A comparison of two gluteus maximus EMG maximum voluntary isometric contraction positions

Bret Contreras, Andrew D Vigotsky, Brad J Schoenfeld, Chris Beardsley, John B Cronin

Background: The purpose of this study was to compare the peak electromyography (EMG) of the most commonly-used positions in the literature, the prone bent-leg (90º) hip extension against manual resistance applied to the distal thigh (PRONE), to a novel position, the standing glute squeeze (SQUEEZE).

Methods: Surface EMG electrodes were placed on the upper and lower gluteus maximus of thirteen recreationally active females (age = 28.9 years; height = 164 cm; body mass = 58.2 kg), before three maximum voluntary isometric contraction (MVIC) trials for each position were obtained in a randomized, counterbalanced fashion.

Results: No significant ($p \leq 0.05$) differences were observed between PRONE (upper: 91.94%; lower: 94.52%) and SQUEEZE (upper: 92.04%; lower: 85.12%) for both the upper and lower gluteus maximus. Neither the PRONE nor SQUEEZE was more effective between all subjects.

Conclusions: In agreement with other studies, no single testing position is ideal for every participant. Therefore, it is recommended that investigators employ multiple MVIC positions, when possible, to ensure accuracy. Future research should investigate a variety of gluteus maximus MVIC positions in heterogeneous samples.

23

INTRODUCTION

24

25 Maximum voluntary isometric contractions (MVIC) are often used to normalize

26 electromyography (EMG) signals. It is important to employ an MVIC position that elicits the

27 highest activation in order to increase the validity of EMG studies and decrease incidents of

28 abnormally high normalized mean and peak EMG data. In order for accurate comparisons to be

29 made between studies, it is also important for researchers to standardize MVIC positions, or at

30 least use positions that elicit similar magnitudes of EMG activity. A number of MVIC positions

31 have been used in the literature to assess the gluteus maximus, including the Biering-Sorenson

32 position (Cambridge et al. 2012; McGill et al. 2009), the prone straight leg hip extension position

33 (Barton et al. 2014; Worrell et al. 2001), the prone bent leg position (Jakobsen et al. 2013;

34 Youdas et al. 2013), the prone straight leg position with 70º of hip flexion (Simenz et al. 2012),

35 and the standing bent leg position (Boudreau et al. 2009). The most commonly used position,

36 however, is the prone bent-leg (90º) hip extension with manual resistance applied to the distal

37 thigh (PRONE) (Choi et al. 2014; Emami et al. 2014; Hislop et al. 2013; Kang et al. 2013;

38 Kendall et al. 1993; Oh et al. 2007).

39

40 A recent study by Simenz et al. (2012) that used a prone gluteus maximus MVIC position in 70º

41 of hip flexion, demonstrates the importance of standardizing MVIC positions across studies.

42 Researchers have shown that lower gluteus maximus amplitude is elicited at higher degrees of

43 hip flexion and reaches a maximum EMG amplitude at end range hip extension (Worrell et al.

44 2001). By employing an MVIC position that renders significantly lower EMG activity than those

45 values that are truly maximal, the normalized data of Simenz et al. (2012) are most likely

46 overestimated. For example, if the work of Worrell et al. (2001) is extrapolated, the MVIC

47   position used by Simenz et al. (2012) would only elicit approximately 80% of true MVIC,

48   translating into 25% greater mean and peak values when compared to the true MVIC position.

49   The data reported by Simenz et al. (2012) therefore cannot be used for comparison with exercises

50   in other studies that utilized alternative MVIC positions with smaller hip flexion angles, as the

51   data would have overestimated how effectively the gluteus maximus was activated. Therefore, it

52   is apparent that researchers should only compare EMG data that utilize positions that render

53   similar values.

54

55   Since Worrell et al. (2001) found that full hip extension elicited the greatest amount of gluteus

56   maximus EMG activity, and this finding is corroborated by earlier work from Wheatley &

57   Jahnke (1951) and Fischer & Houtz (1968), it is postulated that the most appropriate gluteus

58   maximus MVIC position is at full hip extension, or hip hyperextension. PRONE is currently the

59   recommended position in several texts on muscle testing (Hislop et al. 2013; Kendall et al.

60   1993), although to the authors' knowledge, this position has not been compared to others in the

61   literature. In order to correct for individual variation, some researchers have employed multiple

62   MVIC positions. For example, McGill et al. (2009) used both the Biering-Sorenson and PRONE

63   positions; whichever position elicited the greatest activity was used for normalization purposes.

