

Humans differ in their personal microbial cloud

James F Meadow, Adam E Altrichter, Ashley C Bateman, Jason Stenson, G Z Brown, Jessica L Green, Brendan JM Bohannon

Dispersal of microbes between humans and the built environment can occur through direct contact with surfaces or through airborne release; the latter mechanism remains poorly understood. Humans emit upwards of 10^6 biological particles per hour, and have long been known to transmit pathogens to other individuals and to indoor surfaces. However it has not previously been demonstrated that humans emit a detectible microbial cloud into surrounding indoor air, nor whether such clouds are sufficiently differentiated to allow the identification of individual occupants. We used high-throughput sequencing of 16S rRNA genes to characterize the airborne bacterial contribution of a single person sitting in a sanitized custom experimental climate chamber. We compared that to air sampled in an adjacent, identical, unoccupied chamber, as well as to supply and exhaust air sources. Additionally, we assessed microbial communities in settled particles surrounding each occupant, to investigate the potential long-term fate of airborne microbial emissions. Most occupants could be clearly detected by their airborne bacterial emissions, as well as their contribution to settled particles, within 1.5-4 hours. Bacterial clouds from the occupants were statistically distinct, allowing the identification of some individual occupants. Our results confirm that an occupied space is microbially distinct from an unoccupied one, and demonstrate for the first time that individuals release their own personalized microbial cloud.

ABSTRACT

Dispersal of microbes between humans and the built environment can occur through direct contact with surfaces or through airborne release; the latter mechanism remains poorly understood. Humans emit upwards of 10^6 biological particles per hour, and have long been known to transmit pathogens to other individuals and to indoor surfaces. However it has not previously been demonstrated that humans emit a detectible microbial cloud into surrounding indoor air, nor whether such clouds are sufficiently differentiated to allow the identification of individual occupants. We used high-throughput sequencing of 16S rRNA genes to characterize the airborne bacterial contribution of a single person sitting in a sanitized custom experimental climate chamber. We compared that to air sampled in an adjacent, identical, unoccupied chamber, as well as to supply and exhaust air sources. Additionally, we assessed microbial communities in settled particles surrounding each occupant, to investigate the potential long-term fate of airborne microbial emissions. Most occupants could be clearly detected by their airborne bacterial emissions, as well as their contribution to settled particles, within 1.5-4 hours. Bacterial clouds from the occupants were statistically distinct, allowing the identification of some individual occupants. Our results confirm that an occupied space is microbially distinct from an unoccupied one, and demonstrate for the first time that individuals release their own personalized microbial cloud.

Keywords: human microbiome, indoor microbiology, built environment, indoor air, microbial cloud

1 INTRODUCTION

2 Humans harbor diverse microbial assemblages in and on our bodies (HMP Consortium, 2012), and these
3 distinctly human-associated bacteria can be readily detected inside of buildings on surfaces, in dust, and
4 as bioaerosols (Hospodsky et al., 2012; Täubel et al., 2009; Fierer et al., 2010; Flores et al., 2011, 2013;
5 Meadow et al., 2013; Kembel et al., 2012, 2014). Human-associated bacteria disperse into and throughout
6 the built environment by three primary mechanisms: 1) direct human contact with indoor surfaces; 2)
7 bioaerosol particle emission from our breath, clothes, skin and hair; and 3) resuspension of indoor dust
8 containing previously shed human skin cells, hair and other bacteria-laden particles. Recent studies of
9 built environment microbes have largely focused on direct human contact with surfaces, and demonstrated

10 that people can leave behind bacterial signatures indicative of particular body parts and types of bodily
11 contact (Flores et al., 2011, 2013; Meadow et al., 2014). Given the long-term identifiability of the human
12 microbiome (Franzosa et al., 2015), in some cases these bacterial assemblages can even be traced back to
13 an individual person (Fierer et al., 2010), though this has only been demonstrated using direct contact.

14 Bioaerosols (airborne biological particles including bacteria and bacteria-laden particles) have often
15 been the focus of infection-control studies, but their role in seeding the built environment microbiome
16 is poorly understood. Research on bioaerosols to date has rarely focused on the direct emission of
17 bioaerosols from human sources, because it is difficult to disentangle direct emission from resuspension
18 of dust observationally (Meadow et al., 2013; Qian et al., 2012, 2014a; Nazaroff, 2014; Hospodsky et al.,
19 2014; Bhangar et al., 2015; Adams et al., 2015). Previous attempts to account for dust resuspension in
20 indoor bioaerosols indicate that active human emission, as opposed to resuspended particulate matter,
21 is an underestimated part of the total indoor airborne bacterial pool in buildings (Qian et al., 2014b).
22 For instance, several recent studies (Hospodsky et al., 2012, 2014; Bhangar et al., 2015; Adams et al.,
23 2015) detected substantial particle concentrations from a group of occupants in a room, as well as a single
24 occupant in a room, even after controlling for resuspended dust. Since humans shed approximately 10^6
25 particles ($>0.5 \mu\text{m}$ diameter) per hour (You et al., 2013; Bhangar et al., 2015), and many of these likely
26 contain bacteria, the actively shed human microbial contribution is thought to play a substantial role in
27 seeding the built environment microbiome. Additionally, microbes from occupants in a new home can
28 be detected inside the house in a matter of days (Lax et al., 2014), illustrating the magnitude of airborne
29 flux from humans to their built environment. This flux potentially also mediates interactions with other
30 humans and their associated microbiota within dispersal range.

31 Human interactions with indoor airborne microbes have been investigated for more than a century
32 (Tyndall, 1881; Carnelley et al., 1887; Tyndall, 1876), although almost exclusively from the perspective of
33 disease and airborne-transmission of pathogens (Noble et al., 1976; Sherertz et al., 2001; Tang et al., 2011).
34 Human interactions with non-pathogenic microbes have recently received increased attention for their
35 integral roles in healthy human function (HMP Consortium, 2012). We are just beginning to understand
36 how these interactions structure the human microbiome, including interactions with indoor bioaerosols
37 and indoor dust (Fujimura et al., 2010, 2013). It is plausible that direct emission of bacterial cells from
38 an individual results in a detectable human microbiome signal that is traceable to a particular individual,
39 similar to what has been reported after contact with indoor surfaces (Fierer et al., 2010), although this has
40 never been demonstrated. Recently emitted bioaerosols potentially represent a distinct microbial source
41 pool if they contain bacterial taxa that are unable to persist in desiccated dust or on surfaces, and therefore
42 might not be otherwise detected. These recently emitted microbes might also more readily colonize other

43 humans within the built environment than those found on surfaces or in resuspended dust, since recently
44 emitted microbes are more likely to be physiologically active and have not been subjected to prolonged
45 desiccation or UV exposure before colonization can successfully occur.

46 In order to understand the human contribution to bioaerosols within built environments, and the
47 extent to which this emitted bioaerosol pool contributes to the residual human-microbial signal detected
48 in indoor dust and on surrounding indoor surfaces, we characterized the airborne bacterial cloud of a
49 person sitting in a sanitized experimental climate chamber (Fig. S1). Background bacterial biomass in the
50 chamber was reduced by a combination of surface disinfection and ventilation control. Over the course of
51 two separate experiments, we used high-throughput DNA sequencing methods to characterize airborne
52 bacterial community composition emitted by 11 different human occupants. During the first experiment,
53 we compared airborne bacterial assemblages to those detected simultaneously in an identical, adjacent
54 unoccupied side of the chamber. This was repeated for three different people, each for 4- and 2-hour
55 sampling periods. To assess the potential for these airborne particles to result in a detectable human
56 microbiome signal as settled dust on surrounding surfaces, we sequenced DNA from settling dishes in
57 each sampling period, and compared those to airborne assemblages. Given that occupants could each be
58 clearly detected and differentiated from one another, we designed a second experiment to further explore
59 the distinguishability of the personal microbial cloud. For this we sampled 8 different people for 90
60 minutes each, and with air flowing at 1 air change per hour (ACH) and 3 ACH. Each occupant's personal
61 microbial emissions were compared among occupants, and to filtered supply and exhaust air from the
62 occupied chamber to assess personal detectability within a building's ventilation system.

