Abstract

Leaf spot of *Hosta ventricosa* is a new disease in China. This disease seriously affects the ornamental value and greening function of *H. ventricosa*. Identification of the causal agent can prevent and control leaf spot in *H. ventricosa* and promote the healthy development of the *H. ventricosa* industry. Known incidents of leaf spot of *H. ventricosa* occurred in three places, and samples were collected. After the fungi were isolated, their pathogenicity was tested according to Koch's postulates. Isolates ZE-1b and ZE-2b were identified as *Fusarium oxysporum* based on morphological features and multi gene phylogenetic analyses of calmodulin (CMDA), RNA polymerase II subunit A(RPB1), RNA polymerase II second largest subunit (RPB2) and translation elongation factor 1-alpha (TEF1). These results provide a theoretical basis for the control of this disease of *H. ventricosa*.

Introduction

H. ventricosa, is a perennial herbaceous plant of the *Hosta* genus in Liliaceae. It originated in China, South Korea and Japan (Yu et al.2015) and is widely distributed in China, including

¹ Corresponding author

maosf@126.com

Jiangsu, Anhui, Hebei and other places (Liu *et al.*, 2008). In addition to its bright leaves and graceful habit, this species has strong adaptability to the environment and is suitable for planting under trees, in the shade of buildings or other exposed shaded places. It is an excellent ground cover with ornamental value and greening functions (Zhao, Chen & Lv, 2009). In addition, the whole plant, flowers, leaves or roots can be used as a traditional Chinese medicinal material with the ability to dissipate blood stasis and relieve pain (Zeng, Zhao & Li, 2020).

However, *H. ventricosa* is impacted by several major pathogens, such as *Sclerotium rolfsii* Sacc. This disease manifests because the *H. ventricosa* leaves are especially thick, and during the rainy season, the *H. ventricosa* rhizome is in contact with water for a prolonged time (Zhao, Chen & Lv, 2009). Thus, the epidermis of the affected area becomes brown and necrotic, and finally a white mycelial layer is formed, which leads to cortex decay (Li, Yang & Zhu, 2013). In addition, excessive humidity and poor drainage in the rainy season can also favor diseases caused by *Colletotrichum*, which mainly damages the leaves, petioles and pedicels of *H. ventricosa*. The plants present round or nearly round discolloid spots that are gray or grayish brown (Zhao, Chen & Lv, 2009). Leaf spot of *H. ventricosa* caused by *F. oxysporum* is a very serious fungal disease (Fisher *et al.*, 2012). *F. oxysporum* is one of the top ten most important plant pathogenic fungi in the world, with high virulence and a wide distribution area. The pathogen can cause plant drying and wilting. *F. oxysporum* can be a saprophytic or parasitic fungus. It is widely found in nature, animals and plants, and has been isolated in cold Arctic areas and arid deserts. This strain can cause wilt and decay of roots, stems, leaves, flowers and fruits in over one hundred plant hosts (Maryani *et al.*, 2019).

Materials and methods

Experimental materials

Leaves of infected *H. ventricosa* were collected in Nanjing from 2020 to 2021. Materials used in this study included PDA plates, tissue separation tools, 2% CTAB, and chloroform.

Sampling and isolation

To isolate the fungus, *H. ventricose* leaves showing leaf spots were collected from three places in Nanjing, China (32°4'47"N, 118°48'31"E; 32°4'45"N, 118°48'31"E; 32°4'44"N, 118°48'31"E), in September 2020. The collected leaves were rinsed under tap water for 15-30 min. After the leaves were dried, both healthy and affected tissues were cut into small pieces, each of which was 2 × 2 mm in size. The pieces were disinfected in 75% ethanol for 30 s and in 2 % NaClO for 90 s, then rinsed with sterile water 3 times for 20 s each time (Si *et al.*, 2021), dried on sterile filter paper and inoculated onto PDA. After the appearance of fungal colonies, blocks of tissue were removed from the edges of the colonies for purification. The morphological characteristics, color, size and shape of the purified colonies were observed and described (Chang *et al.*, 2020). Two single-spore cultures were used for further study and were also deposited in the China Forestry Culture Collection Center (CFCC).