64   The authors, however, are unaware of any existing research that quantitatively compares gluteus

65   maximus MVIC positions.

66

67   The gluteus maximus muscle appears to be segmented into at least two subdivisions, which may

68   display different EMG activity in response to certain muscle actions. McAndrew et al. (2006)

69   used a laser-based mechanomyographic (MMG) technique to measure the mean contraction time

70   in six subdivisions of the gluteus maximus, both in the sagittal plane (superior, middle, inferior)

71   and in the frontal plane (medial and lateral). The superior region displayed the longest

72   contraction time followed by the middle region and then the inferior region. On the basis of these

73   findings, McAndrew et al. (2006) suggested that the superior region may contain more slow

74   twitch fibers and be more involved in postural tasks compared to the inferior region, while the

75   inferior region may contain more fast twitch fibers and be more involved in dynamic tasks. This

76   is further substantiated by the work of Lyons et al. (1983) and Karlsson & Jonsson (1965), who

77   found differences between upper and lower gluteus maximus EMG during functional movement;

78   for example, load acceptance during stair ambulation better targets the lower gluteus maximus

79   (Lyons et al. 1983), while hip abduction better targets the upper gluteus maximus (Karlsson &

80   Jonsson 1965).

81

82   Pilot data from our lab showed that some subjects were able to elicit greater EMG activity during

83   a standing glute squeeze (SQUEEZE) when compared to PRONE, and this was especially true

84   for the upper gluteus maximus. Given this observation and the findings articulated in previous

85   paragraphs, the purpose of this investigation was to compare upper and lower gluteus maximus

86   EMG activity in PRONE versus SQUEEZE. Based on our pilot data, it was hypothesized that

87   SQUEEZE would elicit greater upper gluteus maximus EMG activity, while PRONE would

88   elicit greater lower gluteus maximus EMG activity.

89

METHODS

90

91 Subjects

92 Thirteen healthy women (age = 28.9 ± 5.1 years; height = 164 ± 6.3 cm; body mass = 58.2 ± 6.4

93 kg) with 7.0 ± 5.8 years of resistance training experience participated in this study. Inclusion

94 criteria required subjects to be between 20 to 40 years of age and have at least 3 years of

95 consistent resistance training experience. All subjects were healthy and free of any

96 musculoskeletal or neuromuscular injuries, pain, or illnesses. Subjects completed an Informed

97 Consent form. Subjects were advised to refrain from training their lower body for 72 hours prior

98 to testing. The study was approved by the Auckland University of Technology Ethics Committee

99 (AUTEC Reference number 13/375).

100

101 Procedures

102 Subjects first performed a 10-minute general warm-up consisting of various dynamic stretches

103 for the lower body musculature. Following warm-up, subjects practiced each testing position

104 several times, until they felt comfortable with the technique. Subjects were asked to wear

105 appropriate clothing for access to the EMG electrode placement sites. Before placing the

106 electrodes on the skin, excess hair was removed with a razor, and skin was cleaned and abraded

107 using an alcohol swab. After preparation, self-adhesive disposable silver/silver chloride pre-

108 gelled dual snap surface bipolar electrodes (Noraxon Product #272, Noraxon USA Inc,

109 Scottsdale, AZ) with a diameter of 1 centimeter (cm) and an inter-electrode distance of 2 cm

110 were attached in parallel to the fibers of the right upper and lower gluteus maximus. More

111 specifically, "[upper gluteus maximus] electrodes were placed two finger's width above the line

112 just under the spina iliaca posterior superior and the trochanter major; [lower gluteus maximus]

113   electrodes were set below the same line" (Fujisawa et al. 2014) (Figure 1, Figure 2). After the

114   electrodes were secured, a quality check was performed to ensure EMG signal validity.

115

116   Following electrode placement, subjects completed three trials of PRONE then SQUEEZE, or

117   vice versa. The PRONE position was performed by having the subject lie prone on the bench,

118   flexing their knee to 90º, and was told to extending her hip while manual resistance was applied

119   to the distal thigh (Figure 1). The SQUEEZE position was performed by having the subject stand

120   with her feet slightly wider than shoulder width apart and hips slightly externally rotated. The

121   subject was instructed to squeeze her glutei and focus on externally rotating and extending her

122   hips (Figure 2). For example, if a subject was randomized to complete PRONE first, her testing

123   order would be PRONE, SQUEEZE, rest, PRONE, SQUEEZE, rest, PRONE, SQUEEZE. Each

124   contraction phase lasted 5 seconds, and each rest phase lasted 3 minutes. Randomization was

125   counterbalanced so that half the subjects performed PRONE first and the other half performed

126   SQUEEZE first. In all MVIC positions, subjects were instructed to contract the gluteus maximus

127   "as hard as possible."