63 **METHODS AND MATERIALS**

64 **Experimental design**

65 All samples were collected over December 5-7, 2012 (first experiment), and April 22 - May 3, 2013
66 (second experiment), at the Energy Studies in Buildings Laboratory, Portland, OR, USA, using the custom
67 Climate Chamber (Fig. S1; interior dimensions = c. 3.7 m long x 2.4 m wide x 2.9m high; 25.75 m³).
68 Filtered air was supplied through a ceiling plenum, and exhausted through a floor plenum. During the first
69 experiment, the chamber floor and walls were lined with 0.15 mm clean-room plastic sheeting (Visqueen,
70 British Polythene Ltd., Heanor, UK). The sheeting was anti-static and fire retardant, and was washed
71 and double bagged by manufacturers. Sheeting edges were sealed to walls, floors and ceilings with
72 vinyl cleanroom tape (UltraTape, Wilsonville, OR, USA). A vertical partition of plastic sheeting was
73 taped down the middle of the chamber to create two identical chambers for simultaneous sampling. This
74 simultaneous design allowed us to monitor any changes to the chamber air not due to the occupant over

75 the course of the first experiment. During the second experiment, the plastic was not used, nor was the
76 chamber divided, and thus the total volume of air in the occupied chamber was doubled for the second
77 experiment.

78 Continuous fan powered supply air was used to maintain positive pressure in the chamber throughout
79 both experiments; this helped to reduce the introduction of background bioaerosols from outside the
80 chamber. Conditioned indoor air (first experiment) or outdoor air (second experiment) passed through a
81 MERV-15 (first experiment) or MERV-8 (second experiment) filter to reduce dust and bacterial introduction
82 into the chamber. However the ductwork was not sterilized after the point of filtration, nor was the inline
83 mechanical equipment. Thus the chamber was not fully sealed to unfiltered air. Ducted supply air was
84 diffused through a ceiling plenum into the chamber. Air was exhausted (second experiment) through the
85 floor plenum under the chamber, and through an exhaust duct. During the second experiment, vacuum air
86 filter samplers were installed in-line to collect supply air after the supply fan and MERV-8 filter, and also
87 in the exhaust duct.

88 Air exchange rates were monitored throughout both experiments by balancing supply and exhaust air
89 velocities, measured in center-of-duct point with a multi-function ventilation meter and a thermoanemome-
90 ter probe (#9555 and #964, respectively; TSI Incorporated, Shoreview, MN). Air pressure within the
91 chamber was measured with a differential air pressure transducer (#T-VER-PXU-L, Onset Computer
92 Corporation, Bourne, MA).

93 All interior chamber surfaces, including plastic lining and sampling apparatuses, were washed with
94 bactericidal chemical treatment (Cavicide, Metrex Research, Orange, CA, USA) before and between each
95 experimental trial to reduce the microbial load in the chamber and to limit cross-contamination between
96 occupant treatments. The occupant chairs used throughout both experiments were Caper Stacking Chairs
97 (Flexnet set, fixed arms, hard-floor casters; Herman Miller, Zeeland, MI). All technical staff entering the
98 chamber for cleaning or sample collection wore sterile, hooded Tyvek garments, gloves and face-masks.

99 All eleven subjects were free of disease symptoms at the time of sampling, had not taken antibiotics
100 for at least 4 months, and were between the ages of 20 and 33. The subjects were informed as to the full
101 nature and design of the study and gave written consent to be participants. All research protocols were
102 approved by the University of Oregon Institutional Review Board (protocol # 03172014.021). Identities
103 of participants were never recorded on samples or in resulting datasets.

104 Standard bioaerosol and settled particle sampling protocols used by Bowers et al. (Bowers et al.,
105 2011, 2012), and Adams et al. (Adams et al., 2013) were modified for our experimental climate chamber
106 approach. Each occupant sat in a disinfected plastic rolling chair surrounded by 12 sterile 0.2 μm
107 cellulose-nitrate air filters that were arranged equidistant from the seat (Fig. S1) Air filters were arranged

108 in rings of 6 samplers each: one ring at shoulder height when seated (1 m) and the other just above
109 floor height (15 cm). During the second experiment, one ring of 6 filters were placed at shoulder height,
110 but not at floor height. Air was drawn through the filters by a pump external to the chamber at c. 10
111 L min⁻¹ for the first experiment, and c. 24.5 L min⁻¹ for the second. Settled particles were collected
112 on both the lid and base of 6 empty, sterile petri dishes (15 cm) that were placed face-up on the floor
113 in a circular pattern surrounding the occupant. In order to expose each air filter to the occupant in a
114 similar manner, the occupant was instructed to rotate approximately 60° on regular intervals to face a new
115 filter or pair of filters; occupants sat in rolling chairs, so rotating required minimal movement within the
116 chamber. The unoccupied chamber was arranged in identical fashion, with the exception that the occupant
117 in the occupied chamber was allowed a ethanol surface-sterilized laptop for entertainment and as a means
118 of communicating with those outside of the chamber; in order to reduce heat generated by the laptop
119 computer, occupants held the laptop on a rubberized, surface-sterilized lap-desk. The laptop and lap-desk
120 were absent from the unoccupied chamber.

121 Occupants self-reported their comfort, and any necessary temperature adjustments were made without
122 tempering air, but rather by adjusting radiant floor temperature. Air temperature and relative humidity
123 were monitored using data loggers (#U12-012, Onset Computer Corporation, Bourne, MA). Temperatures
124 inside the climate chamber throughout both experiments ranged from 22-26 °C, and relative humidity
125 ranged from 25-45%.

126 During the first experiment, each day consisted of a single occupant in the chamber for one 240- and
127 one 120-minute sampling period, with a break between sampling periods. During the second experiment,
128 each occupant was in the chamber for two separate 90-minute periods, once at 3 air changes per hour
129 (ACH) ventilation rate, and again for 1 ACH.

130 Particle count data was collected at a rate of 2.83 L minute⁻¹ in 1 minute intervals, and size fractionated
131 with the AeroTrack 9306-V2 (TSI Inc., Shoreview, MN, USA). Three different particle size classes (2.5-5
132 μm, 5-10 μm and 10+ μm) were considered for this study. All particle counts were averaged over 10
133 minute intervals (5 for the second experiment) and converted to L minute⁻¹ ratio above simultaneous
134 unoccupied values for the first experiment. Since no unoccupied chamber was used in the second
135 experiment, we calculated a particle deposition loss coefficient (Tracy et al., 2002) by comparing particle
136 counts in the occupied chamber to particle counts in the supply duct system. Filters and settling dishes
137 were immediately packaged, transported on dry ice, and stored at -80 °C until further processing.

138 **16S library preparation and sequencing**

139 To avoid confounding effects introduced during library preparation, all samples were randomized across
140 extraction batch, amplification batch, and processing order. Air filters and settling dishes from both

141 experiments were all processed using methods specifically for low-biomass samples adapted from Kwan
142 et al. (Kwan et al., 2011), and amplicon libraries were constructed following methods from Caporaso et
143 al. (Caporaso et al., 2012), and Fadrosh et al. (Fadrosh et al., 2014).