Pathogenicity test

The experiments were replicated three times, and a total of 30 seedlings were used. Healthy *H. ventricosa* leaves were collected and rinsed with clean water. The leaves surface were disinfected and dried on an aseptic bench. Pathogenic isolates were inoculated on PDA plates and cultured in an incubator at 25°C for 5 days. To test the pathogenicity of the isolates, *H. ventricosa* leaves were wounded with a sterile needle and then inoculated with 5 mm plugs cut out from the growing edges of 5-day-old cultures (Feng *et al.*, 2019). Three replicates were used (Yang *et al.*, 2021). At the same time, isolates were inoculated onto plants in the natural environment in the wild. Leaves mock inoculated without isolates were used as controls, and the incidence of leaf spot was observed after three days (Yang *et al.*, 2021).

Morphological analysis

Pathogenic isolates were inoculated on PDA plates and incubated in an incubator at 25°C for one week to observe and record the morphology, color, surface characteristics and growth status at the edges of the colonies (Zhang, 2014). The morphology, size and presence of spore septations

were recorded under a microscope (*Murugan et al., 2020*).

DNA extraction, amplification, sequencing and phylogenetic analyses

Before DNA extraction, a small portion of mycelia taken from a 7-day-old culture of the pathogen grown on PDA plates at 25°C was collected and transferred to 2-ml Eppendorf tubes. Genomic DNA was extracted by the CTAB method (*Freeman et al., 1996*). After passing the test, the mycelia were stored at -18°C (*Guo, Hyde & Liew, 2000; Sahai-Maroo et al., 1984*).

The extracted DNA was subjected to polymerase chain reaction (PCR) amplification of partial regions of five genes/regions, namely, calmodulin (CMDA), RNA polymerase II subunit A (RPB1), RNA polymerase II second largest subunit (RPB2) and translation elongation factor 1-alpha (TEF1), which were amplified with primers CL1/CL2A, FA/G2R, 5F2/7CR, and EF1/EF2, respectively (Table 1).

The total volume of the PCR mixture was 50µL (*Lombard, Van & Crous, 2019*), containing 19 µL double-distilled water, 2 µL genomic DNA, 2 µL of each primer, and 25 µL Taq DNA polymerase mix. After PCR, the products were sent to Shanghai Jieli Biotechnology Co., Ltd. for DNA sequencing. All sequences with primers CL1/CL2A, FA/G2R, 5F2/7CR, and EF1/EF2 of ZE-1b was deposited in GenBank under accession numbers MW890756, MZ146450, MW890757, MZ088053, and ZE-2b was deposited in GenBank under accession numbers MW885175, MZ127817, MZ126726 and MW885176, respectively.

The CAMD, RPB1, RPB2, and TEF sequences were compared to sequences in GenBank using BLAST. The sequences were obtained from GenBank for phylogenetic analyses (Table 2). We downloaded sequences for which the comparison results showed higher than 99% similarity. Using *Fusarium aywerte* as the outgroup. The arrangement of each gene/region was compared with MAFFTver.7.313 (*Katoh & Standley, 2013*) and manually adjusted with BioEditver.7.0 (*Hall, 1999*). It was a combination of these five genes/regions. The ModelFinder was used to select the best-fit model (*Kalyaanamoorthy et al., 2017*). In IQTree ver.1.6.8, the alternative model of GTR + F + I + G4 was adopted, 1000 iteration guidance methods were used,

and the maximum - likelihood ground method (ML) analysis was used to estimate the system relationship (Nguyen *et al.*, 2015). In the GTR + I + G + F model (2 parallel runs, 2 million generations), MRBayesver.3.2.6 was used for Bayesian analysis. Using burn-in, 25% of sampled data were discard (Ronquist *et al.*, 2012). The phylogenetic trees were drawn with FigTree ver. 1.4.4 (<http://tree.bio.ed.ac.uk/software/figtree/>)

Results

Incidence of disease and symptoms

The incidence of leaf spot of *H. ventricosa* in three areas of Nanjing City was investigated, and the results showed that the incidence of leaf spot of *H. ventricosa* in the field was 40%. When the *H. ventricosa* leaves were infected, the edge of leaves will turn green and yellow, and be dull. With the development of disease, the leaf spots extended and gradually turned yellowish brown.

Pathogenicity of fungal isolates

Base on the colony morphology, fifty fungal samples were divided into seven types. More than 50% are classified as ZE-1b/ZE-2b types. According to the colony morphology, fungi were divided into 7 kinds namely ZE-a - ZE-g. According to the ITS sequence ZE-a - ZE-g were identified as *Fusarium oxysporum* (50%), *Fusarium ipomoeae* (20%), *Fusarium equisiti* (10%), *Colletotrichum spaethianum* (9%), *Nigrospora spherica* (5%), *Colletotrichum gloeosporioides* (4%), *Colletotrichum siamense* (2%). All of the seven kinds of isolates were inoculated seedlings, replicated three times.

