The development of coral reefs results from an interaction between ecological and geological processes in space and time. Their difference in scale, however, makes it difficult to detect the impact of ecological changes on geological reef development. The decline of coral cover over the last 50 years, for example, has dramatically impaired the function of ecological processes on reefs. Yet given the limited-resolution of their Holocene record, it is uncertain how this will impact accretion and structural integrity over longer timescales. In addition, reports of this ecological decline have focused on intrinsic parameters such as coral cover and colony size at the expense of extrinsic ones such as geomorphic and environmental variables. Despite these problems, several attempts have been made to predict the long-term accretion status of reefs based entirely on the contemporary health status of benthic communities. Here we explore how this ecological decline is represented within the reef geomorphic structure, which represents the long-term expression of reef development. Using a detailed geomorphic zonation scheme, we analyze the distribution and biodiversity of reef-building corals in fringing-reef systems of the Mesoamerican Reef tract. We find a depth-related pattern in community structure which shows that the relative species distribution between geomorphic zones is statistically different. Despite these differences, contemporary coral assemblages in all zones are dominated by the same group of pioneer generalist species. These findings imply that first, coral species distribution is still controlled by extrinsic processes that generate the geomorphic zonation; second, that coral biodiversity still reflects species zonation patterns reported by early studies; and third that dominance of pioneer species implies that modern coral assemblages are in a prolonged post-disturbance adjustment stage. In conclusion, any accurate assessment of the future viability of reefs requires a

consideration of the geomorphic context or risk miscalculating the impact of ecological changes on long-term reef development.

## 19 **ABSTRACT**

20 The development of coral reefs results from an interaction between ecological and geological processes  
21 in space and time. Their difference in scale, however, makes it difficult to detect the impact of ecological  
22 changes on geological reef development. The decline of coral cover over the last 50 years, for example,  
23 has dramatically impaired the function of ecological processes on reefs. Yet given the limited-resolution  
24 of their Holocene record, it is uncertain how this will impact accretion and structural integrity over longer  
25 timescales. In addition, reports of this ecological decline have focused on intrinsic parameters such as  
26 coral cover and colony size at the expense of extrinsic ones such as geomorphic and environmental  
27 variables. Despite these problems, several attempts have been made to predict long-term accretion  
28 status of reefs based entirely on the contemporary health status of benthic communities. Here we explore  
29 how this ecological decline is represented within the reef geomorphic structure, which represents the  
30 long-term expression of reef development. Using a detailed geomorphic zonation scheme, we analyse  
31 the distribution and biodiversity of reef-building corals in fringing-reef systems of the Mesoamerican  
32 Reef tract. We find a depth-related pattern in community structure which shows that the relative species  
33 distribution between geomorphic zones is statistically different. Despite these differences, contemporary  
34 coral assemblages in all zones are dominated by the same group of pioneer generalist species. These  
35 findings imply that first, coral species distribution is still controlled by extrinsic processes that generate  
36 the geomorphic zonation; second, that coral biodiversity still reflects species zonation patterns reported  
37 by early studies; and third that dominance of pioneer species implies that modern coral assemblages are  
38 in a prolonged post-disturbance adjustment stage. In conclusion, any accurate assessment of the future  
39 viability of reefs requires a consideration of the geomorphic context or risk miscalculating the impact of  
40 ecological changes on long-term reef development.

# INTRODUCTION

The declining cover of reef-building corals on modern reefs has become a global concern for both scientists and citizenry. The gravity of the situation became clear after only a decade of systematic monitoring, when a series of acute disease outbreaks decimated the dominant reef-building acroporid corals in the Caribbean (Knowlton et al., 1981; Gladfelter, 1982; Hughes, 1994; Aronson and Precht, 2001). Along with destruction caused by multiple strikes from intense hurricanes (e.g., Woodley et al., 1981), these outbreaks were quickly followed by regional mass mortality of algal-grazing Diademid urchins, which resulted in macroalgal blooms (Lessios et al., 1984; Gladfelter, 1982; Lewis, 1984). By the 1990's acroporid reefs began suffering climate-induced mass-bleaching episodes and disease epidemics also began affecting other major reef-builders (orbicellids) that had survived previous disturbances (Eakin et al., 2010; Weil, 2004; Bruckner and Bruckner, 2006). These losses from disease and destruction were exacerbated by overfishing and nutrient pollution resulting from widespread and uncontrolled coastal development (Grigg and Dollar, 1990; Rogers and Beets, 2001; Hughes et al., 2003). By the turn of the century, surveys were reporting a regional decline in coral cover of more than 50 % across the Western-Atlantic Reef Province (Gardner et al., 2003; Schutte et al., 2010; Jackson et al., 2014; Cramer et al., 2020), producing a functional homogenization of coral species and a flattening of reef structure (e.g., Álvarez Filip et al., 2009; González-Barrios et al., 2021). Understanding of the extent of this decline on a regional scale, however, has relied exclusively on the data pooling from limited local observation, and this has led to significant uncertainty regarding its principal cause (Murdoch and Aronson, 1999; Wood, 2007; Jackson et al., 2014).

It is well understood that pooling ecological data from local studies can lead to inaccurate results, predict potential pseudo-trends, or misinterpret ecological processes because of scale changes in the analysis (Guzmán et al., 1991; Karlson and Hurd, 1993; Williams et al., 2015; Medina-Valmaseda et al., 2020; Dietzel et al., 2020). This is because regional meta-analyses extrapolate from small-scale coral abundance and coverage data gathered with different primary objectives in mind. A common problem, for example, is the relation between sampling scale and sensitivity of the observed ecological changes (e.g., Edmunds and Bruno, 1996), with extrapolation from small- to large-scale being performed without explicit sampling at new scales (Wiens, 1989). Furthermore, although regional meta-analyses account for inconsistencies among the various survey methods (Côté et al., 2005), they cannot account for inconsistencies resulting from omissions. The omission of the geomorphic context of ecological data by local studies, for example, can lead to inaccuracies in abundance-based data and thus misrepresent long-term spatial complexity and the ecological functioning of coral reefs at larger scales (e.g., Jackson et al., 2014; Williams et al., 2015; Medina-Valmaseda et al., 2020).