144 ***First experiment***

145 Particles and nucleic acids from the lid and base of each settling dish were collected and combined using a
146 PBS-moistened, DNA-free cotton swab (Cat. 25-806 1WC FDNA, Puritan Medical, Guilford, ME, USA)
147 to wipe the lid and base twice-over on each, in perpendicular directions and rotating the swab a quarter
148 turn with each pass. Cells and nucleic acids were then eluted from the air filters and swabs by vortexing
149 each sample in 4 mL of sterile PBS (biotechnology grade, Amresco, Solon, OH, USA). The eluate was
150 subsequently concentrated to approximately 500 μL in an Amicon Ultra-4 centrifugal filter (30 kDa). 200
151 μL of this concentrated sample was extracted using the MoBio htp-PowerSoil DNA Isolation kit according
152 to the manufacturer's specifications with the following modifications: samples were individually bead
153 beat in 2 mL collection tubes with 0.1 mm glass beads, 200 μL of phenol:chloroform:IAA was added to
154 the bead tube prior to beat beating, tubes were beat using a FastPrep1200 homogenizer at setting 5.0 for
155 40 seconds, solutions C2 and C3 were added together in equal volumes, solution C4 and absolute ethanol
156 were added in equal volumes to the lysate, 650 μL of absolute ethanol was used to wash the spin column
157 prior to solution C5, and DNA was eluted in 70 μL of elution buffer.

158 Sequencing libraries were prepped using a modification of the Caporaso et al. (Caporaso et al., 2012)
159 protocol wherein 16S rRNA gene primers 515F and Golay-barcoded 806R were used in triplicate PCRs
160 per sample, followed by equivolume combination of all samples, and concentrated to 25 μL (Zymo
161 Research Clean and Concentrate-5). This was followed by gel electrophoresis size selection and extraction
162 of the pooled samples (Qiagen MinElute Gel Extraction), with a final clean up step (Zymo Research
163 Clean and Concentrate-5). The PCR had the following components (25 μL total volume): 13.25 μL
164 DNA-grade water, 5 μL 5x HF Buffer, 0.5 μL dNTPs (10 mM), 0.5 μL each primer (10 μM), 0.25 μL
165 Phusion Hot Start II polymerase (2 U/ μL), and 5 μL of genomic DNA template. The PCR was carried
166 out under the following conditions: an initial denaturation step of 98 °C for 1 min, followed by 35 cycles
167 of 98 °C for 20 sec, 52 °C for 30 sec, and 72 °C for 30 sec, with a final extension at 72 °C for 10 min.
168 The final library was then sent to the Dana-Farber Cancer Institute Molecular Biology Core Facilities for
169 250 PE sequencing on the Illumina MiSeq platform.

170 ***Second experiment***

171 Air samples from the second experiment were processed using the following modifications to the Mo-
172 Bio PowerSoil-htp kit: filters were bead beat for 1.5 min at maximum speed with the FastPrep1200
173 homogenizer and heated for 10 min at 65 °C, Solutions C2 and C3 were omitted prior to loading on the

174 spin-column, and samples were eluted into 70 μL .

175 Each sample was amplified with a 2 step PCR prep method for Illumina sequencing of the V3-V4
176 region with 319F and 806R dual indexed primers including heterogeneity spacers to improve low plexity
177 libraries, similar to methods used by Fadrosh and colleagues (Fadrosh et al., 2014). PCR1 was run in
178 triplicate for each sample and included 11.75 μL PCR-grade water, 0.25 μL Phusion HS II polymerase (2
179 U/ μL), 5 μL 5x HF buffer, 0.5 μL dNTPs, 2.5 μL forward and reverse gene primer mix (5 μM each) with
180 heterogeneity spacers, and 5 μL template genomic DNA. PCR1 was run under the following conditions:
181 98 °C for 2 min, followed by 25 cycles of 98 °C for 20 sec, 50 °C for 30 sec, and 72 °C for 30 sec, with
182 a final extension of 2 min at 72 °C. Triplicates were pooled and cleaned with Qiagen MinElute 96 UF
183 PCR Purification kit prior to PCR2. PCR2 contained 6.75 μL PCR-grade water, 0.25 μL Phusion HS II
184 polymerase (2 U/ μL), 5 μL 5x HF buffer, 0.5 μL dNTPs, 1.25 μL of forward and reverse primers (10
185 μM each) with Illumina adapter and index sequences, and 10 μL template from cleaned PCR1 products.
186 PCR2 was run under the following conditions: 98 °C for 1 min, followed by 10 cycles of 98 °C for 20
187 sec, 63 °C for 30 sec, and 72 °C for 30 sec, with a final extension of 3 min at 72 °C. Samples were then
188 cleaned, multiplexed and concentrated to be run on a 1% gel for size-selection, then underwent a final
189 clean-up step with Zymo Research Clean and Concentrate-25 kit. The final library was submitted for 300
190 PE sequencing run on the Illumina MiSeq platform at the Molecular Biology Core Facility at Harvard's
191 Dana Farber Cancer Institute.

192 **Data processing and statistical analysis**

193 Raw sequences from the first experiment were processed using a QIIME v. 1.7 pipeline (Caporaso et al.,
194 2010). We retained and demultiplexed 1.007×10^7 sequences with an average quality score of 30 over
195 97% of the sequence length. Sequences were binned into OTUs at 97% similarity using UCLUST denovo
196 clustering (Edgar, 2010), which resulted in c. 2.4×10^5 OTUs across 300 samples. Raw sequences from
197 the second experiment were processed using the QIIME v. 1.8 pipeline, except that OTUs were clustered
198 using USEARCH v. 7 (Edgar, 2013). We retained and demultiplexed 7.5×10^7 sequences with expected
199 error rates less than 0.5. Taxonomy was assigned to OTUs using the RDP classifier and Greengenes
200 version '4feb2011' core set (DeSantis et al., 2006).

201 After quality filtering, demultiplexing, and OTU clustering, all statistical analyses were conducted
202 in R (R Development Core Team, 2010), primarily with the vegan, labdsv and ape packages (Oksanen
203 et al., 2011; Roberts, 2010; Paradis et al., 2004). Plant chloroplast and mitochondrial sequences were
204 removed from both datasets prior to analysis. Apparent contaminants were also analyzed separately for
205 their influence on results, and those exerting influence were removed from downstream analysis (4 OTUs
206 from the first experiment, and 10 from the second).

207 First experiment

208 All samples in the first experiment were rarefied to 1000 sequences per sample to achieve approximately
209 equal sampling depth. β -diversity was calculated using the Canberra taxonomic metric, and ordinations
210 were constructed using iterative non-metric multi-dimensional scaling (NMDS). Community differences
211 were assessed using permutational multivariate analysis of variance tests (PERMANOVA). Since commu-
212 nity differences were tested with permutational tests, we report p-values down to, but not below, 0.001.
213 Clustering was conducted with an average linkage method based on Canberra distances. Indicator species
214 analysis followed Duf rene and Legendre (1997), and OTUs were further investigated if uncorrected
215 p-values were less than 0.05. The most significant indicator OTUs from 4-hour air filters (indicator
216 value >0.6 and p-value <0.001) are shown in Table S1. Representative sequences from each OTU were
217 BLAST'ed against the NCBI 16S isolate database, resulting in putative species assignments and NCBI
218 accession numbers.

219 Second experiment

220 The goal of the second analysis was different from the first. We were primarily interested in the
221 subset of OTUs that help to distinguish each occupant, and not in the OTUs that were abundant in
222 both the unoccupied and occupied air. These targeted OTUs were selected based on their GreenGenes
223 taxonomic assignments: *Corynebacteriaceae*, *Staphylococcaceae*, *Streptococcaceae*, *Lactobacillaceae*,
224 *Propionibacteriaceae*, *Peptostreptococcaceae*, *Bifidobacteriaceae*, *Micrococcaceae*, *Carnobacteriaceae*,
225 *Dietziaceae*, *Aerococcaceae*, and *Tissierellaceae*. Thus we didn't rarefy the second dataset, but rather
226 created a subset of relative abundances for analysis. Additionally, since several of these human-associated
227 groups were the most abundant and distinguishing among occupants, we used the Bray-Curtis dissimilarity
228 metric for multivariate analyses, and the Jaccard distance (as a percent of shared OTUs) to show the
229 average shared relationships in Fig. S4. Since community differences were tested with permutational tests,
230 we report p-values down to, but not below, 0.001. Clustering was conducted with Ward's linkage method
231 based on Bray-Curtis dissimilarities.