128

129   **Figure 1.** Prone bent-leg hip extension position. Force is applied to the distal thigh while the

130   subject produces a hip extension moment.

132

133   **Figure 2.** Standing glute squeeze position. The subject squeezes her glutei, which generates hip

134   extension and external rotation moments.

135

136   Raw EMG signals were collected at 2000 Hz by a Myotrace 400 EMG unit (Noraxon USA Inc,

137   Scottsdale, AZ). Data was sent in real time to a computer via Bluetooth and recorded and

138 analyzed by MyoResearch 3.6 Clinical Applications software (Noraxon USA, Inc., Scottsdale,

139 AZ). A 10-500 Hz bandpass filter was applied to EMG data. Signals of all MVIC trials were full-

140 wave rectified and smoothed with a root mean square (RMS) algorithm with a 100 ms window.

141 Maximal peak EMG values over a 1000 ms window, or the 1000 ms window with the greatest

142 average EMG amplitude within the 5 second contraction, were then used to normalize peak

143 EMG signals obtained during each MVIC trial (Vera-Garcia et al. 2010).

144

145 Statistical Analysis

146 Paired samples *t*-tests were performed after checking normality using Shapiro-Wilk test in Stata

147 13 (StataCorp LP, College Station, TX). Alpha was set *a priori* at 0.05 for significance. Effect

148 sizes (ES) were calculated by Cohen's *d* using the formula $d = \dfrac{M_d}{s_d}$, where M_d is the mean of

149 differences and s_d is the standard deviation of differences (Becker 1988; Morris 2007; Smith &

150 Beretvas 2009). This method is slightly different than the traditional method of calculating

151 Cohen's *d*, as it calculates the within-subject effect-size rather than group or between-subject

152 effect size. ES were defined as small (0.20-0.49), moderate (0.50-0.79), and large (≥ 0.80)

153 (Cohen 1988). Confidence intervals (95% CI) for each ES were also calculated.

154

155 **RESULTS**

156 The normalized peak EMG for the different exercises and gluteus maximus sections can be

157 observed in Table 1. In terms of the upper gluteus maximus comparison, no significant

158 differences were observed in the peak EMG for both exercises (ES = 0.005; 95% CI = −0.599 −

159 0.609; t(12) = 0.018; *p* = 0.986). With regards to the lower gluteus maximus, a small ES was

160   observed (0.412; 95% CI = −0.193 − 0.102) between the two positions in favor of the PRONE

161   position; however, this outcome may have been due to chance alone (t(12) = −1.485; p = 0.164).

162

163   **Table 1.** Group mean ± SD of normalized peak EMG amplitudes.

	PRONE	SQUEEZE
Upper gluteus maximus	91.94 ± 11.64	92.04 ± 11.30
Lower gluteus maximus	94.52 ± 13.59	85.12 ± 12.64

164
165

166   **DISCUSSION**

167   The purpose of this investigation was to compare a novel gluteus maximus MVIC position,

168   SQUEEZE, to the current gold standard, PRONE. We have failed to reject the null hypotheses,

169   as there were no statistically significant differences between the two positions tested (Table 1).

170   However, despite no statistically significant differences, the peak EMG values for the lower

171   gluteus maximus were approximately 9% higher for the PRONE compared to the SQUEEZE.

172   Consequently, if the SQUEEZE test were used for normalization, it would render approximately

173   10% higher mean and peak EMG values compared to the PRONE test. Therefore, although not

174   statistically significant, the findings could be considered practically meaningful. Furthermore,

175   these data show a large amount of individual variation (Table 2), which has been previously

176   described by McGill (1990) and Vera-Garcia et al. (2010) for other muscles.

177

178 **Table 2.** Number of subjects (percentage of subjects (%)) which each MVIC technique resulted
179 in the greatest peak EMG amplitude.

