CoV-2 rapidly spread across the
 44 globe and has resulted in approximately 171 million cases and 3.6 million deaths worldwide, as
 45 of June 1, 2021 [2]. Because of the initial lack of prophylactic or therapeutic treatments, the
 46 pandemic caused the implementation of unprecedented control measures, which culminated in
 47 the lockdown of several billion people in over 100 countries during April–May 2020 [3].
 48 Although a number of fixed (e.g., greater age, male sex) and chronic (e.g., hypertension,
 49 diabetes) risk factors of mortality have now been identified [4], the time-varying drivers of
 50 COVID-19 epidemiology remain poorly understood. Experience gained from past pandemics has
 51 highlighted the potentially large contribution of co-circulating pathogens to the burden of an
 52 emerging disease [5]. Despite the relevance for epidemic forecasting and for designing control
 53 strategies, the impact of co-circulating pathogens on SARS-CoV-2 epidemiology has remained
 54 largely unexplored [6].

55 Respiratory viruses—including SARS-CoV-2 and other coronaviruses, rhinoviruses,
 56 influenza viruses, etc.—form a large class of viruses that cause seasonal infections of the
 57 respiratory tract in humans. Mounting evidence indicates that their epidemiologies are not
 58 independent, as a result of interaction mechanisms that may operate at different scales and that
 59 can be classified as either facilitatory or antagonistic [7,8]. The interaction between the
 60 respiratory syncytial virus (RSV) and influenza may provide an example of antagonism. Indeed,
 61 experimental evidence in ferrets has shown that influenza viruses induce an antiviral state that
 62 transiently limits secondary infection with RSV [9], an effect postulated to explain the delayed

epidemic of RSV during the 2009 influenza pandemic [10,11]. Although such antagonistic interactions appear, to date, to be the most common among respiratory viruses [8], experimental evidence indicates that co-infections may have a facilitatory effect, for example by increasing viral growth [12]. Increased transmission of influenza during co-infection with other respiratory viruses was also proposed to explain the multiple waves during the 1918 influenza pandemic [13]. Interestingly, according to recent evidence a viral respiratory infection (in particular with influenza viruses) can up-regulate the expression of ACE2—the cognate receptor of SARS-CoV-2 in human cells—in the respiratory epithelium [14,15]. In addition, this up-regulation was demonstrated experimentally to increase infectivity of SARS-CoV-2 in mice co-infected with influenza A virus [16]. This suggests that respiratory viruses could affect the epidemiology of SARS-CoV-2. Here, we hypothesized that influenza—which peaked in February 2020 and therefore co-circulated during the early spread of COVID-19 in Europe (Fig. 1B)—interacted with SARS-CoV-2.

To test this hypothesis, we developed a semi-mechanistic, population-based model of SARS-CoV-2 transmission and of COVID-19 mortality. Using likelihood-based statistical inference methods, we confronted this model to mortality incidence data in four European countries to test a range of assumptions about the impact of influenza on the transmission dynamics of SARS-CoV-2. We find that influenza may have transiently increased the transmission of SARS-CoV-2 during the first wave of COVID-19 in Europe. Although further confirmatory evidence is required, our results suggest that influenza could facilitate the spread of SARS-CoV-2 and, more generally, emphasize the potential role of co-circulating pathogens in the epidemiology of COVID-19.

85 **Materials & Methods**

86 *Data*

87 *Stringency index data*

88 Country-level time series of the stringency index were available from the Oxford COVID-19
 89 Government Response Tracker, developed at the University of Oxford and described
 90 elsewhere [3]. Briefly, the stringency index provides an aggregate measure of the number and of
 91 the strictness of non-pharmaceutical control measures implemented by governments in response
 92 to the COVID-19 epidemic. The stringency index is defined as the average of 9 normalized
 93 ordinal variables, which quantify the strength (e.g., recommended or required) and the scope
 94 (e.g., targeted or general) of closure and containment measures (8 variables) and of health
 95 measures (1 variable). The resulting index allows quantifying the strength of control measures in
 96 a systematic way, on a scale ranging from 0 (no interventions) to 100 (maximum number and
 97 maximal intensity of control measures). Of note, however, the stringency index does not quantify
 98 the impact of control measures, which likely varied across countries [17]. In formulating our
 99 model, we therefore modeled the relationship between the stringency index and the relative
 100 reduction in SARS-CoV-2 transmission using a non-decreasing function, whose parameters
 101 represented the impact of control measures and were estimated from the data.

102 *Influenza incidence data*

103 Virological data on the weekly numbers of samples tested and of samples positive to any
 104 influenza virus were available from the FluNet database, compiled by the WHO (Fig. S1A).
 105 Parallel syndromic data on the weekly incidence rate of influenza-like illnesses (ILI) were
 106 available from the FluID database, also compiled by the WHO (Fig. S1B). These data were

deemed high-quality and used in a previous study on influenza forecasting in the countries considered here [18]. The weekly incidence rate of influenza was then calculated as the product of ILI incidence and of the fraction of samples positive to any influenza virus (Fig. 1B). Because the magnitude of influenza incidence thus calculated varied markedly across countries (e.g., as a result of different surveillance systems and case definitions), we rescaled each time series by its average during the period of co-circulation of influenza and SARS-CoV-2 (Fig. 1B). The resulting time series was therefore dimensionless and equalled 1 when influenza incidence equalled its average value during that period.

COVID-19 mortality data

Data on the daily number of deaths caused by SARS-CoV-2 (counted by date of death) were available from national public health public institutes, in Belgium (Sciensano [19]), in Italy (*Dipartimento della Protezione Civile* [20]), and in Spain (*Instituto de Salud Carlos III*, official data with historical corrections compiled by the media DATADISTA [21]). In Norway, the data were available from the worldwide database compiled by the European Center for Disease Control and Prevention [22]. Following a previous study [17], and to avoid a possible bias caused by the dominance of deaths due to non-locally acquired infections early in the epidemic, we included observed deaths from the date after which the cumulative observed death count exceeded 10. Data points before that date were treated as missing and were assigned a conditional log-likelihood of 0, such that they did not contribute to the overall log-likelihood. The data were not further pre-processed, except in Italy, where a negative death count was reported on 24 June 2020 and was treated as missing and also assigned a log-likelihood of 0.