232 Data and Analysis Availability

233 All raw sequence data are available on the Figshare open-access data repository under DOI:
234 <http://dx.doi.org/10.6084/m9.figshare.1506779>. All data analysis details and R scripts are available on
235 GitHub: https://github.com/jfmeadow/Meadow_HumanMicrobialCloud_Analysis.

236 RESULTS

237 Sequencing of bacterial 16S rRNA genes across the two experiments resulted in more than 14×10^6
238 quality-filtered sequences. Since the objective of the first experiment was to determine the detectability of

239 a single occupant in a cleaned room, we first focused on differentiating occupied air from unoccupied.

240 **Human occupants shed a detectable bacterial cloud**

241 In the first experiment, bacterial assemblages in samples from occupied and unoccupied air were signifi-
 242 cantly different, regardless of occupant, collection method or trial duration ($p = 0.001$; from PERMANOVA
 243 tests on Canberra distances; Table 1). When considering individual sampling periods (Table 2 and Fig. 1),
 244 all three individuals could be clearly detected above background airborne communities after 4- and 2-hours
 245 from the airborne bacteria collected on air filters. Only Subjects 1 and 3 were consistently detectable from
 246 particles in settling dishes at both time intervals; Subject 2 was significantly detectable during the 4-hour
 247 sampling period, but not during the 2-hour sampling period ($p = 0.34$).

248 These community differences were evident in a few specific human-associated bacterial taxa. Indicator
 249 analysis (Dufrêne and Legendre, 1997) identifies those operational taxonomic units (OTUs) that signifi-
 250 cantly and consistently distinguish a given treatment, in this case bacterial groups that were especially
 251 abundant in occupied chambers or those that helped to differentiate among individual occupants. All
 252 significant indicator taxa (defined as having an indicator value >0.5 and p -value <0.01) detected in 4-hour
 253 air filters from the occupied chamber were closely related to human-associated bacterial taxa found in the
 254 NCBI bacterial isolate database. Conversely, all top indicator taxa from unoccupied samples were related
 255 to bacteria from non-human environments, ostensibly introduced by supply air to the climate chamber.
 256 Taxa with indicator values >0.7 are shown in Table 3.

Table 1. During the first experiment, occupied chambers were significantly different from unoccupied across every 4-hour sampling period, regardless of sampling method. The tests for “*occ vs. unocc*” consider two different groups, combining all occupied samples and all unoccupied samples, whereas “*3 people vs. unocc*” considers 4 different groups including 3 separate occupants and all unoccupied samples together.

Data Subset	Test	n	R^2	p^*
all samples	occ vs. unocc	211	0.01	0.001
all 4-hour	occ vs. unocc	106	0.017	0.001
all 2-hour	occ vs. unocc	105	0.014	0.001
all air filters	occ vs. unocc	140	0.014	0.001
all settling dishes	occ vs. unocc	71	0.018	0.001
only 4-hour samples				
air filters	occ vs. unocc	71	0.023	0.001
air filters	3 people vs. unocc	71	0.061	0.001

*Results are from PERMANOVA on Canberra distances.

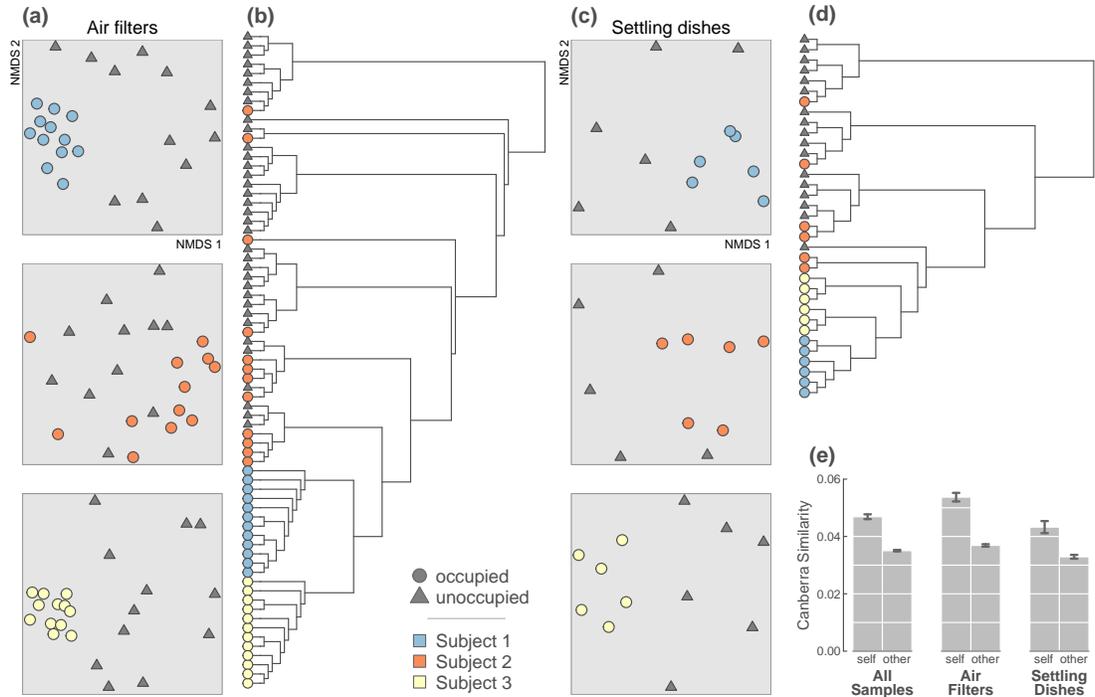

Figure 1. Occupied and unoccupied bioaerosols during the first experiment were significantly different, and occupants were distinguishable during all 4-hour sampling periods. (a) All three occupants were discernible from simultaneously unoccupied air (all p -values = 0.001). Ordination plots are 2-dimensional NMDS from Canberra distances. (b) Occupants were distinguishable from one another based on bacteria collected in air filters (p -value = 0.001). (c) Occupants were discernible from unoccupied samples based on bacteria collected in settling dishes (p -values = 0.003, 0.044, and 0.005; for Subjects 1, 2, and 3). (d) Settled particles from each occupant were somewhat less consistently identifiable, even though the three occupants were significantly different (p -value = 0.001). (e) Occupant microbial clouds were more similar to other samples from the same person than to other occupants, regardless of sampling method. This difference was significantly more pronounced than that of unoccupied samples taken simultaneously during sampling periods (Fig. S1). Error bars represent ± 1 standard error on pairwise Canberra similarities.

Table 2. During the first experiment, occupants were always detectable in air filters, and generally in settling dishes.

* Corresponding OTU was also among the most abundant and thus included in Fig. 2

** Individual occupants are shown if indicator taxa were significant for that particular person, and “occupied” if significant for all occupants together.

257 **Occupants differ in their personal microbial cloud**

258 In addition to our finding that occupants were detectable from their microbial contributions of bioaerosols
259 and/or settled particles, bacterial assemblages were also *unique* to each of the three occupants, meaning
260 that samples from each individual were statistically distinct and identifiable to that occupant ($p = 0.001$;
261 from PERMANOVA on 4-hour air filters from each occupant; Fig. 1 and Table 1). Each occupant,
262 however, was identifiable in different ways. For instance, microbial assemblages in air filters from Subject
263 2's 4-hour sampling periods were statistically more variable than the other two occupants ($p < 0.0001$;
264 from ANOVA test on beta-dispersion distances); the 2-hour sampling period followed the same general
265 pattern.