Although elucidating the role of abiotic factors in coral community structure is challenging because of these scale differences (Murdoch and Aronson, 1999), separating ecological data from its geomorphic context risks obscuring spatial trends (e.g., Williams et al., 2015). From an ecological perspective alone, the use of single ecological metrics, such as coral cover, to evaluate heterogeneous processes at regional scales gives an overly simplistic representation of reef structure (Viehman et al., 2009). A better understanding of the relationship between biotic data and its geomorphic context at larger scales, however, might be useful in interpreting the real signal of functional changes and improving long-term predictions of coral reefs and their response to global threats. Accretion potential, for example, has been reported to be heterogeneous among geomorphic zones (Perry, 1999; Blanchon et al., 2017) and also species-dependent (Perry and Alvarez-Filip, 2019; González-Barrios et al., 2021). This issue is relevant at larger temporal scales because not all coral species contribute equally to reef accretion (Macintyre and Glynn, 1976; Kuffner et al., 2019; Toth et al., 2019) and there are some biases and uncertainties in linking contemporary coral patterns with accretion potential (Wood, 2007).

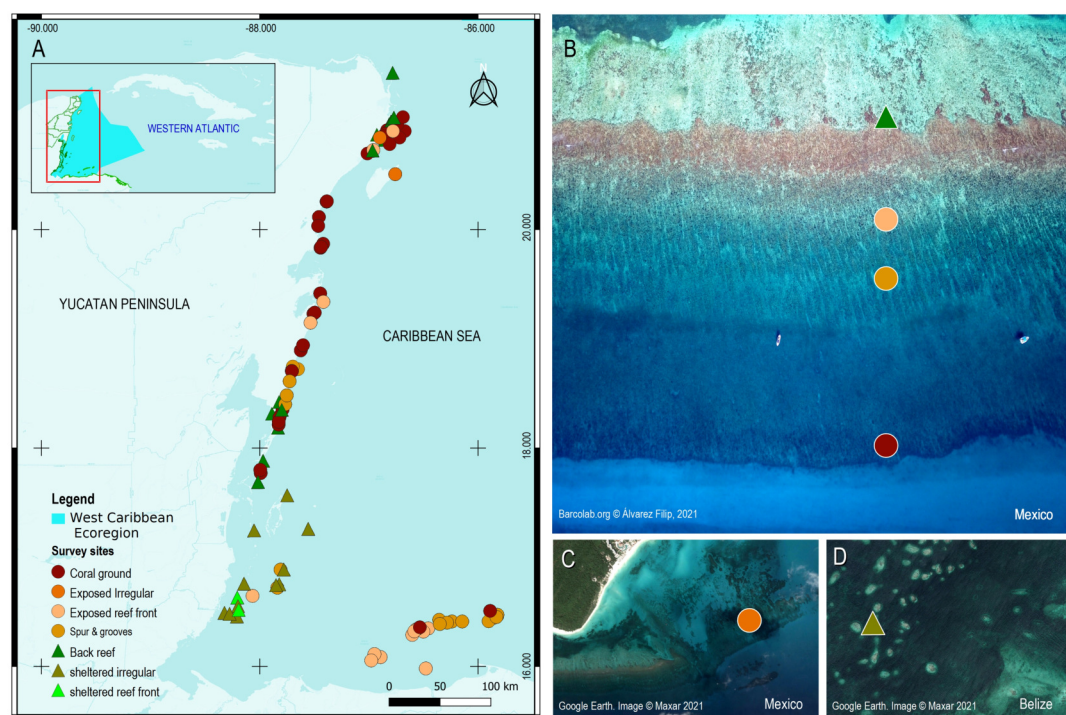

Here we investigate whether geomorphically-controlled patterns in the decline of coral cover reported by Medina-Valmaseda et al. (2020) can be extended to the entire shallow geomorphic framework of the Mesoamerican reef tract. Using a standard geomorphic scheme and multi-year coral-cover and composition data, we analyze regional patterns in coral distribution and biodiversity. Then, using GIS-based environmental data, we explore how these patterns are influenced by key environmental controls on

reef geomorphology: depth, wave exposure and hurricane incidence. We find that contemporary coral assemblages are dominated by the same group of pioneer species but that their distribution between geomorphic depth zones is statistically different, and has not been completely homogenized by the decline in reef condition over the last 50 years.

## METHODS

### Study region & geomorphic framework

The Mesoamerican Reef Tract (MART), located within the Western Caribbean marine ecoregion, stretches ~ 1000 kilometres along the coasts of the Yucatan peninsula and northeast sector of Central America (Figure 1; Spalding et al., 2007). It is composed of shallow detached fringing reefs that consist of two main geomorphic zones, a protected back-reef zone and an exposed reef-front zone separated by a crestline where waves break. These breakwater structures are limited to shallow water (< 10 m deep) and are developed over and adjacent to a bedrock terrace which is veneered by coral grounds (Rodríguez-Martínez et al., 2011). Together the reef and terrace form a relatively consistent seascape over the inner fore-reef shelf (< 15 m) throughout the Caribbean (Blanchon, 2011). The shallow geomorphic framework of the MART is therefore consistent with the geomorphic zonation scheme first described from Grand Cayman by Blanchon and Jones (1995) and later summarized by Blanchon (2011), who both used slope breaks to identify reefal boundaries. We adopted this basic geomorphic scheme for all sectors of the MART including both Belize and Honduras.