128 *Transmission model*

129 *Model formulation*

130 We formulated a variant of the standard Susceptible–Exposed–Infected–Recovered transmission
 131 model [23], using the method of stages to allow for a realistic distribution of the latent,
 132 infectious, and onset-to-death periods [24,25]. Specifically, we assumed that the latent and
 133 infectious periods were Erlang-distributed with shape parameter 2 and mean $1/\sigma = 4$ days and
 134 $1/\gamma = 5$ days, respectively [26]. The resulting generation time T_g (i.e., the time from infection of
 135 a primary case to transmission to a secondary case) had a mean of 6.5 days and a coefficient of
 136 variation of 0.58 (see Fig. S2 for the full distribution and the details of the calculation), consistent
 137 with empirical observations and with the values fixed in a previous modeling study [17,27]. To
 138 model the impact of the gradual implementation of non-pharmaceutical control measures (e.g.,
 139 border closure, school closure, lockdown), we mapped the stringency index (denoted by $si(t)$) to
 140 the time-varying relative reduction in transmission of SARS-CoV-2 (denoted by $r_\beta(t)$).
 141 Specifically, we used the following simple linear scaling function, with saturation:

$$142 \quad r_\beta(t) = \min\left(1, b \times \frac{si(t)}{100}\right)$$

143 Here the parameter b quantifies how steeply the transmission rate of SARS-CoV-2 decreases as
 144 the stringency index increases. Hence, this parameter can be interpreted as a measure of the
 145 impact of non-pharmaceutical control measures on SARS-CoV-2 transmission. The deterministic
 146 variant of the model was represented by the following set of differential equations:

$$\begin{aligned}
 \dot{S} &= -\lambda(t)S \\
 \dot{E}_1 &= \lambda(t)S - 2\sigma E_1 \\
 \dot{E}_2 &= 2\sigma(E_1 - E_2) \\
 \dot{I}_1 &= 2\sigma E_2 - 2\gamma I_1 \\
 \dot{I}_2 &= 2\gamma(I_1 - I_2) \\
 \dot{R} &= 2\gamma I_2
 \end{aligned}$$

The force of infection (that is, the per capita rate at which susceptible individuals contract infection [23]), $\lambda(t)$, was modeled as:

$$\begin{aligned}
 \lambda(t) &= \beta(t) \frac{I_1 + I_2}{N} \\
 \beta(t) &= \beta_0(1 - r_\beta(t))\beta_F(t) \\
 r_\beta(t) &= \min(1, b \times \frac{si(t)}{100}) \\
 \beta_F(t) &= \max(0, 1 + \beta_F F(t)) \\
 R_e(t) &= \frac{\beta(t)}{\gamma} \times \frac{S(t)}{N}
 \end{aligned}$$

where R_0 represents the basic reproduction number of SARS-CoV-2, $\beta_0 = R_0\gamma$ the basic transmission rate, $R_e(t)$ the time-varying effective reproduction number, N the population size (assumed constant during the study period), and $F(t)$ the renormalized time series of influenza incidence, incorporated as a covariate into the model (Fig. 1). With this formulation, the parameter β_F quantifies the impact of influenza on SARS-CoV-2 transmission: $\beta_F > 0$ if influenza increases transmission, $\beta_F < 0$ if influenza decreases transmission, and $\beta_F = 0$ if influenza has no impact on transmission (null hypothesis). More specifically, the average incidence of influenza during the period of co-circulation with SARS-CoV-2 corresponds to $F(t) = 1$, such that $1 + \beta_F$ represents the average relative variation of SARS-CoV-2 transmission associated with influenza. In writing the equations, we implicitly assume that the

161 impact of influenza on SARS-CoV-2 transmission, if any, is short-lived and does not extend long
162 after influenza infection.

163 Finally, we incorporated an observation model that related the dynamics of SARS-CoV-
164 2 infection to that of COVID-19 mortality, taking into account the fact that only a fraction of
165 infections results in death and that, among those, death occurs some time after symptom
166 onset [17,28,29]. We assumed an average duration of pre-symptomatic of 2.5 days, resulting in
167 an average incubation period of 6.5 days, in broad agreement with previous empirical
168 studies [29,30]. Hence, individuals in the first infected state (I_1) were considered pre-
169 symptomatic, and the onset of symptoms was assumed to coincide with the transition from I_1 to
170 I_2 . The onset-to-death time was then assumed to be Erlang distributed with shape parameter 5
171 and mean $1/\kappa = 17.8$ days (coefficient of variation of 0.45), the value estimated in a previous
172 epidemiological study [28]. In a sensitivity analysis, we also tested a mean onset-to-death time of
173 $1/\kappa = 13$ days, the lower bound estimated in a meta-analysis [29]. According to previous studies
174 in European countries, the infection fatality ratio (IFR) typically ranged from 0.5% to 1% early
175 in the epidemic [31–33]. We fixed the IFR to $\mu = 0.01$ in the base model, but we considered an
176 alternative value of 0.005 in a sensitivity analysis. Given those assumptions, the observation
177 model was modeled by the following set of ordinary differential equations:

$$\begin{aligned} \dot{Q}_1 &= 2\gamma\mu I_1 - 5\kappa Q_1 \\ \dot{Q}_{i=2,\dots,5} &= 5\kappa(Q_{i-1} - Q_i) \\ \dot{D}_M &= 5\kappa Q_5 \end{aligned}$$

179 Here D_M is the simulated number of daily deaths, modeled as an accumulator variable and reset
180 to 0 at the end of each day. The observed number of daily deaths, D_O , was modeled using a

negative binomial distribution with mean D_M and over-dispersion k_D (i.e., $\mathbb{V}(D_O|D_M) = D_M + k_D D_M^2$), a standard distribution used in previous modeling studies [17,34].