266 Each of the three occupants was also identifiable by distinct bacterial OTUs. For example, an OTU
267 99% similar to *Dolosigranulum pigrum* (Fig. S2) was similarly enriched in all of Subject 1's samples,
268 yet it was absent for other occupants. Subject 2's samples were dominated by a *Staphylococcus* OTU
269 (100% similar to *Staphylococcus epidermidis*; Fig. S2). Although other closely related OTUs were present
270 throughout the study, this same OTU was less abundant in unoccupied samples, and when the chamber
271 was occupied by anyone else. The sole female in the first experiment, Subject 3, was strongly associated
272 with a *Lactobacillus* OTU (Fig. S2) 100% similar to *Lactobacillus crispatus*, a bacterium that is commonly
273 found dominating healthy vaginal samples. This OTU was essentially absent throughout the rest of the
274 first experiment. All OTUs discussed above were also significant indicator taxa (Table 3).

275 **Occupant microbial clouds can be detected on surrounding surfaces**

276 In addition to airborne particles, we collected settled particles in sterile settling dishes as an estimate of
277 the pool of potentially persistent particles. Consistent with results from air filter samples, occupied vs.
278 unoccupied samples were always significantly different during 4-hour time periods (Tables 1 & 2), and
279 the most abundant OTUs in each trial reflect those found in air filters (Fig. S2).

280 **Targeted subset of human-associated OTUs**

281 Based on the predominance of these human-associated OTUs over background air in the first experiment,
282 and on previous human microbiome research, we designed the second experiment and subsequent analyses
283 around this subset of bacterial families (*Corynebacteriaceae*, *Staphylococcaceae*, *Streptococcaceae*,
284 *Lactobacillaceae*, *Propionibacteriaceae*, *Peptostreptococcaceae*, *Bifidobacteriaceae*, *Micrococcaceae*,
285 *Carnobacteriaceae*, *Dietziaceae*, *Aerococcaceae*, and *Tissierellaceae*). These are hereafter referred to as
286 "targeted OTUs." Specifically, we selected these families based on three criteria: 1) OTUs representing
287 these families were consistently significant predictors of human occupants vs background air in the first
288 experiment (Table 3); 2) the relative abundances of these families were always elevated in occupied

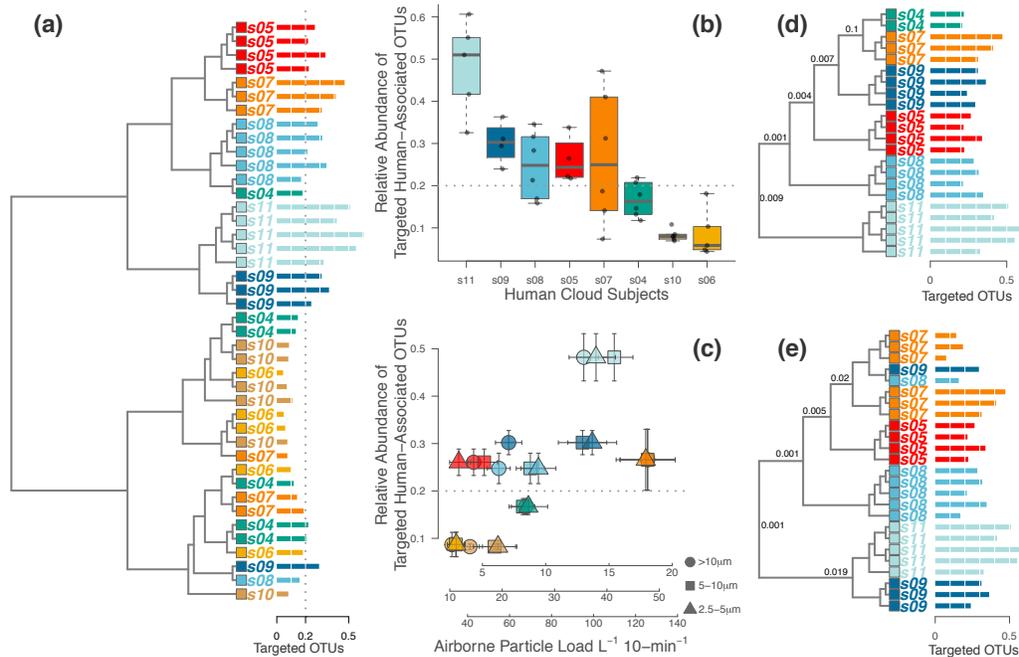

Figure 2. Half of the occupants in the second experiment were clearly distinguishable, but this depended on the magnitude of human-associated bacteria shed during occupation. (a) When analyzing only the targeted human-associated bacterial taxa, only samples in the top half of the dendrogram tended to be correctly classified together. Those samples that failed to cluster together were generally below the apparent 20% human-associated threshold (gray dotted line). Each tip on the tree is a separate sample from a single occupant (*subject s04–s11*). Each occupant is a different color, and the colors correspond with Figs 3 & 4. Horizontal bars (identical to those used in d & e) show the proportion of targeted human-associated bacterial OTUs in each sample. These same values are shown as the y-axes in b & c. (b) Each occupant yielded a consistent proportion of human-associated taxa. (c) Airborne particle counts (x-axis) correlate with the proportion of airborne human-associated taxa detected around each occupant (y-axis). (d) When the dataset was limited to only those samples above the 20% threshold, all samples cluster appropriately by individual human subject. (e) Alternatively, if limiting the dataset to only those *occupants* whose median sample proportion was above 20%, results were nearly identical except for two misclassifications. P-values shown at major nodes in d & e are from PERMANOVA tests on separation of individual clades.

289 samples compared to unoccupied samples; and 3) all of these families are consistently detected as
290 members of the healthy human microbiome (HMP Consortium, 2012; Grice and Segre, 2011; Ravel et al.,
291 2011), and as indicators for human occupancy in the built environment (Fierer et al., 2010; Flores et al.,
292 2011; Meadow et al., 2013; Kembel et al., 2014; Meadow et al., 2014).

293 **Occupant identifiability**

294 Results from the first experiment illustrated that a) occupants emit a detectable airborne signal; b) that
295 signal is the result of elevated abundance of a specific set of human-associated bacterial taxa; and c) each
296 occupant's personalized airborne signal can be statistically differentiated from other occupants. Thus our
297 second experiment was focused on directly analyzing the subset of targeted human-associated airborne
298 bacteria to determine the detectability and personalized nature of a given individual's microbial cloud. To
299 do this, we sampled the air surrounding each of 8 occupants, as well as the supply and exhaust air moving
300 into and out of the occupied chamber, respectively (Fig S1b). We then analyzed the targeted subset of
301 human-associated bacterial OTUs, described above, to determine if and how many occupants could be
302 statistically differentiated just by the air around them.

303 We found that each of the eight occupants emitted their own characteristic concentration of airborne
304 particles. These particle concentrations were correlated with the proportion of human-associated bacteria
305 in the surrounding air, and subsequently with our ability to identify each unique occupant from their
306 microbial cloud (Fig. 2a-c). As before, some occupants' microbial clouds were more detectable than
307 others, and for each person this was predicted by the proportion of targeted human-associated OTUs in
308 an occupant's respective dataset. Samples where the targeted subset of OTUs composed more than 20%
309 of the total generally clustered correctly by occupant, while those with less were generally unable to
310 be classified as being from a specific occupant (Fig. 2a, d & e). The same apparent 20% threshold also
311 applied to the human cloud signal detected in the exhaust air leaving the chamber. We were only able
312 to classify exhaust air as coming from a particular occupant if sufficient human-associated taxa were
313 detected, and this was only possible for two of the eight occupants. For four others, the air in the occupied
314 chamber was distinct from background air and generally from other occupants, but they could not be
315 detected in exhaust air, while two occupants could not be detected from airborne sources at all. Fig. 3
316 displays three such examples of detectability in occupied air and exhaust air.

317 As in the first experiment, each distinguishable occupant was strongly associated with individual
318 OTUs from human-associated taxonomic groups. For example, both of the female occupants shown in
319 Fig. 4 (orange and red bars) were associated with OTUs related to common vaginal bacteria (*Lactobacillus*
320 *crispatus* and *Gardnerella vaginalis*), mirroring the gender-relevant findings from the first experiment.
321 Additionally, while some *Corynebacterium* and *Propionibacterium* OTUs were abundant and common

322 among all occupants, some individual OTUs within these genera were indicative of individual occupants
323 (Fig. 4), indicating that species- or strain-level variation in airborne bacteria can inform future microbial
324 cloud and identifiability studies.