Inoculated *H. ventricosa* showed leaf spot disease consistent with that observed previously. Two isolates (ZE-1b and ZE-2b) were proven pathogenic to *H. ventricosa* leaves. Lesions appeared on detached leaves 3 days after inoculation using mycelial plugs (Fig. 1G-H). In live plants, one week after inoculation, the leaves began to show obvious symptoms of infection, turning yellow and withering (Fig. 1D-E). In addition, no lesions were observed on leaves from the control plants (Cong *et al.*, 2017) (Fig. 1C, F). The symptoms on detached leaves and live plants after

inoculation were the same as those in the field (Fig. 1A-B). The reisolated pathogens from inoculated diseased leaves were consistent with those obtained in the first isolation. Therefore, it was determined that ZE-1b and ZE-2b were the main pathogens causing *H. ventricosa* leaf spot.

Morphological characteristics of fungal isolates

Morphological observations of the pathogenic fungi were carried out. Colonies were inoculated on PDA plates and cultured at 25°C for 4 days, and the colony diameter was 7 cm (Fig. 2I, N). The hyphae grew radially, luxuriously and densely, and the aerial hyphae were velvety, white or pink-white (Liu et al., 2020).

Fusarium has three types of conidia for reproduction and survival under adverse environments: microconidia, macroconidia, and chlamydospores. Microconidia were numerous, oval or kidney-shaped, and scattered, with the size of 4.7 - 8.6 $\mu\text{m} \times 2.5 - 4.7\mu\text{m}$ (Fig. 2J, O). Macroconidia were sickle-shaped, generally symmetrical, slightly curved, and tapering toward the ends, with the size of 23 - 50.6 $\mu\text{m} \times 3 - 5 \mu\text{m}$ (Fig. 2K, P). Chlamydospores were readily produced, with smooth and spherical surfaces (Fig. 2L, Q). They were solitary, paired or clustered between hyphae (Du, 2017).

Phylogenetic analyses

Sequences of the genes/regions CAMD, RPB1, RPB2, and TEF1 from the two isolates (ZE-1b and ZE-2b) were deposited in GenBank, and the accession numbers are shown in Table 2. The sequences from ZE-1b and ZE-2b showed 100% similarity with *F. oxysporum*. These results further indicate that isolation, purification, morphological identification and molecular biology can be used in combination for accurate and reliable results (Cong et al., 2017).

In the ML phylogenetic tree, two isolates (ZE-1b and ZE-2b) were in the same cluster as *F. oxysporum* with 100% RAxML bootstrap support values (Fig. 3). The phylogenetic tree obtained by Bayesian analysis was consistent with the ML tree. Bayesian analyses showed that the isolates clustered with *F. oxysporum* with a high Bayesian posterior probability. Two isolates

(ZE-1b and ZE-2b) were identified as *F. oxysporum* based on multigene phylogeny and morphology.

Discussion

In this study, a novel leaf spot disease was studied through pathogenicity determination, morphological identification, and molecular biological identification, and the results showed that the pathogen was *F. oxysporum*. Herein, wilt of *H. ventricosa* leaves caused by *F. oxysporum* was reported for the first time in China.

F. oxysporum is a facultative parasitic fungus that can both infect plants and live in soil (Yang et al., 2021; Cong et al., 2017). The transmission of the isolate is either vertical transmission through the mother line to the next generation of seeds or horizontal transmission when the fungi in soil or crops infects the host through wounds. The main means of horizontal transmission are as follows: fungal isolates infect and destroy the vascular bundle from the roots (Foley, 1962) and stems of the plant and spread to various parts of the plant. Due to the exposure of stomata and other external tissues of crops as well as plant wounds, spore and mycelial infection via the air can also occur (Headrick, 1991). Most *Fusarium* enter through natural openings in plants or seeds, such as stomata (Lin et al., 2014).

F. oxysporum is highly destructive and can destroy many plant organs and cause very severe diseases, such as leaf spot, root rot, stem rot, flower rot and grain wilt (Liu et al., 2020). Globally, *F. oxysporum* has been identified as a wilt pathogen in many host plants, such as bananas (Maryani et al., 2019; Forsyth, Smith & Aitken, 2006), cotton (Xie et al., 2020; Davis et al., 2006; Zhu et al., 2020), cucumbers (Jaber et al., 2020), sesame (Khalifa, 1997), grapes (El-Sayed et al., 2011), basil (Chen, Lin & Chung, 2017; Mamta et al., 2013; Salim, Salman & Jasim, 2017; Basco et al., 2017), lettuce (Guerrero et al., 2020) and pecan (Rolom et al., 2020). Leaves wilt and eventually drop to the ground, leading to a large area of growth decline; at worst, the whole plant withers and dies, which eventually leads to reductions in yield and quality, causing huge economic losses (Yang et al., 2021; Li et al., 2020; Cong et al., 2017).