As in Flaxman et al. [17], simulations were started 30 days before the date from which the cumulative observed death count first exceeded 10. At that date, we assumed that $E_1(0)$ individuals had been exposed to SARS-CoV-2; other individuals were assumed susceptible to infection (i.e., $S(0) = N - E_1(0)$), and all other compartments were initialized to 0.

Stochastic variant and modeling of superspreading

The stochastic variant of the model was implemented as a continuous-time Markov process approximated via a multinomial modification of the τ -leap algorithm [35], with a fixed time step of $\Delta t = 10^{-1}$ day. To model the effect of superspreading events—a key feature of SARS-CoV-2 transmission dynamics [36]—, extra-demographic stochasticity was added to the transmission rate $\beta(t)$. Specifically, as proposed by Kain et al. [37], at every time step we drew a value of β_0 from a Gamma white noise distribution:

$$\beta_0 \sim \Gamma_{\text{WN}}(\sigma = \sqrt{\frac{R_0}{(I_1 + I_2)k\Delta t}}\mu = R_0\gamma)$$

with mean μ and variance $\mu\sigma^2$. Here k represents the dispersion parameter of the Negative-binomial distribution for the individual reproduction number (with mean R_0 and variance $R_0 + \frac{R_0^2}{k}$), as estimated in previous studies [38,39]. As in [37] and in keeping with empirical estimates from contact tracing studies of SARS-CoV-2 [39], we fixed $k = 0.16$.

199 Model estimation

200 Following the method presented in [17], we estimated unknown model parameters using observed
 201 COVID-19 mortality data alone. Indeed, because of the initially limited testing capacity
 202 (typically reserved to severe cases or high-risk groups), mortality data were arguably more
 203 reliable than case data early in the epidemic in most countries [17]. By incorporating known
 204 epidemiological parameters (key among those the onset-to-death time, the IFR, and the
 205 generation time), however, the method allows back-calculating infection rates from observed
 206 death rates. Hence, in addition to the dynamic of mortality, we also reconstructed the dynamic of
 207 infection and, as a validation, compared it to external epidemiological data—like cross-sectional
 208 seroprevalence estimates—when available.

209 The following five parameters were estimated from the data:

- 210 1. The basic reproduction number, R_0 . According to a previous meta-analysis [40], this
 211 parameter was searched in the interval 1–10.
- 212 2. The impact of non-pharmaceutical control measures, b . The lower bound of the search
 213 interval of this parameter was fixed to 0.5, such that the maximal value of the stringency
 214 index ($s = 100$) corresponded to a minimal reduction of SARS-CoV-2 transmission of
 215 50% [17].
- 216 3. The impact of influenza on SARS-CoV-2 transmission, β_F (search interval: \mathbb{R}).
- 217 4. The initial number of individuals exposed to SARS-CoV-2, $E_1(0)$ (search interval: $0-10^4$).
- 218 5. The over-dispersion in death reporting, k_D (search interval: \mathbb{R}^+).

219 A summary list of fixed and estimated model parameters is presented in Table 1.

220 All parameters were transformed to be estimated on the real line, using a log
 221 transformation for positive parameters and the extended logistic function $f(\theta) = \log \frac{\theta - a}{b - \theta}$ for
 222 parameters constrained in the interval $[a, b]$. The maximum iterated filtering algorithm
 223 (MIF2 [41]), implemented in the R (version 3.6.3) package pomp [42,43] (version 2.7), was used
 224 to estimate model parameters. The R checkpoint package was used to freeze all the packages'
 225 version at the date of April 3, 2020 [44]. The estimation was completed in several steps, starting
 226 with trajectory matching to identify good starting parameters for MIF2, followed by 100
 227 independent runs of MIF2 to locate the maximum likelihood estimate (MLE). Each MIF run had
 228 150 iterations with 5,000 particles, geometric cooling, and a random walk standard deviation of
 229 0.1 for the initial condition $E_1(0)$ and of 0.02 for the other parameters. The log-likelihood of
 230 every parameter set was calculated as the log of the mean likelihood of 5 replicate particle filters,
 231 each with 20,000 particles. The profile likelihood was calculated to verify the convergence of
 232 MIF2 and to derive an approximate 95% confidence interval for the parameter β_F [45]—the
 233 parameter of key interest in our study. For the other parameters, a parametric bootstrap was used
 234 to calculate approximate 95% confidence intervals, by re-estimating the parameters for each of
 235 200 synthetic datasets simulated at the MLE [46,47]. Compared with the profile likelihood, the
 236 parametric bootstrap requires less computation and was found to perform well in previous
 237 applications [46, 47].

238

239 Sensitivity analyses

240 To verify the robustness of the parameter estimates, we conducted six sensitivity analyses
 241 (further detailed in the Supplementary Results). First, we estimated an extended model in which
 242 the reduction of SARS-CoV-2 transmission was allowed to scale non-linearly with the stringency
 243 index. Second, to test the possible presence of other variables confounded with influenza, we
 244 estimated a model that included an exponential trend in the transmission rate of SARS-CoV-2.
 245 Finally, we varied the fixed value of 3 parameters and re-estimated the parameters of the base
 246 model. Specifically, we tested two alternative values of the average generation time ($\mathbb{E}(T_g) = 5$
 247 days and $\mathbb{E}(T_g) = 7.5$ days), one alternative value of the infection fatality ratio ($\mu = 0.005$), and
 248 one alternative value of the average onset-to-death period ($\frac{1}{\kappa} = 13$ days).

249 Results

250 Parameter estimates

251 As shown in Fig. 1A, the number and the intensity of control measures against COVID-
 252 19 gradually increased from January until the nationwide lockdown in March, before a relaxation
 253 from May 2020. During this time period, the epidemic of influenza started in January 2020 and
 254 ended in March 2020, with a peak during February in each country (Fig. 1B and S1). Despite
 255 correlations between some parameters (in particular the reproduction number and the impact of
 256 control measures, see Fig. S4), all parameters were identifiable in each country (Table 2).
 257 Parameter estimates indicated that, during the period of co-circulation, influenza was associated
 258 with an average 1.8–3.4-fold (uncertainty range across countries: 1.1 to 5.0) population-level
 259 increase in SARS-CoV-2 transmission (Table 2 and Fig. S3). After controlling for the impact of
 260 influenza, our estimates of the basic reproduction number (R_0) ranged from 1.2 (in Italy) to 3.4

(in Belgium). Although the increased transmission associated with influenza early during the SARS-CoV-2 epidemic explained the data significantly better (Table 2), a model without influenza led to higher R_0 estimates (range 2.4–5.2, Fig. 2A), consistent with those of a previous study [17]. Also in line with [17], we found consistent evidence for a marked impact of non-pharmaceutical control measures (Table 2), which were associated with a decrease in SARS-CoV-2 transmission below the reproduction threshold from mid-March to June 2020 (Fig. 2A).