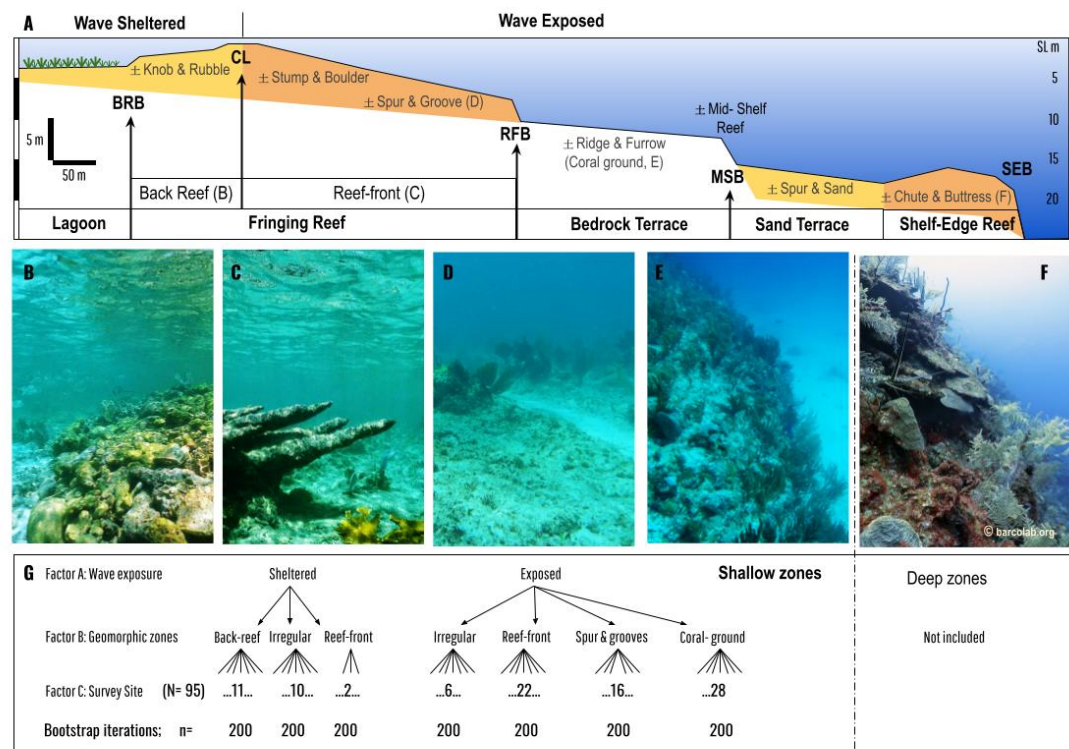

**Figure 1.** Survey sites and their geomorphic zones in the Mesoamerican reef tract (MART). Panel A. The MART is located in the West Caribbean ecoregion (represented by the irregular light blue polygon). Panel B, C, D. Reef sites are represented by colored symbols that correspond either to their benthic geomorphic zone and/or wave-energy designation. Map product was created with QGIS 3.14 Pi (QGIS Development Team, 2020)

In the northern Mexican sector of the MART, fringing reefs are relatively underdeveloped with

111 limited reef-fronts that only extend to a depth of  $\sim 6 - 8$  m, thereby producing a more extensive bedrock  
112 terrace veneered by coral grounds (Blanchon et al., 2017). The edge of this terrace is marked by a  
113 slope break (mid-shelf break) and is commonly covered by a non-accretionary coral-ground community  
114 (Rodríguez-Martínez et al., 2011). In the Belize sector, fringing reefs transition into better developed  
115 Barriers and Atolls, and their reef-fronts extend into deeper water covering the bedrock terrace. At some  
116 sites, reef-front subzones like the spur-and-groove can extend all the way to the shelf edge in 25-30 m of  
117 water (James and Ginsburg, 1979; Burke, 1982). In the Honduras sector, reef development is restricted  
118 to the offshore Bay Island group: Roatan, Utila, Guanaja, and Cayos Cochinos. These reefs also have  
119 extensive spurs-and-groove zones extending to the shelf edge (Almada-Villela et al., 2003).

**Figure 2.** Geomorphic zonation of an idealized shelf showing shallow reef and benthic zones typical of Mesoamerican reef seascapes (following Blanchon et al., 2017). Zones are delineated by slope breaks: Back-Reef break (BRB), Crestline (CL), Reef-Front break (RFB), Mid-Shelf break (MSB), and Shelf-Edge break (SEB). Main benthic zones in bold are divided into wave sheltered (such as lagoon and back-reef) and wave exposed (such as reef-front, bedrock terrace, sand terrace etc) (see Blanchon and Jones (1995) for their descriptions). Each benthic zone can be divided into sub-zones that may or maynot be present ( $\pm$ ). Coloured zones are depositional or accretionary (like the fringing reef, or shelf-edge reef) whereas non-coloured are erosional or non-accretionary (like the bedrock terrace with its superficial coral ground). Our analysis is restricted to coral communities covering the fringing reef and the adjacent bedrock terrace (coral ground). Panels B, C, D, E and F give an overview of these coral communities: Back Reef (B), Reef Front (C), Spur & Groove (D), Coral-ground, and mid-shelf reef (E), and Shelf-Edge reef (F, which is not included in the study). Panel G is a schematic of the asymmetrical design for PERMANOVA analysis, encompassing three factors (wave exposure, geomorphic zones and survey site) with different levels of nested factors (back reef, reef front, irregular etc) encompassed by 2 upper levels (sheltered and exposed)

120 We follow the geomorphic scheme of Blanchon (2011) to classify all sites based on retrospective  
121 satellite imagery from virtual globes such as Google Earth and ArcGIS online. A small number of sites

(~ 2%) had unclear images due to cloud cover and/or sea state, and geomorphic zoning was more difficult to delineate at the subzone level (for example, defining the boundary between the spur and grooves reef and non-tree bedrock terrace). In these few cases, we classify the sites as the most common type for that depth and zone based on field experience and expert consultation. Sites where reefs are less organized (~ 17%) and lack a clear geomorphic structure, are simply classified as undifferentiated zones and assigned as either protected or exposed wave environments. Although uncommon, some of these ‘exposed’ zones can be found in semi-sheltered sites with complex coastal geography, (e.g. the barrier reef fronts behind offshore atolls in the Belize sector).