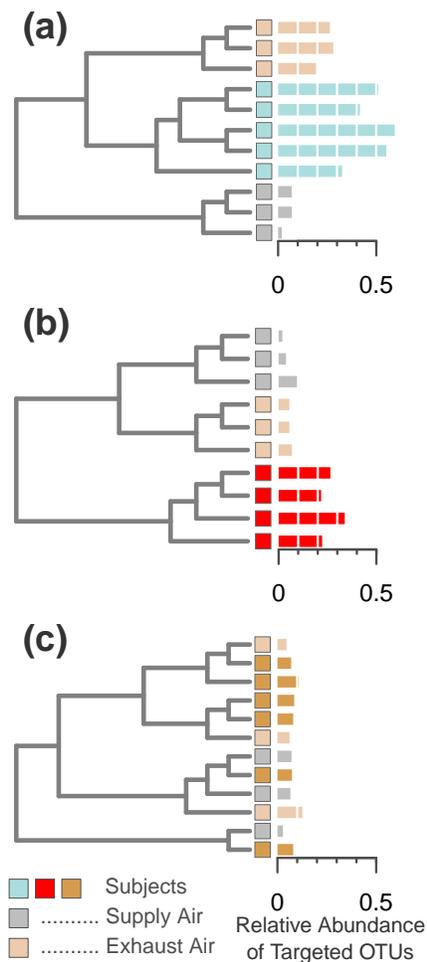

Figure 3. Three example cases of detectability in the occupied chamber and the exhaust ventilation system: (a) Subject 11 was an example of ideal detection in the ventilation system – we were able to find sufficient human-associated OTU concentrations to correctly classify the air leaving the occupied chamber. (b) Most occupants, however, did not emit sufficient bacterial concentrations to be detected in the ventilation system, even when they were readily detected within the occupied chamber. (c) Two subjects emitted nearly undetectable concentrations of particles (Fig. 2c) and human-associated bacterial OTUs (Fig. 2b), and were thus impossible to detect or identify in either the occupied chamber or the exhaust ventilation system.

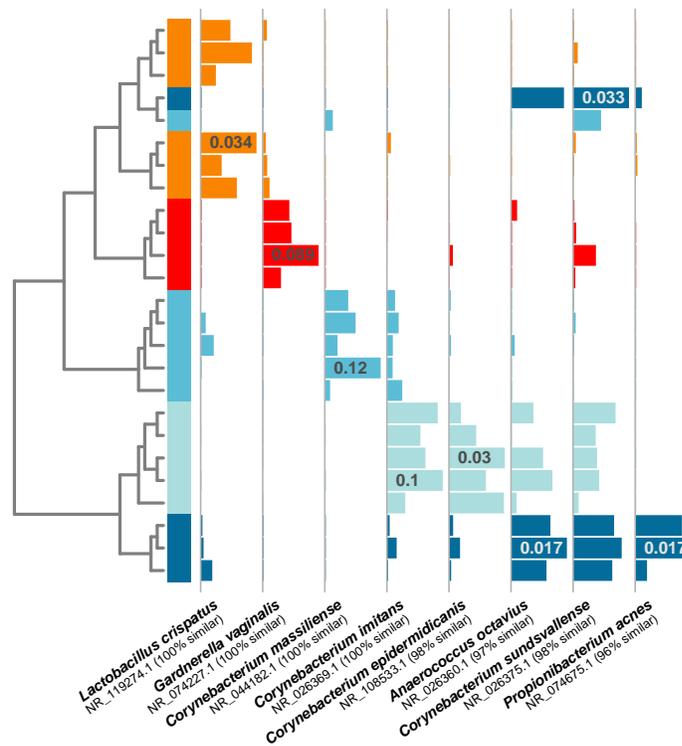

Figure 4. Individual human-associated bacterial OTUs helped to distinguish occupants. When considering the five most statistically distinguishable occupants (cluster diagram from Fig. 2e), each was associated with a set of significant indicator OTUs, and eight examples are shown here. Each was a) significantly associated with an occupant (all p-values < 0.01), b) among the 10 most abundant for that given occupant, and c) among the 50 most abundant targeted OTUs in the whole dataset. Horizontal bars show each OTU's relative abundance, with maximum relative abundance shown in a single bar. OTU names matched from the NCBI 16S isolate database are given below each set of bars.

DISCUSSION

Our data make clear that an occupied space is microbially distinct from an unoccupied one, and reveal for the first time that individuals occupying a space can emit their own distinct personal microbial cloud. It is unsurprising that humans leave their microbial signature behind in the built environment (Hospodsky et al., 2012; Täubel et al., 2009; Fierer et al., 2010; Flores et al., 2011, 2013; Meadow et al., 2013; Kembel et al., 2012) or that inactive humans emit particles (You et al., 2013), but our study suggests that bacterial emissions from a relatively inactive person, sitting at a desk for instance, have a strong influence on the bacteria circulating in an enclosed space and on surrounding surfaces. Previous research has found that human activity in an indoor space results in the detection of human-associated airborne bacteria (Hospodsky et al., 2012; Meadow et al., 2013; Qian et al., 2012); this human-microbial signal is due to a combination of resuspended dust, emission from clothing, and active particle emission from occupants. In our study, we made all attempts to eliminate the potential for resuspended dust by heavily cleaning the interior of a controlled climate chamber and eliminating most movement within the chamber. We controlled for clothing-related particle emission by having all occupants wear identical, clean, newly purchased, minimal clothing (tank-top and shorts). The result is that we now have a clearer picture of individual shedding rates, personal identifiability, and the residual fate of the personal microbial cloud in the built environment.

Our approach was to measure several different aspects of the personal microbial cloud: airborne particle load, airborne bacterial communities, and settled bacterial communities. When we just tried to detect an occupant, all 4-hour sampling periods during the first experiment resulted in highly significant airborne community differences between simultaneously sampled occupied and unoccupied chambers (Tables 1 & 2; Fig. 1). This difference was evident regardless of which person was occupying the space, whether air or settled particles were used, and regardless of whether occupants were analyzed alone or in combination with other occupant sampling periods. The prominent bacterial OTUs detected in each trial were clearly indicative of their ostensibly human source (Fig. S2), and this was evident in the most abundant OTUs as well as indicator taxa (i.e., those most strongly associated with each trial across replicates). When sampling time, and thus airborne microbial biomass, was cut in half to 2-hour trials, results were generally consistent (Table 2), although with more variability among occupants, and this suggests a potential detection threshold given the current technology employed here. Approximately 1.2 m³ of air passed through each sampler during the 2-hour trials, and 2.4 m³ in the 4-hour trials; one m³ of air can contain as many as 10⁶ bacterial cells, but this concentration can fluctuate based on location, bioaerosol source, and ambient conditions (Rook, 2013; Burrows et al., 2009; Tong and Lighthart, 2000; Lighthart and Shaffer, 1995). It is possible that a person occupying a room for a shorter amount of

358 time will not shed a sufficient number of bacterial particles to overcome background airborne bacterial
359 concentrations, and thus go undetected. Although further investigation is required to fully understand the
360 limits of human bioaerosol detection, results from our second experiment supported the assumption that
361 detectability is a function of the amount of bacterial biomass shed by an occupant. The airborne particle
362 load was generally predictive of each occupant's airborne load of human associated bacterial OTUs, and
363 subsequently of each person's classifiability.