Model evaluation

Visual inspection of simulations suggested that our model correctly captured the dynamics of COVID-19 mortality in every country (Fig. 2B). A more detailed model–data comparison of summary statistics confirmed that our model accurately reproduced the peak time, the peak number and the total number of deaths, and the death growth exponent [48], except in Italy and Spain where the latter statistic was systematically under-estimated (Fig. S5). Our model-based estimates of the total proportion of individuals infected with SARS-CoV-2 (as of 4 May 2020, Table 2) were also comparable with those of a previous modeling study [17] and of a seroprevalence study conducted in early May in Spain (approximate seroprevalence estimate of 5% [49]). Hence, our model appeared to precisely recapitulate the epidemiology of SARS-CoV-2 morbidity and mortality over a period of ~ 4 months.

Sensitivity analyses

The results of the sensitivity analyses are presented in Tables S1–S3. We found little statistical evidence that the model with non-linear scaling of the stringency index outperformed the model with simple linear scaling in any country ($\Delta \log L \in [0.0, 1.1]$, likelihood ratio test P-value $P \in [0.14, 1.00]$, Table S1). Of note, although our estimates of the impact of influenza varied

little, the additional estimated parameter resulted in higher parametric uncertainty, particularly in Norway where the approximate 95% CI embraced the null value. Similarly, the model with an unexplained exponential trend in transmission did not substantially improve model fit ($\Delta \log L \in [0.0, 3.2]$, likelihood ratio test P-value $P \in [0.01, 1.00]$, Table S2). Despite higher parametric uncertainty caused by the estimation of the trend, our results regarding the impact of influenza remained robust, but once again the approximate confidence interval embraced the null value in Norway. In addition, we found that the parameter estimates varied little when testing alternative hypotheses about the fixed value of the average generation time, of the onset-to-death time, and of the infection fatality ratio (Table S3). Finally, because our R_0 estimates were lower than previous estimates in Italy and Spain, we tested an alternative model with R_0 fixed to 2.5 in each country. This model led to broadly similar conclusions, although the estimated impact of influenza was lower both in Italy ($\beta_F = 1.4$, approximate 95% CI [1.2, 1.5], $\log L = -692.3$ [SE<0.1]) and in Spain ($\beta_F = 0.7$, approximate 95% CI [0.4, 1.0], $\log L = -567.7$ [SE=0.1]). In sum, our main result about the impact of influenza remained robust to a variety of alternative assumptions regarding the epidemiological traits of SARS-CoV-2 and the modeled impact of control measures.

Discussion

The main goal of this study was to test the hypothesis that influenza impacted the epidemiological dynamics of SARS-CoV-2, building on previous experimental evidence of a positive interaction between the two viruses [14–16]. To do so, we developed a semi-mechanistic, population-based model of SARS-CoV-2 transmission and of COVID-19 mortality, which simultaneously incorporated the impact of non-pharmaceutical control measures and of

influenza. Using likelihood-based statistical inference techniques, we confronted this model with mortality incidence data in four European countries to systematically test a range of assumptions about the possible impact of influenza and of control measures. In keeping with previous studies [17], we found robust and consistent evidence that control measures markedly reduced the transmission of SARS-CoV-2. In addition, we also found consistent evidence suggesting that co-circulation of influenza transiently facilitated the transmission of SARS-CoV-2 early in the epidemic in Europe.

Our study has a number of important limitations. First, as in other studies [17,26,50] and because of a lack of appropriate age-specific data (for example on the temporal changes in the contact matrix and in the incidence of influenza), our model was not age-structured, even though many aspects of COVID-19 and of influenza epidemiology—like disease severity and lethality—vary markedly with age [28]. The susceptibility to SARS-CoV-2 infection was also found to increase with age [51], a finding potentially explained by lower baseline expression of the ACE2 receptor in children [52]. A testable prediction of our model, therefore, is that influenza should be associated with a transient increase in susceptibility to SARS-CoV-2 infection, commensurate with the variations of influenza incidence over age. Second, we modeled the impact of non-pharmaceutical control measures using a simple, linear function scaling the stringency index to the reduction of SARS-CoV-2 transmission. Even though this simple hypothesis provided a more parsimonious fit (except in Italy), that result may be specific to Europe, where control measures gradually increased in number and in intensity (Fig. 1A). In general, the association is likely non-linear (e.g., if a high-impact intervention like a lockdown is implemented early on), and we therefore recommend testing a variety of scaling functions. More generally, although our model builds on a previously validated method to estimate the time-

varying reproduction number [17], we acknowledge that the stringency index may not fully capture temporal variations in SARS-CoV-2 transmission, in particular behavior changes outside of what was mandated by governments. Even though we tested a model with an unexplained trend in transmission (Table S2), more complex temporal functions may be required to fully capture such changes. Third, we did not incorporate climate into our model, even though, as for other respiratory viruses, environmental variables like temperature and humidity may affect the transmission of SARS-CoV-2. According to previous studies conducted in a variety of locations worldwide, however, the impact of weather on the SARS-CoV-2 epidemic appears to have been modest, at least during the first wave in early 2020 [53–55]. These findings are also consistent with epidemiological theory, which predicts that, because of lack of population immunity, the initial pandemic trajectory may be relatively insensitive to climate [56]. Fourth, we did not specifically model fully asymptomatic cases, which may represent a large fraction of SARS-CoV-2 infections [26]. The omission of asymptomatic infections may lead to biased R_0 estimates if their duration significantly differs from that of symptomatic infections [57]. A previous study, however, estimated that the duration of both types of infection is comparable [26], such that our estimates should be robust in more complex model structures. Finally, we assessed only the impact of influenza, because of its high prevalence and period of overlap with SARS-CoV-2 in early 2020 in Europe and of the availability of high-quality data [18]. Nevertheless, other respiratory viruses, like RSV and rhinoviruses [58], may also interact with SARS-CoV-2 and could be considered.