## Coral distribution in geomorphic zones

To document the spatial distribution of scleractinian coral within shallow geomorphic zones we use information from two databases, the Caribbean Reef Information System (CRIS, Barcolab.org) and the Healthy Reefs Initiative ([www.healthyreefs.org](http://www.healthyreefs.org)), which contain data on coral cover estimates at site level. Data in these sources come from published literature, research projects, and monitoring programs. In all cases, coral cover information was obtained using two similar benthic survey methodologies (Line Intercept Transect- LIT and Point Intercept Transect-PIT) according to Atlantic and Gulf Rapid Reef Assessment Benthic Protocol (AGRAA, [Lang et al., 2012](#)) available at <https://www.agrra.org/coral-reef-monitoring> and the Mesoamerican Barrier Reef System monitoring program ([Almada-Villela et al., 2003](#)). Each survey includes between six and ten transects (10 or 30 m in length) haphazardly deployed at the reef sites. From these databases we select only the most recent data from sites in a 1-10 m depth range that contain coral cover estimates at species level. After discarding sites outside these requirements (e.g., depth range, data quality at species level), we compile a subset of coral coverage from 95 survey sites between 2016 and 2018 (Table 1)

Based on this subset, we calculate the (i) overall site coral-cover data and (ii) the relative coral cover of each species (i.e. the relative contribution of each species to the total coral cover). To avoid potential confusion stemming from using the term coral cover to refer to the relative coral cover of each species hereafter we refer to the latter as coral species contribution. Because of our interest in analyzing spatial patterns within the geomorphic framework, coral-cover data are pooled and analyzed according to geomorphic zone, and not survey site. Therefore, we compare overall coral-cover data of multiple sites as a comparative sampling unit, for example, pooling coral-cover from all back-reef sites (Figure 2B). The time period of data is chosen to avoid potential bias caused by the recent outbreak of the Stony Coral Tissue Loss Disease (SCTLD) reported in the Mexican sector during 2018 ([Alvarez-Filip et al., 2019](#)).

## Statistical analysis

Derivatives of abundance usually violate the assumptions of traditional parametric statistics, which makes it difficult to deal with using traditional univariate methods ([Fieberg et al., 2009](#)). Therefore we use a multivariate analysis which is effective in dealing with those data ([Beals, 1984](#); [Fieberg et al., 2020](#)). This type of analysis requires data to be transformed to reduce the differential between the largest and smallest non-zero value in the transformed matrix ([Clarke and Gorley, 2015](#)). For the comparative analysis based on the overall coral cover of each site, we use raw data, which is a standard procedure in ecological analysis. But for the analysis of coral-community contribution to relative cover, although optional, a pre-treatment of data standardization is made to reduce the differences in magnitude generated by the disparate benthic methods and to reduce method-bias related to the effect of the former benthic scheme that included other benthic classes ([Vallès et al., 2019](#)). In both analyses for the multivariate pre-treatment, we choose a medium level (square-root) of data transformation. Further transformation is followed by an ordination process where we construct the correspondent Bray-Curtis matrix of similarities. All subsequent multivariate statistical analyses and graphical outputs are performed and constructed using Plymouth Routines in Multivariate Ecological Research (Primer-e version 7.0.13, serial number 4901, [Clarke and Gorley, 2015](#)).

To compare overall coral cover and related coral species contribution to relative cover of the com-

170 munities between geomorphic zones, we conduct asymmetrical analyses of permutational variance  
 171 (PERMANOVA) at both levels of aggregation for factor 'site' (nested within the geomorphic zones by  
 172 wave exposure) and nested in wave exposure regimes on the basis of Bray-Curtis similarity measures of  
 173 transformed square-root matrix of ecological data (Anderson, 2006). Including these permutations, proce-  
 174 dures offer an alternative to Normal-based inferential methods as they are adaptable and require fewer  
 175 assumptions, whereas the asymmetrical design deals with a different number of geomorphic zones by  
 176 wave exposure, three sheltered and four exposed. The experimental design consisted of 3 factors (Figure  
 177 2.C): Factor A: wave exposure (fixed with a = 2 levels: sheltered and exposed), Factor B: Geomorphic  
 178 zones (fixed, nested in wave exposure with 3 levels nested in sheltered, and 4 levels nested in exposed),  
 179 and Factor C: Site (random, nested in geomorphic zones, wave exposure) with 95 levels. The test uses  
 180 permutation of residuals under a reduced model and Type III (partial Square Sums) in 9999 permutations.