364 Airborne bacteria are only a short-term pool of microbes emitted by occupants in a given space; those
365 that settle out over time have the potential to be dispersed through surface contact, or be resuspended by
366 subsequent occupant movement. To better understand the fate of the personal microbial cloud, we also
367 collected settled particles in sterile collecting dishes around each occupant as a proxy for the potential
368 residual signal that an occupant might leave behind. Bacteria detected in these dishes mirrored those found
369 in air filters (Fig. S2; Fig. 1; Tables 1 & 2), and the same hallmarks of an occupied space were reflected
370 in the most abundant OTUs and the most significant indicator taxa (Fig. S2 and Table 3). Results from
371 the two different durations (2- and 4-hour sampling periods in the first experiment) were also consistent
372 with air filter data; all three occupants in the first experiment were clearly discernible at 4-hours, while
373 occupant signals were less pronounced after only 2 hours (Table 2).

374 One of the most surprising results from the first experiment was the extent to which the three different
375 occupants were easily discernible from one another, both from a microbial community perspective and
376 also when considering individual bacterial OTUs (Figs. 1 and S2; Tables 1, 2 & 3). We designed the
377 second experiment to better understand what leads to airborne detectability and identifiability. Since the
378 most indicative OTUs were from human-associated bacterial groups, we focused analytical efforts on just
379 this subset of airborne bacteria. Individual occupants varied in their proportion of these targeted OTUs,
380 from 4-61% in a given sample, but each occupant was generally consistent in the concentration of their
381 own detectable microbial cloud (Fig. 2c).

382 Airborne particles, regardless of their biological nature, were also optically measured throughout the
383 experiment in addition to microbial communities, to better understand personalized particle emissions
384 from different people (Qian et al., 2014a). Particle emissions from the eleven occupants in this study
385 varied substantially but were consistent for each person (Table S1 and Fig. 2c). We might expect that the
386 occupant emitting the most particles would also be the most easily discernible from their microbial cloud.
387 This was generally the case, since airborne particle concentrations tended to correlate with the proportion
388 of human-associated taxa, and with personal identifiability. We did see, however, clear exceptions to
389 this assumption. For example, Subject 3 was always consistently discernible from microbial data, and
390 yet was nearly undetectable via airborne particle counts, while Subject 2 revealed the opposite pattern.

391 Although this raises questions that cannot conclusively be answered here, this discrepancy might suggest
392 that particle counts alone cannot be used as a proxy for personal microbial cloud identifiability, but rather
393 reflect interpersonal variation in hygiene, skin health, respiration and perspiration rates, or other occupant
394 characteristics that should be investigated in the future.

395 The potential identifiability we report for individual personal microbial clouds clearly suggests a
396 forensic application for indoor bioaerosols, for example to detect the past presence of a person in an
397 indoor space. Such applications will certainly require further research; the patterns we found are likely to
398 be more nuanced in a crowd of occupants, in a larger indoor space, or in the presence of resuspended dust.
399 Personal classifiability in our study was likely dependent on relatively low background microbial biomass
400 (e.g., dust) in our experimental chamber, and these patterns were not evaluated in the presence of multiple
401 occupants, similar to the recent surface identifiability study from Fierer and colleagues (Fierer et al., 2010).
402 However, unlike identifiability after surface contact, the personal microbial cloud is highly ephemeral,
403 such that detection of an occupant after they have left a space will almost inevitably rely on either settled
404 particles or capture in ventilation systems. To this point, we found that settled particles revealed occupant
405 individuality, and that at least two people were detectable in exhaust air leaving the occupied chamber.
406 Notably, when air exchange rates were increased from 1 to 3 ACH, detectability and identifiability are
407 much more difficult due to increased dilution with background air (Fig. S4). This suggests important
408 applications for understanding the impact of ventilation on person-to-person microbial transmissions in
409 health-care facilities, or during disease outbreaks in the built environment. Ventilation has long been
410 acknowledged as important for indoor disease transmission, and our findings suggest that increasing air
411 flow rates from 1 to 3 ACH nearly eliminates the detectible human microbial cloud.

412 The eleven different occupant trials were each conducted on different days, requiring occupation of
413 the chamber by a different person each day. Short-term temporal bioaerosol dynamics have been detected
414 in previous studies (Meadow et al., 2013; Bowers et al., 2013), and we did find marginal differences
415 among the background bioaerosols during both experiments reported here. However, the day-to-day
416 differences among unoccupied sampling periods in the first experiment, and among supply air samples
417 from different days in the second, was much smaller in all instances than the differences among occupied
418 samples (Fig. S3). Nor was day-to-day variation accompanied by significant indicator taxa differentiating
419 unoccupied samples from one day to the next, whereas most occupants were personalized in their emitted
420 indicator taxa. Furthermore, the most abundant OTUs detected in occupied samples changed along with
421 the occupants, while the same OTUs were most abundant in unoccupied samples each day regardless of
422 when they were taken. Thus day-to-day temporal dynamics were less substantial than the clear difference
423 we observed among occupants.

424 As humans we spend a substantial portion of our lives indoors, up to 90% in industrialized nations
425 (Klepeis et al., 2001), and human density in urban areas is expected to increase. While indoors, we are
426 constantly interacting with microbes other people have left behind on the chairs in which we sit, in dust
427 we perturb, and on every surface we touch. These human-microbial interactions are in addition to the
428 microbes our pets leave in our houses, those that blow off of tree leaves and soils, those in the food we
429 eat and the water we drink. It is becoming increasingly clear that we have evolved with these complex
430 microbial interactions, and that we may depend on them for our well-being (Rook, 2013). It is now
431 apparent, given the results presented here, that the microbes we encounter include those actively emitted
432 by other humans, including our families, coworkers, and perfect strangers.

433 **ACKNOWLEDGMENTS**

434 We thank members of the Biology and the Built Environment Center for their input in experimental
435 design, and Energy Studies in Buildings Laboratory for assistance at their climate chamber facility. We
436 also thank Dr. Seema Bhangar for her advice in collecting and analyzing particle data. Finally, we thank
437 11 anonymous volunteer human occupants for shedding their bioaerosols into our sampling apparatuses.
438 This work was funded by a grant to the Biology and the Built Environment Center from the Alfred P.
439 Sloan Foundation Microbiology for the Built Environment Program.

573 SUPPORTING FIGURES

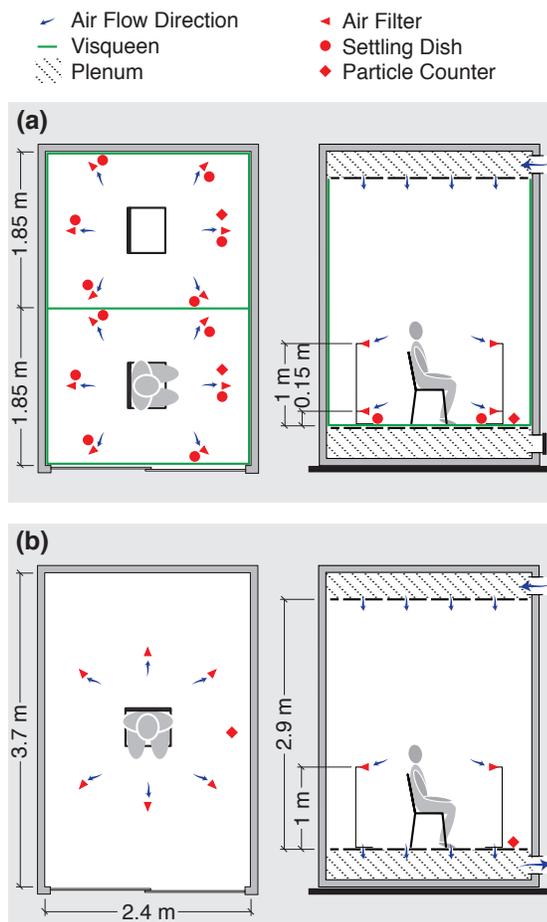

Figure S1: **Schematic of the experimental chamber during both experiments.** (a) The objective of the first experiment was to distinguish occupied from unoccupied airborne bacterial communities. Thus the test chamber was split into two identical portions, and air was collected on both sides simultaneously. Supply air velocity (entering through the ceiling plenum) was determined to replace the volume of air removed by vacuum sampling, as well as create slight positive pressure within the occupied chamber. (b) The second experiment was designed to distinguish among occupants, so the test chamber was not divided, but rather vacuum samples were taken in the supply ventilation system, surrounding the occupant in the chamber, and also in the exhaust ventilation system. During the second experiment, supply air velocity resulted in 1 & 3 ACH.