Acknowledging these limitations, our model makes at least two other predictions that could be tested to provide confirmatory evidence. First, even though our results did not allow to distinguish between higher transmissibility or higher susceptibility in individuals co-infected

351 with influenza and SARS-CoV-2, previous experimental work suggests that the latter mechanism
 352 may operate, as a result of up-regulation of the ACE2 receptor caused by influenza
 353 infection [14,15]. Hence, we predict that a recent influenza infection should be an independent
 354 risk factor for subsequent SARS-CoV-2 infection. Estimates of the frequency of co-detection of
 355 influenza and SARS-CoV-2 by polymerase chain reaction (PCR) testing in nasopharyngeal
 356 swabs were highly variable in previous studies (range 0–60% [6,59]). Although the marked
 357 seasonality of influenza in temperate regions likely explains in part the low frequency found in
 358 some studies [59], we propose that differences in the natural history of influenza and SARS-
 359 CoV-2 infections also lead to a systematic under-estimation of co-infection. Specifically, because
 360 the incubation period of SARS-CoV-2 infection (estimated to average 5.7 days [29]) exceeds that
 361 of influenza (A, 1.4 days or B, 0.6 days [60]), it is likely that, by the time SARS-CoV-2 infection
 362 becomes detectable, influenza no longer is. To make that statement more precise, we calculated
 363 the probability of detectability of a co-infection, with influenza first then SARS-CoV-
 364 2 (Table S4). Assuming that influenza is detectable by PCR up to 4–5 days after [61], and SARS-
 365 CoV-2 from 2–4 days before [30], symptom onset, we find that a large fraction (30–50%) of co-
 366 infections may not be detectable at all. These results may help explain the low frequency of co-
 367 detection found in some studies [62], and suggest that the time window of co-detectability may
 368 be too short to adequately infer the association between influenza and SARS-CoV-2 using PCR
 369 testing. Serological studies comparing the prevalence of antibodies against influenza in SARS-
 370 CoV-2 cases and non-cases may therefore be required to test the prediction that influenza is a
 371 risk factor for SARS-CoV-2 infection. Second, we predict that individuals vaccinated against
 372 influenza should be at lower risk of SARS-CoV-2 infection than those unvaccinated. The
 373 findings of a negative association between influenza vaccine coverage and COVID-19 mortality

in ecological studies (in Italy [63] and in other countries [64]) and of a lower risk of SARS-CoV-2 infection in influenza vaccinees in some individual-level epidemiological studies (reviewed in [65]) are consistent with our prediction, but further epidemiological investigations are needed. Importantly, our results can explain these findings as the direct effect of influenza vaccines on influenza infection, instead of indirect effects on non-influenza pathogens (e.g., as a result of trained immunity) [66].

With the likely prospect of COVID-19 becoming endemic, the potential interactions of SARS-CoV-2 with other respiratory pathogens—in particular respiratory viruses—may become a key public health issue. In this context, our results suggest that influenza could facilitate the circulation of SARS-CoV-2 and therefore increase the burden of COVID-19. As outlined above, these results are consistent with several lines of experimental [16, 14, 15] and epidemiological [65, 64, 63] evidence. We note, however, that a previous study proposed that influenza and SARS-CoV-2 have competitive interactions [67]. Specifically, using a within-host model of viral replication Pinky and Dobrovolny found that the low growth rate of SARS-CoV-2 may result in limited access to target cells and therefore suppression by other respiratory viruses [67]. Although this mechanism may be generally relevant for respiratory viruses, the ability of influenza to up-regulate ACE2 [14, 15]—a feature not included in the within-host model [67]—could counteract this mechanism and explain the increased infectivity of SARS-CoV-2 found experimentally [16]. Of note, in keeping with [67], another experimental study found evidence that the interferon response caused competitive interactions between rhinoviruses and SARS-CoV-2 [58]. Hence, these different biological mechanisms suggest that every respiratory virus interacts with SARS-CoV-2 in a highly specific way, with influenza being unique in its ability to up-regulate ACE2 and to increase SARS-CoV-2 infectivity [16].

397

398 Conclusions

399 In conclusion, our results suggest that influenza virus infection could have increased the
 400 transmission of SARS-CoV-2 and facilitated its spread during the early 2020 epidemic of
 401 COVID-19 in Europe. Hence, an increase in the uptake of influenza vaccines may be called for,
 402 not only to reduce hospitalizations due to influenza infections [59,68], but also to reduce their
 403 downstream impact on SARS-CoV-2 transmission and on COVID-19 mortality. More generally,
 404 taking into account the microbial environment of SARS-CoV-2 may be essential, not only to
 405 better understand its epidemiology, but also to enhance current and future infection control
 406 strategies.

408 Availability of data and materials

409 The data used for this analysis are freely available from the databases cited in the references and
 410 have been compiled into a database available from Edmond, the Open Data Repository of the
 411 Max Planck Society: <https://edmond.mpg.de/imeji/collection/eUiBI4vpiGxi4126>. The R
 412 programming codes to implement and estimate the models are also available on this repository.

413 Competing interests

414 MDdC received postdoctoral funding (2017–2019) from Pfizer and consulting fees from GSK.
 415 JSC declares no competing interests. BL is chair of the ISC for the Global Influenza Surveillance
 416 Network, and co-chair of the Global Influenza and RSV initiative; he is also a member of the
 417 French COVID-19 Scientific Committee (no personal income for all these activities). LO has
 418 received consulting fees from WHO for work on antimicrobial resistance and funding from
 419 Pfizer (2017–2019).