181 To test the homogeneity of multivariate data dispersion in each case, we performed a non-parametric  
 182 permutational analysis of multivariate dispersion (PERMDISP), along with pairwise comparisons of the  
 183 Bray-Curtis matrix of similarities. PERMDISP is performed based on distances to centroids, with P-values  
 184 (p(per)) obtained from 9999 permutations, giving the best overall results expected in terms of type I  
 185 error and power (Anderson et al., 2006). To determine the species contributions to coral cover within  
 186 each geomorphic zone we conduct a two-way similarity percentage analysis (SIMPER) for zones by  
 187 wave exposure, based on Bray-Curtis similarity measures of transformed square-root matrix of abundance  
 188 data, making a 70 % cut-off for low contributions (Clarke and Warwick, 1994; Clarke et al., 2014a). We  
 189 present the results through the metric MDS of bootstrapped averages for 95 % region estimates. Bootstrap  
 190 averages test iteratively resamples each group by its geomorphic zone type 200 times creating a plot of 4m  
 191 dimensions multivariate effect. Such a bootstraps procedure allows better visualization of how the mean  
 192 response of each data group varies with changes in predictor values if we were to collect another sample  
 193 of observations from a different set of geomorphic zones (Fieberg et al., 2009). The arrangement of the  
 194 number of sites by its geomorphic zone classification lacks sampling balance (Figure 2B) and therefore,  
 195 another advantage of this approach is its success in estimating parameters of a statistical distribution for a  
 196 balanced number of copies from our data whereas preserving the original structure of its data set (Fieberg  
 197 et al., 2020).

## 198 Extrinsic factors

199 For the purposes of this study, we consider extrinsic factors to be the diverse environmental variables that  
 200 describe the abiotic context of coral communities including physicochemical variables and non-biotic  
 201 disturbances, such as depth gradient, wave exposure and hurricane impacts. To evaluate the response of  
 202 the biotic multivariate data to its corresponding multivariate environmental data we select information  
 203 from both benthic surveys and cyclonic disturbances available for the MART. We use depth of benthic  
 204 surveys and environmental information extracted from the open-source Physical Environments of the  
 205 Caribbean Sea classification of Chollett et al. (2012) as geographic information system layers. For this,  
 206 we extract data of physical disturbances including exposure to wind- and tropical-storm waves and the  
 207 number of hurricane impacts using the QGIS (v. 3.14 Pi) Point Sampling Tool plugin, v.0.5.3 available at  
 208 <https://github.com/borysiasty/pointsamplingtool>. Where the plugin failed because  
 209 of no-value pixels, we manually selected the neighbouring major value. Furthermore, we check the  
 210 distribution of all environmental variables for skewness and outliers and log-transform all data except the  
 211 depth of each sampling site (following Clarke and Gorley, 2006). Finally, we normalize data to place  
 212 each variable on the same dimensionless scale (for example, Clarke et al., 2014b). Environmental data  
 213 are graphically represented through a Principal Coordinate Analysis (PCO) where vectors are the raw  
 214 Pearson correlations of variables with the Principal Component Analysis (PCA) values (Torgerson, 1958;  
 215 Gower, 1966).

216 To analyze and generate an exploratory hypothesis model on the spatial relationship between mul-  
 217 tivariate data clouds of the biotic response variables (coral species distribution) and that of regional  
 218 environmental gradients, we test a distance-based linear model (DISTLM, Legendre and Anderson, 1999).  
 219 The DISTLM test includes the Bray-Curtis matrices of previously square transformed data of coral species  
 220 distribution and logarithm Euclidean distance-based matrix of previously normalized environmental

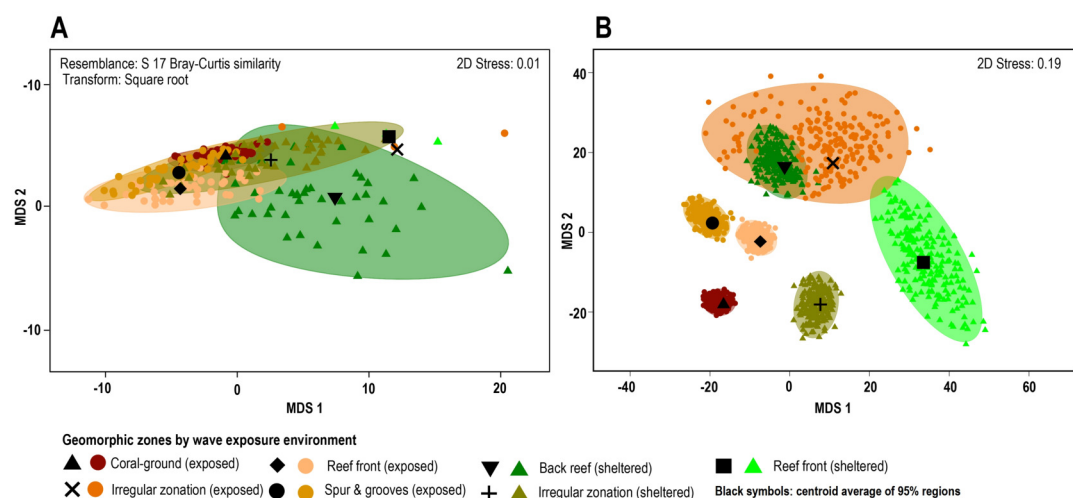

data in 9999 permutations within the factor Geomorphic zone for the environment. The test assumes non-linearity and additivity of the abiotic variables on the high-d community response. To visualize fitting models in multi-dimensional space we use the distance-based redundancy analysis (dbRDA, Legendre and Anderson, 1999; McArdle and Anderson, 2001) based on the Euclidean-distance matrix of environmental data.

## RESULTS

### Coral cover patterns in geomorphic zones

A total of 95 survey sites with 50 from Mexico, 25 from Belize and 20 sites from Honduras are included in this study. Sites encompass seven different types of geomorphic zones and subzones in both wave-exposed and protected environments along the regional latitudinal gradient. The result of the PERMANOVA test indicates that there are no significant differences in LCC between wave sheltered and wave-exposed geomorphic zones ( $P(\text{perm}) = 0.39$ ; Figure 3A; *Data S1*), although when species identity is included in the relative composition analysis, there are significant differences between geomorphic zones (Fig. 3B). The asymmetrical PERMANOVA test including the three terms ‘wave exposure’, ‘Geo zone (wave exposure)’ and ‘site (Geo zone (wave exposure))’ results in a statistically significant  $P(\text{perm})$  and  $P(\text{MC}) < 0.01$ , (Fig.3A; *Data S2*).