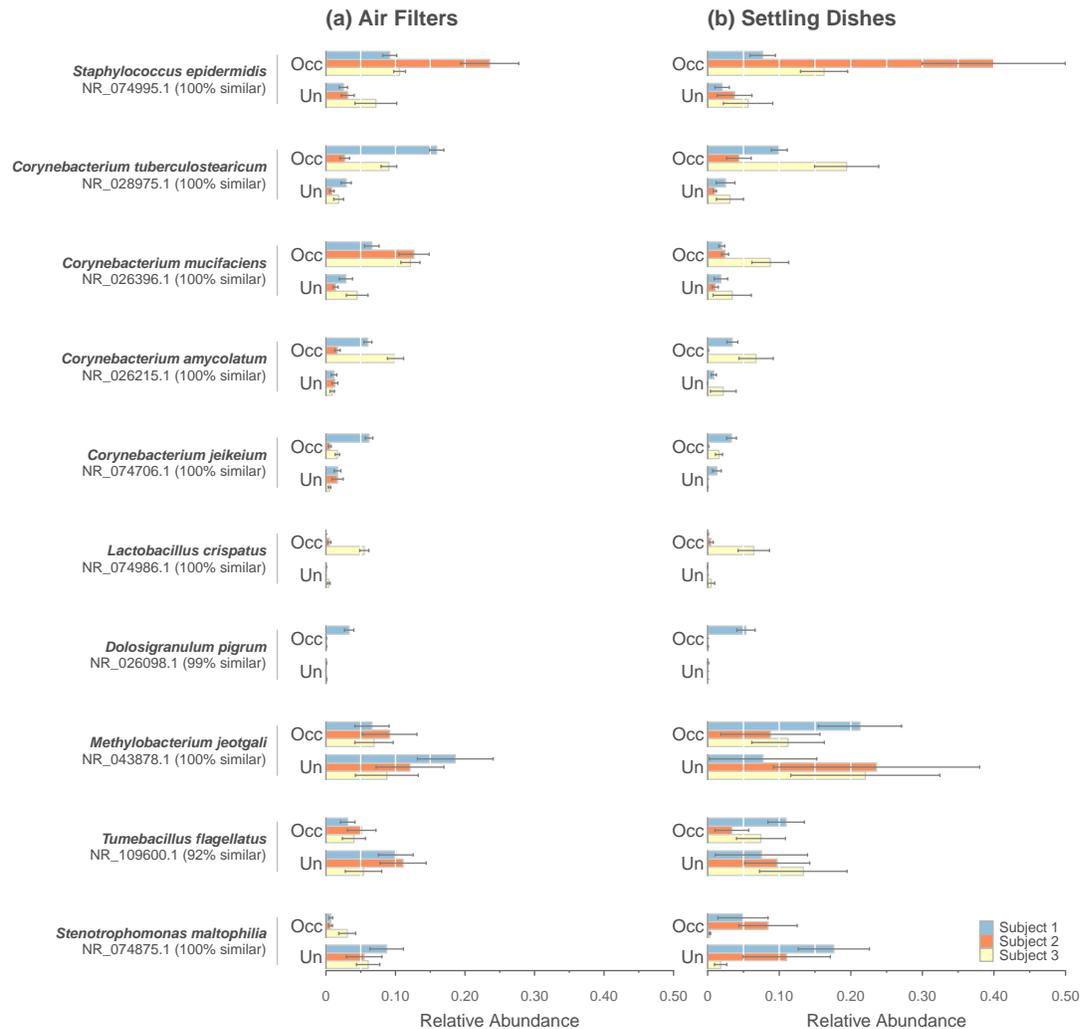

Figure S2: **Indicator OTUs from the first experiment were consistent for occupants regardless of sampling method.** (a) The most abundant OTUs in 4-hour air filters were clearly indicative of either occupied air (top seven OTUs) or unoccupied air (bottom three OTUs), regardless of occupant. The top OTU (*Staphylococcus epidermidis*) was the most abundant OTU found in occupied samples. (b) These same OTUs were also consistently abundant in settling dishes. Bars are mean relative abundance, and error bars show ± 1 standard error; the number of replicates in each treatment is detailed in Table 2. Eight of these ten OTUs were also significant indicator taxa included in Table 3.

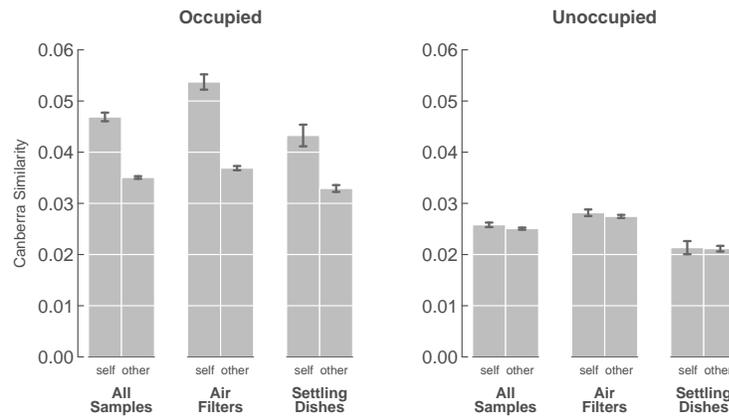

Figure S3. **Significant differences among occupant personal microbial clouds are not explained by temporal changes in background airborne microbial assemblages.** We detected marginal differences in background bacteria (i.e., day-to-day temporal changes). These differences, however, were negligible when compared to differences among the different occupants. (left) Community similarities in the left plot (occupied samples from the first experiment; same data as shown in Fig. 1e) show that occupants were more similar to other samples from the same person than to other occupants, regardless of sampling method. This difference was significantly more pronounced than that of unoccupied samples (right) taken simultaneously during sampling periods. Error bars represent ± 1 standard error on pairwise Canberra similarities.

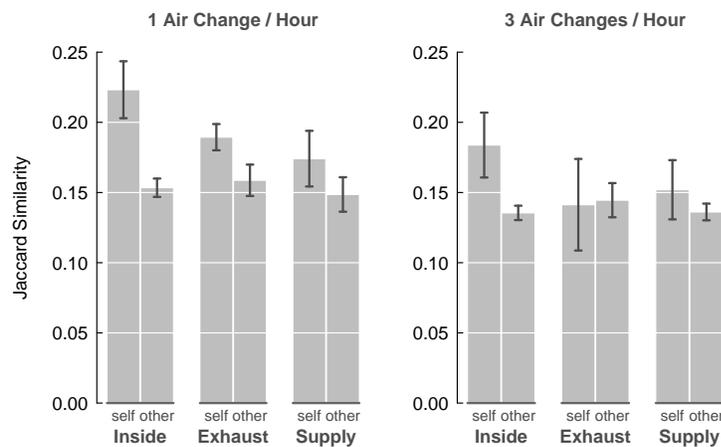

Figure S4. **At 1 air change per hour (left), occupants were, on average, detectable inside the chamber, but less so in exhaust air.** When air exchange rates were tripled (right), these signals disappeared, and not a single occupant was consistently detectable, even in occupied indoor air. Bars show average Jaccard Similarity values ± 1 standard error.

574 **SUPPORTING TABLES****Table S1: Particle counts during the first experiment generally increased with occupation over 4 hours.**

	10+ μm^*	5-10 μm	2.5-5 μm
Subject 1	14.74	2.58	1.66
Subject 2	29.29	4.31	2.31
Subject 3	1.84	0.99	0.96
mean	15.29	2.63	1.64

575 * All counts are expressed as ratios of particles $\text{L}^{-1} \text{ minute}^{-1}$ above unoccupied controls.