420 Authors contributions

421 MDdC conceived of the study design and performed the analysis. JSC and BL provided content
 422 expertise. LO conceived of the study design and oversaw the analysis.

423 Acknowledgements

424 We thank Arturo Zychlinsky and Klaus Osterrieder for helpful comments on the manuscript.
 425 Computations underlying the present analysis were performed at the Max Planck Computing and
 426 Data Facility (MPCDF).

Figure 1

Potential drivers of SARS-CoV-2 transmission in Belgium, Italy, Norway, and Spain.

A: time plot of the stringency index, a country-level aggregate measure of the number and of the strictness of non-pharmaceutical control measures implemented by governments. The vertical dashed line indicates the start of the nationwide lockdown [17]. B: time plot of influenza incidence, calculated as the product of the incidence of influenza-like illnesses and of the fraction of samples positive to any influenza virus (see also Fig. S1 for a time plot of the latter two variables). The vertical dashed lines delimitate the period of overlap between SARS-CoV-2 and influenza, defined as the period between the assumed start date of SARS-CoV-2 community transmission and 6 weeks after the epidemic peak of influenza[68]. In each country, the time series displayed were incorporated as covariates, which modulated the transmission rate of SARS-CoV-2 in our model (see Methods). In B, the y-axis values differ for each panel.