**Figure 3.** Coral cover patterns by geomorphic zone. Panel A shows the similitude of overall coral cover for each geomorphic zone type and wave exposure through a metric MDS of ‘whole sample’ bootstrap averages resampling the n-transects of each sampling site 200 times (arranged by geomorphic zones and wave environment). nMDS shows the approximate 95% region estimates fitted to the bootstrap averages and the relative estimated position of centroids for each group (symbols in black, Figure 3A, B). Panel B shows Species contribution to the relative cover within each geomorphic zone. The contribution of coral species to each geomorphic zone clearly represents long-term spatial patterns and highlights the absence of real species homogenization through the reef seascape (3D stress: 0.08).

The estimates of components of variation (S) for the three orthogonal factors were wave exposure: 178.52; Geo zone nested in wave exposure: 214.98; and site nested in Geo zone nested in wave exposure: 875.33. The site factor, therefore, contributes most to differences in species contribution, followed by the geomorphic zone, with wave exposure having the least control. A posteriori pairwise PERMDISP test at the LCC level shows homogeneity of variance in all groups (F: 1.49, df1: 6, df2: 84; p(perm): 0.3422; *Data S3*), whereas the species contribution level shows heterogeneity in data variance involving pairwise tests for single or combined irregular and exposed zones (F: 13.23, df1: 6, df2: 543; p(perm): < 0.01; *Data S4*). Other cases, including the irregular and combined sheltered/exposed geomorphic zones, show homogeneity in data variances (F: 13.23, df1: 6, df2: 543; p(perm): < 0.01; Figure 3B). In total 61% of possible pairwise tests show homogeneity in data variance and do not show a particular trend under the current PERMANOVA design. These tests indicate that there are differences in coral-species distribution between geomorphic zones (PERMANOVA), and in the variance of data distribution (PERMDISP) in several geomorphic zones within the same environments (Fig. 3, *Data S4*).

The contribution of individual species to observed differences is assessed using the SIMPER test (*Data S5*). Results show that in exposed geomorphic zones three species overlap: *Agaricia agaricites*, *Porites astreoides* and *Siderastrea siderea* (Average similarity: 30.0) with relative contributions of 32.2 %, 24.3 % and 15.1% respectively. In sheltered zones another trio of species overlap, *P. astreoides*, *Orbicella annularis* and *Agaricia agaricites*, (Average similarity 25.7) with relative contributions of 49.0 %, 18.5 % and 8.4 % respectively (*Data S*). Interestingly, an almost identical group of species accounts for the 81.2 % average dissimilarity between samples. In terms of dissimilarity, only four species (*S. siderea*, *Porites astreoides*, *O. annularis* and *A. agaricites*) which contribute ~ 10 %, form roughly 53 % of the differences between samples. Overall, across all wave exposure zones, the largest average similarity of 34.9 % corresponds to the exposed Coral-ground zone, and the lowest 18.2 % to the sheltered Back-reef zone.

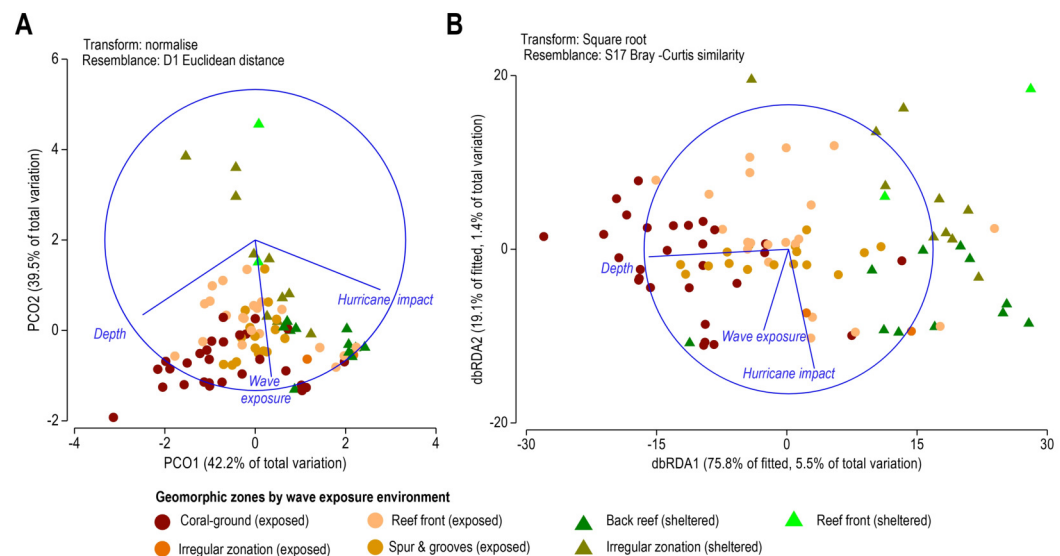

## Coral species patterns and extrinsic factors

Average species richness (number of species identified to lowest possible taxonomic level; S) increase with the depth being the lowest in sheltered back- reef (2.1) whereas the deeper coral- ground zone exhibit the highest value (4.9). Also species diversity as measured by the Shannon– Weiner index ( $H'$ ) follows the same pattern increasing seaward from the back- reef (0.9) towards coral-ground zone (1.4; Table 1).