	PRONE	SQUEEZE
Upper gluteus maximus	7 (53.85)	6 (46.15)
Lower gluteus maximus	10 (76.92)	3 (23.08)

180
181
182 There are several kinematic and kinetic differences between PRONE and SQUEEZE, any of

183 which may have affected our results, either individually or in combination. During PRONE, the

184 knee is bent to 90º, whereas during SQUEEZE, the knees are fully extended. Previous research

185 has shown that gluteus maximus EMG activity during hip extension is greater with the knees

186 flexed than when extended, presumably resulting from a greater reliance upon the gluteus

187 maximus for hip extension due to decreased hamstrings length (Kwon & Lee 2013). On the other

188 hand, extended knees allow for greater hip extension range of motion compared to flexed knees,

189 thereby shortening the gluteal fibers to a greater extent (Van Dillen et al. 2000) and leading to a

190 greater amount of gluteus maximus EMG activity (Worrell et al. 2001). In addition, PRONE

191 involved primarily hip hyperextension since the pelvis was fixed, whereas SQUEEZE appeared

192 to involve a combination of hip extension and posterior pelvic tilt. Although posterior pelvic tilt

193 mimics hip extension (Neumann 2010), it is unclear how each of these kinematic variables might

194 affect gluteus maximus EMG activity individually. To our knowledge, no study to date has

195 investigated gluteus maximus EMG activity with varying combinations of hip extension and

196 posterior pelvic tilt during MVIC actions. Moreover, PRONE is an open kinetic chain maneuver

197 with the torso stabilized onto a bench, whereas SQUEEZE is a closed kinetic chain maneuver

198 performed in a standing position. Stensdotter et al. (2003) investigated the EMG activity of the

199 quadriceps muscle group during open kinetic chain and closed kinetic chain positions during

200 MVIC actions and reported significant differences in EMG amplitude. The rectus femoris

201 displayed greater EMG activity during open kinetic chain maneuvers while the vastus medialis

202 displayed greater EMG activity during closed kinetic chain maneuvers. It is therefore hard to

203 predict whether the gluteus maximus would inherently display greater or lesser EMG activity

204 during either open or closed kinetic chain maneuvers. Finally, PRONE required manual

205 resistance, whereas SQUEEZE relied upon anatomical structures surrounding the hip to provide

206 resistance against hip extension. Whether this factor has any effect on EMG activity recorded in

207 a muscle is unclear, as the authors are unaware of any previous investigations into the effect of

208 squeezing a muscle whereby range of motion is limited by anatomical structures on EMG

209 activity rather than against external resistance.

210

211 This investigation was subject to several important limitations. Firstly, although we observed

212 what may have been a practically important difference between the MVIC positions, this

213 difference was not found to be statistically significant, which suggests that our initial estimates

214 for the appropriate sample size may have been too small. Secondly, there were several kinematic

215 differences between the two positions that were explored (PRONE and SQUEEZE), including

216 different pelvic, hip, and knee joint angles. There were also kinetic differences between the two

217 positions, in that PRONE was an open kinetic chain maneuver and SQUEEZE was a closed

218 kinetic chain maneuver. Moreover, PRONE used external resistance and SQUEEZE utilized

219 oppositional torques produced by internal, anatomical structures. These multiple differences

220 make it difficult to assess whether our results arose from a combination of biomechanical factors

221 acting in opposing directions, heterogeneity, or genuinely no difference between the conditions.

222 Thirdly, we only compared two MVIC positions, and it is feasible that other positions might

223 result in superior or inferior levels of EMG activity. Fourthly, we only investigated two

224 subdivisions of the gluteus maximus muscle and there are indications that there may be others,

225 from proximal-to-distal, medial-to-lateral, and superficial-to deep. Furthermore, our statistical

226 analysis was not designed to assess whether there was a difference between the EMG activity of

227 the upper and lower gluteus maximus during either MVIC position and therefore this remains

228 uncertain.

229 **Conclusions**

230 Although these data are inconclusive as to which position is superior, they do provide insight as

231 to the complexity of MVIC positions for the gluteus maximus. More specifically, due to the large

232 individual variations (Table 2), it is recommended that multiple MVIC positions be utilized to

233 ensure that the greatest possible EMG amplitude be the divisor during normalization. These

234 recommendations are well in line with other studies, which have utilized or recommended

235 multiple MVIC positions (McGill et al. 2009; Vera-Garcia et al. 2010). Future research should

236 use heterogeneous samples, such as athletic males, and also test more positions, such as the

237 Biering-Sorenson position, quadruped hip extension position, and top hip thrust position

238 (Contreras et al. 2011), each with manual resistance, along with the tall kneeling position.