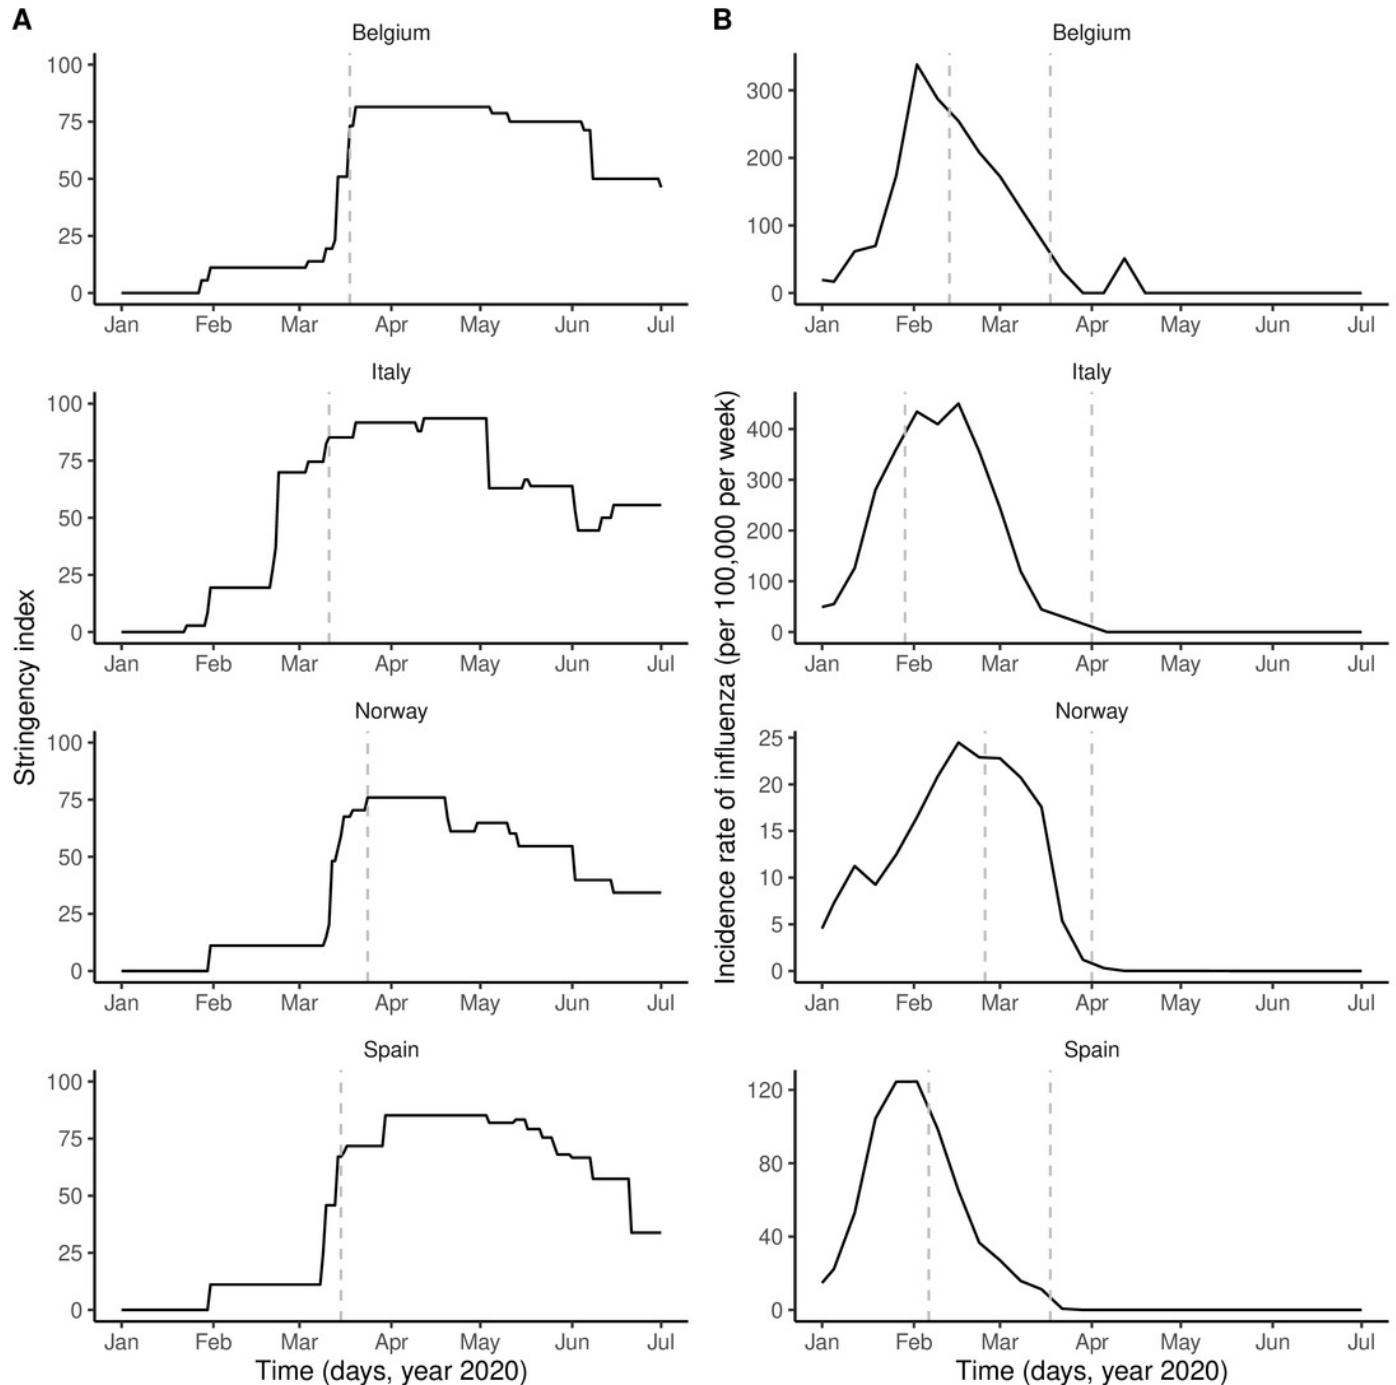

Figure 2

Dynamics of SARS-CoV-2 transmission and of COVID-19 mortality in Belgium, Italy, Norway, and Spain.

A: time plot of the estimated effective reproductive number (R_e). In each panel, the black line represents the maximum likelihood estimate and the grey ribbon the 95% confidence interval (calculated based on the likelihood profile of the influenza impact parameter, cf. Table2) in each country. The dotted black line represents the effective reproduction number estimated from a model without influenza (i.e., with the influenza impact parameter fixed to 0 and the other parameters estimated from the data). The horizontal grey line is at $R_e = 1$. B: time plot of the simulated and observed numbers of daily deaths caused by SARS-CoV-2. In each panel, the light grey lines represent 1,000 model simulations at the maximum likelihood estimate, with one simulation highlighted in dark grey; the black line represents the actual death counts. In A and B, the x-axis and the y-axis values differ for each panel.