On a regional scale, all sites are exposed to similar wave-exposure regimes regardless of geomorphic zone, whereas hurricane impact varies between sites (Figure 4). When analyzed by geomorphic zone and wave exposure, the average depth of sites varies from  $1.8 \pm 2.9$  m in sheltered reef-front zones, to  $11.2 \pm 4.2$  m in exposed coral-ground zones. Chronic stress derived from wave-exposure for these sites varies between  $5.9 \pm 0.9$  and  $7.4 \pm 0.2$  J m<sup>-3</sup>. Whereas acute mechanical stress derived from hurricane frequency in the last 157 years (1851–2008) varies between  $11 \pm 2$  y and  $20 \pm 2.8$  yr (Table 1). Regional patterns of three selected environmental data are presented in the Principal Coordinates Analysis (PCO) of Figure 4. It shows that the first two axes explain 81.6 % of the internal variability of these three environmental variables, indicating that the 2-d ordination is likely to have captured the majority of the patterns of multidimensional data variation. Accordingly, the depth of the reef site and hurricane impact explain 42.2 % of variations of the PCO1 axis, whereas wave energy exposure alone explains roughly the same percentage (39.5 %) of the PCO2 axis. In addition, depth and hurricane impact appear to act inversely over coral species patterns (Figure 4A).

Geomorphic zone	S $\pm$ SD	H' (av.) $\pm$ SD	D $\pm$ SD	WE* $\pm$ SD	HO* $\pm$ SD
Reef Front_sheltered	2.1 $\pm$ 1.2	0.5 $\pm$ 0.5	1.8 $\pm$ 2.9	5.9 $\pm$ 0.9	14 $\pm$ 2.1

**Table 1.** Species richness (S), Diversity (H') and abiotic factors (D, WE, HO) by geomorphic zone and environmental exposure. Abiotic factors correspond to physical environments of the Caribbean Sea stratification scheme of mechanical disturbances acting over coral communities at the surveyed reef sites. These include both chronic disturbances from wind-driven wave exposure and acute disturbance after [Chollett et al. \(2012\)](#). Chronic stress, given by wave exposure (WE), is related to wind conditions between 1999–2008 for the entire basin, whereas acute stress is given by the frequency of occurrence of hurricanes (HO) with Category 1–5 magnitudes in the last 157 yr (1851–2008). Values of mechanical disturbances (\*) are extracted from geographic information layers. D: average depth in meters, WE: Wave exposure in  $\text{J m}^{-3}$ , HO: hurricane occurrence in number of events, SD: standard deviation.

**Figure 4.** Panel A. Principal Coordinates Analysis (PCO) shows the multivariate environmental data cloud of three selected variables. Note the first two axes explain 81.6 % of the internal variability of these three environmental variables with depth having a contrasting effect with hurricane depth and wave exposure acting differently. Panel B. Distance-based Redundancy Analysis (db-RDA) graphically illustrates the Distance-based linear model (DISTLM) results. It shows correlation trends between the Bray-Curtis distance matrix of biotic response and the explanatory Euclidean distance matrix of environmental variables.

Results from the DISTLM marginal tests (Data S6) show how much can be explained by each abiotic variable alone, ignoring other variables. Tests show that the depth of reef sites exert the highest influence explaining 5.5 % of the overall variability in coral species contribution ( $p < 0.01$ , Data S4A, Fig. 4B). Wave exposure and the number of major hurricane impacts when each is considered alone explain roughly 1 to 1.5 % ( $p < 0.01$ , Data S4A, Fig. 4B) of variability in species contribution to each geomorphic zone. These results indicate that spatial patterns in coral species contribution by geomorphic zones are still responsive to these three environmental variables.

## DISCUSSION

Our findings confirm the decline in acroporids on Mesoamerican reefs and the shift to an alternate ‘weedy’ state but show that this has not yielded a complete homogenization of the coral community. Although data analysis shows that the overall cover of corals is similar between geomorphic zones, species patterns within them are statistically different. All zones are dominated by the same community of generalist species (*Agaricia* and *Porites*), but these are distributed differently in space. In exposed zones, *Agaricia agaricites* makes the largest contribution followed by *P. astreoides* and *Siderastrea siderea*, whereas in sheltered zones *Porites astreoides* dominates followed by *Orbicella annularis* and *A. agaricites*. The species responsible for differences between zones are *S. siderea*, *P. astreoides* and *O. annularis*. These differences confirm that extrinsic factors such as wave and hurricane exposure still have an impact on species distribution patterns, despite the large historical decline in coral cover.

We recognise that these extrinsic factors generate a weak signal in the degraded coral community and this is likely impacted by the methodological protocol. For example, only a limited number of long-term variables were considered in analysing the species distribution patterns and, two of these (waves and hurricanes), exhibit significant variability over short temporal scales. Nevertheless, both have been reported as major environmental drivers of ecological processes including species zonation (Geister, 1977; Hughes et al., 2019). Moreover, the impact of such disturbances creates an adaptive biotic response by influencing the life-history traits of coral assemblages and creating scale-dependent patterns of species distribution, with some being better adapted to hurricane impacts (e.g. Chollett and Mumby, 2012). In addition, the result is also consistent with multiple reports of the increasingly important role that tropical cyclones play in shaping coral reef ecosystems at both short- and long-term scales (Blanchon et al., 1997; Lugo et al., 2000; Blanchon et al., 2017; Hogan et al., 2020; Puotinen et al., 2020). Moreover, several schemes have proposed an adaptive response of coral assemblages to wave exposure regimes (e.g. Adey and Burke, 1977; Geister, 1977). To some extent, our results augment these schemes by assigning a geomorphic framework and providing an alternative approach to imprecisely defined species-zonation limits. However, wave-fetch becomes saturated on a regional scale and its role in these schemes has been questioned (Adey, 1978). If this is accurate then it could help explain the linkage weakness in Mesoamerican reefs.