Originally by scientists abroad, *Fusarium* was considered a crescent-shaped fungus born on the seed coat. Because many other fungi also produce such sickle-like spores and fungal culture techniques have limitations, the classification of *Fusarium* has long been in a state of confusion. Later, German scientists introduced the first systematic classification of *Fusarium* and proposed a relatively complete classification system based on the biological characteristics of these fungi, combined with their morphological structures, which laid the foundation for classification research on *Fusarium* (Du, 2017). *Fusarium* was initially divided into 44 strains, with 35 strains in China, laying a foundation for the study of *Fusarium* here (Yu, 1977). Currently, more than 3000 strains of *Fusarium* have been studied, 40 physiological strains have been identified and collected, and 1 new strain was found. Twenty-eight strains of *Fusarium zhejiangensis* were identified in Zhejiang, and *Fusarium zhejiangensis* was first recorded in the literature. "*Fusarium* disease in Taiwan" was published in Plant Pathology, Chung Hsing University, Taiwan (Du, 2017).

In recent years, research on *Fusarium* taxonomy in China has developed rapidly based on both morphology and molecular biology. This experiment provides a basis for field prevention and treatment of *H. ventricosa* leaf spot caused by *Fusarium* and provides a reference for further genetic analysis and cultivation of disease resistant varieties of *H. ventricosa* (Zhi, 2020).

Conclusion

This is the first report of *H. ventricosa* leaf spot in China and Chinese *H. ventricosa* is a new host of *F. oxysporum*. We should take reasonable preventive measures against diseases. This study provided theoretical guidance for the control of Chinese *H. ventricosa* leaf spot.

Figure 1

Pathogenicity in detached leaves and in live plants.

1

2

3 (A and B) Diseased leaves naturally infected. (C) No symptoms were observed on
4 leaves from control plants 7 days after inoculation with sterile water; (D) Symptoms on
5 live leaves 7 days after
6 inoculation with mycelial plugs of ZE-1b; (E) Symptoms on live leaves 7 days after
7 inoculation with mycelial plugs of ZE-2b; (F) No symptoms were observed on detached
8 leaves from control plants 3, 5, 7 or 10 days after inoculation with sterile water; (G)
9 Symptoms on detached leaves 3, 5, 7 and 10 days after inoculation with mycelial plugs
10 of ZE-1b; (H) Symptoms on detached leaves 3, 5, 7 and 10 days after inoculation with
11 mycelial plugs of ZE-2b; Bars A=2 cm; B=5 cm; C-E=3 cm; F-H=1 cm.

Figure 2

The morphology of hyphae and conidia.

1

2

3 (I) The front and reverse colony morphology of ZE-1b; (J) microconidia of ZE-1b; (K)
 4 macroconidia of ZE-1b; (L) chlamydospore formation of ZE-1b; (M) conidiophores of ZE-1b; (N)
 5 front and reverse colony morphology of ZE-2b; (O) microconidia of ZE-2b; (P) macroconidia of
 6 ZE-2b; (Q) chlamydospore formation of ZE-2b; (R) conidiophores of ZE-2b; Bars I, N=1 cm; J-M,
 7 O-R=10µm.

Figure 3(on next page)

A maximum parsimony phylogeny for *Fusarium oxysporum*.

1

2 Phylogenetic relationship of ZE-1b and ZE-2b with related taxa derived from

3 maxmum-likelihood (ML) analysis using combined CAMD, RPB1, RPB2, and TEF

4 sequence alignment of *Fusarium* spp., With *Fusarium aywarte* (NRRL 25410) as the

5 outgroup. RAxML bootstrap support values ($ML \geq 50$) and Bayesian posterior

6 probability ($PP \geq 0.80$) are shown at the nodes (ML/PP). Ex-type strains are marked in

7 bold. Isolates from *H. ventricosa* marked in red.

Table 1 (on next page)

Primers for PCR and DNA sequencing.

1 Table 1 Primers for PCR and DNA sequencing.

Locus	Primer	Designation Sequence (5'-3') *	PCR amplification procedures	Reference