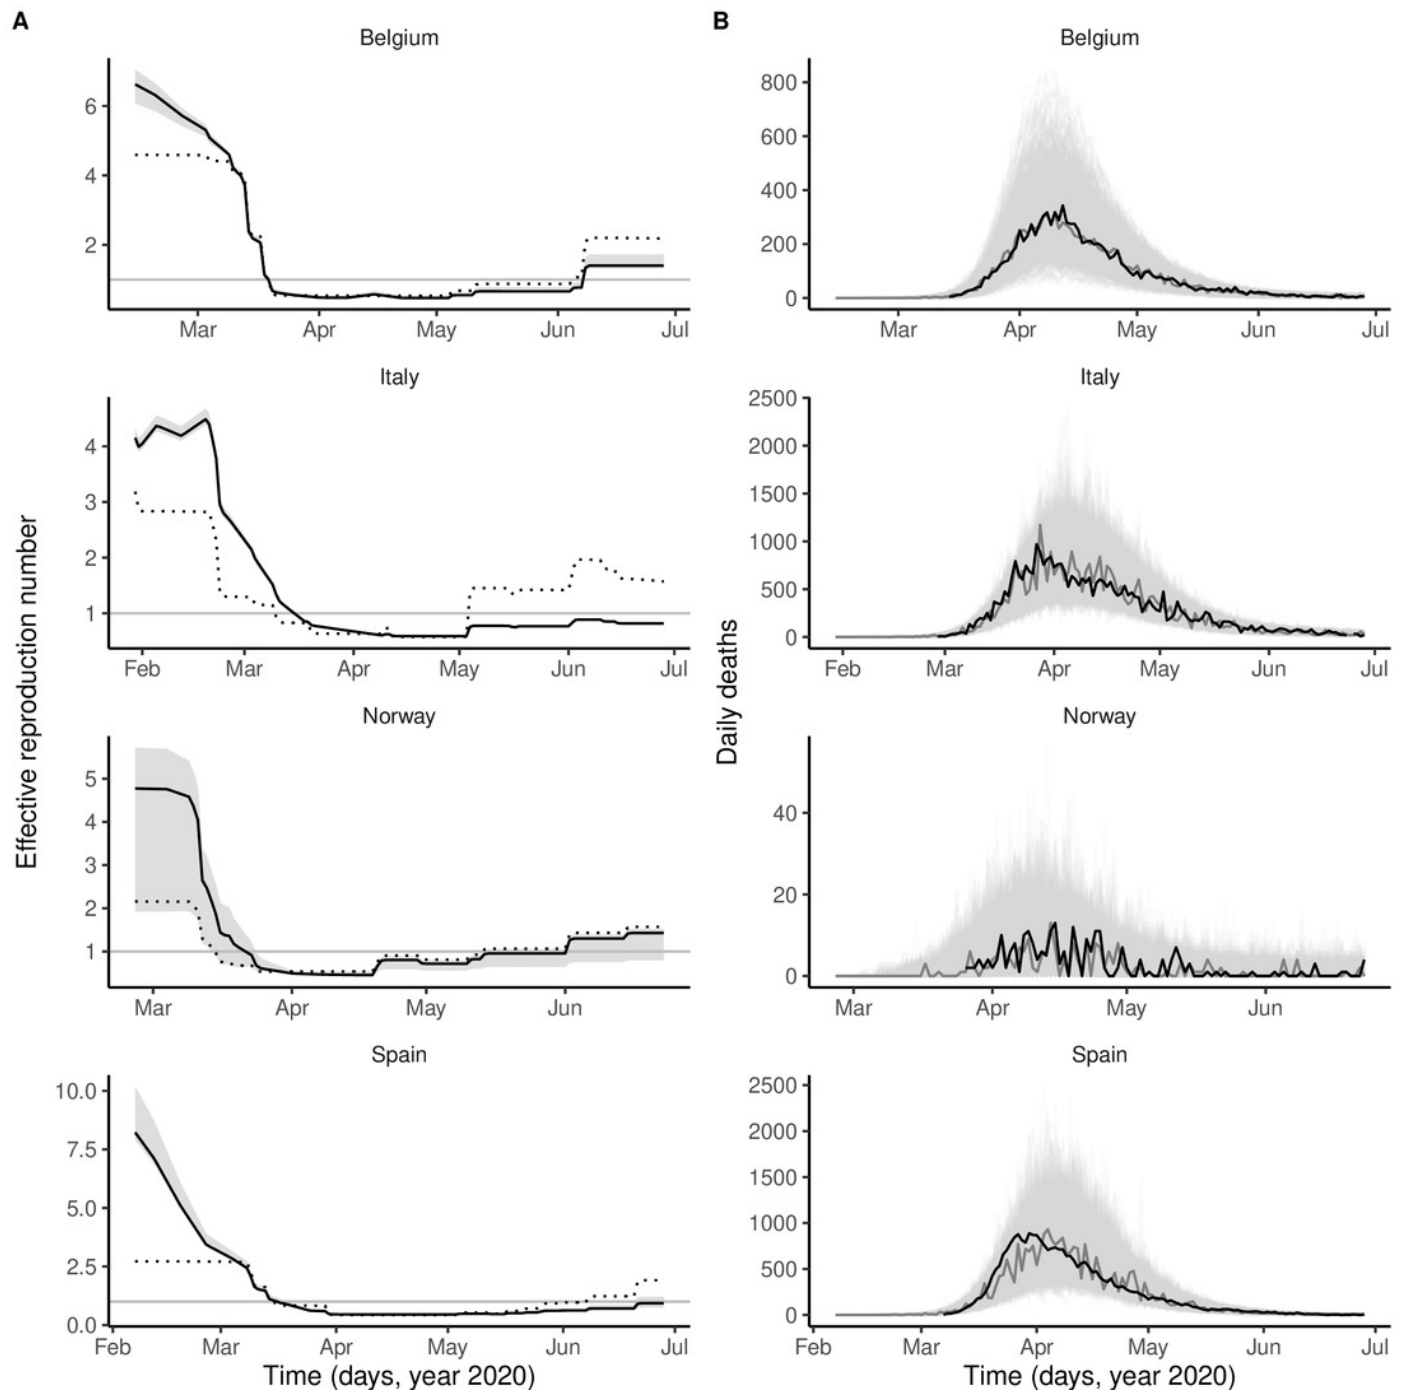

Table 1 (on next page)

List of model parameters.

Symbol	Meaning	Fixed value or estimation range	Comment/Source
$D_E = 1/\sigma$	Average latent period	4 days	[26]
$D_I = 1/\sigma$	Average infectious period	5 days	Fixed to have average generation time of 6.5 days. Sensitivity analyses: 2,7days
$T_g = D_E + D_I/2$	Average generation time	6.5 days	[17, 27]
$1/\kappa$	Average onset-to-death time	17.8 days	[28, 17] Sensitivity analysis: 13 days
μ	Infection- fatality ratio	0.01	[17, 32] Sensitivity analysis: 0.005
N	Population size	Belgium: 11.50 M; Italy: 60.32 M; Norway: 5.37 M; Spain: 47.01M	2019 demographic data from the World Bank
$si(t)$	Stringency index	fixed (covariate)	Fig. 1A
$F(t)$	Incidence of influenza (rescaled)	fixed (covariate)	Fig. 1B
R_0	Basic reproduction number	1–10	[40]
b	Impact of non-pharmaceutical control measures	0.5–2	[17]
β_F	Impact of flu on SARS-CoV-2 transmission	\mathbb{R}	
k	Dispersion of individual reproduction number	0.16	[37, 39]
k_D	Over-dispersion in death reporting	\mathbb{R}^+	
$E_1(0)$	Initial no exposed	0–10 ⁴	Initial condition

Table 2 (on next page)

Model parameter estimates in Belgium, Italy, Norway, and Spain.

For the proportion infected as of May 4, the numbers between parentheses represent a 95% prediction interval, based on 1,000 simulations at the maximum likelihood estimate. For the other parameters, they represent an approximate 95% confidence interval, calculated using either the profile likelihood[45] (parameter β_F) or a parametric bootstrap (other parameters). SE: standard error, calculated using 5 replicate particle filters, each with 20,000 particles, at the maximum likelihood estimate.

Quantity	Belgium	Italy	Norway	Spain
Study period (year 2020)	13 Feb–28 Jun	29 Jan–28 Jun	25 Feb–28 Jun	06 Feb–28 Jun
Log-likelihood (SE)	−384.4 (<0.1)	−649.5 (0.1)	−161.8 (<0.1)	−558.5 (0.2)
Basic reproduction number (R_0)	3.4 (2.5, 4.1)	1.2 (1.1, 1.4)	2.2 (1.0, 2.5)	1.4 (1.0, 1.9)
Impact of control measures (b)	1.03 (0.96, 1.07)	0.53 (0.50, 0.61)	1.05 (0.53, 1.08)	0.75 (0.56, 0.86)
Average relative variation in SARS-CoV-2 transmission rate associated with influenza (β_F)	0.8 (0.5, 1.3)	1.8 (1.5, 2.0)	1.0 (0.1, 2.0)	2.4 (1.7, 4.0)
Initial number exposed to SARS-CoV-2 ($E_1(0)$)	100 (20, 200)	530 (260, 1000)	130 (100, 2800)	400 (170, 780)
Over-dispersion in death reporting (k_D)	7×10^{-4} (1,47) \times 10^{-4}	0.07 (0.05, 0.09)	0.16 (0.01, 0.42)	0.08 (0.05, 0.10)
Proportion infected, as of 4 May 2020 (%)	8.8 (3.7, 17.1)	5.4 (3.9, 7.3)	0.4 (0.2, 0.8)	6.0 (3.8, 8.6)