The replacement of former acroporid-dominated zones by modern generalist assemblages may result from a species succession associated with hurricane disturbance, where an initial post-hurricane adjustment stage is combined with the loss of species redundancy (McWilliam et al., 2018). Generalist assemblages are formed by pioneer species which are considered to be adapted to repeated disturbance but controlled by depth-related parameters. The evolutionary success of *P. astreoides*, for example, is supported by its limited longevity and its weedy life-history strategy which allows it to thrive in a wide variety of shallow habitats (Tomascik and Sander, 1987). In addition, pioneer assemblages that remain after disturbances are vestigial, given the large historical reductions in absolute abundance (which has dropped ~ 50 %) and loss in species redundancy (leaving only generalists). Consequently, some weakness is expected in the biotic-environmental signal and, with these data, it is not possible to rule-out a successional community status (González-Barrios et al., 2021). The environmental variables may also act as a proxy for other unknown variables influencing coral assemblages (Ellis et al., 2019; Hughes et al., 2019).

The impact of reef geomorphology on coral species composition has been largely ignored in both original (local) and regional analyses (e.g., Rioja-Nieto and Álvarez-Filip, 2019; Contreras-Silva et al.,

2020; Estrada-Saldívar et al., 2019). In the case of local studies, that omission has less impact given that the environment is more homogeneous (but see Medina-Valmaseda et al., 2020), but becomes a problem at a regional scale as environment heterogeneity increases. Furthermore, many local studies pooled data from combined geomorphic zones such as the ‘fore-reef’ which lump non-accreting zones from the surrounding seascape with accretionary reef zones (Williams et al., 2015; Medina-Valmaseda et al., 2020). By providing a more accurate geomorphology our results clearly show a pattern of depth-related geomorphic control down the entire Mesoamerican reef tract, implying that the geomorphic framework is a long-term result of the feedback between environmental processes and coral communities. A similar finding from another site in the region has been reported by Medina-Valmaseda et al. (2020) who found that the inclusion of geomorphic zones in factor-analysis helped identify differences in coral species distribution patterns. Together, these findings underline the importance of depth-related geomorphic controls on large-scale coral-species patterns. Indeed, it is remarkable that geomorphic control prevails on coral communities despite the long duration over which reef decline has occurred.

Geomorphic context was indirectly addressed by a recent province-wide meta-analysis Jackson et al. (2014), which highlighted the significance of reef environment and depth amongst others. The resulting trends, however, are still based on pooling of local data, and thereby relegate the role of environmental factors. Perhaps this lack of consideration of geomorphic context in ecological studies is a methodological artifact whereby reef environment and geomorphic context are relegated to the study site section. Regardless of the cause, the use of a detailed geomorphic zonation within any ecological analysis facilitates the consideration of extrinsic long-term factors. It also provides long-term accretion boundaries to benthic communities and thus incorporates geological models of reef development which are an important source of information on spatial and temporal heterogeneity of the seascape. As a consequence, although ecological studies provide a detailed snapshot of recent changes in coral communities, without a precise geomorphic context, they risk providing an inaccurate picture of both ecological and long-term reef development (Aronson and Precht, 1997; Bellwood et al., 2004; Bruckner, 2012).

## 353 CONCLUSIONS

354 Despite a large decline in historical cover, the depauperate coral communities on fringing reefs of the  
355 Mesoamerican Reef Tract still show species-level differences between depth-related geomorphic zones.  
356 These spatial differences, however, are subtle and have been missed by previous ecological surveys, which  
357 have claimed that communities are homogenized and therefore represent an unnatural alternative state  
358 and compromise the accretion potential of future reef development. Although the decline of acroporid  
359 framebuilders has resulted in a partial homogenization between zones, it is still uncertain if the new  
360 ‘pioneer state’ is stable on the long timescales over which reef accretion occurs. Moreover, species-level  
361 differences in the distribution of pioneer species between geomorphic zones may be a response to their  
362 adaptive life-history traits after prolonged disturbance. The fact that these species are early colonizers  
363 therefore points towards a post-disturbance adjustment and implies that this community may result from  
364 a successional failure induced by chronic anthropogenic disturbance (related to mass tourism along the  
365 Mayan Riviera). But the health status of local communities can vary on short-term scales and adapt to  
366 fluctuations in disturbances.

367 We conclude that an accurate analysis of spatial ecological trends in coral reefs requires a detailed  
368 geomorphic framework in order to identify subtle changes in communities at large spatial scales. If  
369 a geomorphic context is not provided, then a random selection of coral sites will under-represent the  
370 complexity in species patterns. Consequently, we suggest that including a geomorphic context is a  
371 fundamental prerequisite for accurately determining the signal of ecological changes on local, regional,  
372 and provincial scales. Finally, our results do not exclude the possibility of similar heterogeneous patterns  
373 in coral communities at other levels of organization, such as reef type.

## ACKNOWLEDGMENTS

We are grateful with all the persons that collected the original survey data stored at the CRIS system of BARCOLAB and Healthy Reef Initiative.

## ADDITIONAL INFORMATION AND DECLARATIONS

**Alexis E. Medina-Valmaseda** conceived and designed the experiments, performed the experiments, analyzed the data, prepared figures and/or tables, helped write and review drafts of the paper, and approved the final draft.

**Paul Blanchon** helped design the experiment, prepared figures, helped write, review drafts of the paper and approved the final draft.

**Lorenzo Álvarez-Filip** collected part of the data, performed the experiments, helped write, reviewed drafts of the paper, and approved the final draft.

**Esmeralda Pérez- Cervantes** collected part of the data, processed and prepared the data, analyzed the data, review drafts of the paper, and approved the final draft.
