Intraspecific trait variation (ITV) enables plants to respond to global changes. However, causes for ITV, especially from biotic components such as herbivory, are not well understood. We explored whether small vertebrate herbivores (hares and geese) impact ITV of a dominant clonal grass (*Elytrigia atherica*) in local communities. Moreover, we looked at the relative importance of their direct (e.g. selective grazing) and indirect effects (altering genotypic richness/diversity and abiotic environment) on ITV. We used exclosures at two successional stages in a Dutch saltmarsh, where the early stage had higher grazing pressure than the intermediate one. We measured key functional traits of *E. atherica* including height, aboveground biomass, flowering (flower or not), specific leaf area, and leaf dry matter content in the local communities (1 m × 1m plots) inside and outside the exclosures. We also determined genotypic richness and diversity using molecular markers. We further measured abiotic variations in topography and clay thickness (a proxy for soil total nitrogen). Structural equation models revealed that small herbivores significantly promoted ITV in height and flowering at the early stage, while they marginally promoted ITV in height at the intermediate stage. Moreover, the direct effects of herbivores played a major role in promoting ITV. Small herbivores decreased genotypic diversity at the intermediate stage, but genotypic richness and diversity did not impact ITV. Small herbivores did not alter topographic variation and variation in clay thickness, but these variations increased ITV in all traits at the early stage. Small herbivores may not only impact trait means as studies have shown but also ITV in plants.

9

10 Abstract

11 Intraspecific trait variation (ITV) enables plants to respond to global changes. However, causes
12 for ITV, especially from biotic components such as herbivory, are not well understood. We
13 explored whether small vertebrate herbivores (hares and geese) impact ITV of a dominant clonal
14 grass (*Elytrigia atherica*) in local communities. Moreover, we looked at the relative importance
15 of their direct (e.g. selective grazing) and indirect effects (altering genotypic richness/diversity
16 and abiotic environment) on ITV. We used exclosures at two successional stages in a Dutch
17 saltmarsh, where the early stage had higher grazing pressure than the intermediate one. We
18 measured key functional traits of *E. atherica* including height, aboveground biomass, flowering
19 (flower or not), specific leaf area, and leaf dry matter content in the local communities (1 m × 1m
20 plots) inside and outside the exclosures. We also determined genotypic richness and diversity
21 using molecular markers. We further measured abiotic variations in topography and clay
22 thickness (a proxy for soil total nitrogen). Structural equation models revealed that small
23 herbivores significantly promoted ITV in height and flowering at the early stage, while they
24 marginally promoted ITV in height at the intermediate stage. Moreover, the direct effects of
25 herbivores played a major role in promoting ITV. Small herbivores decreased genotypic
26 diversity at the intermediate stage, but genotypic richness and diversity did not impact ITV.
27 Small herbivores did not alter topographic variation and variation in clay thickness, but these
28 variations increased ITV in all traits at the early stage. Small herbivores may not only impact
29 trait means in plants as studies have shown but also their ITV.

31 saltmarsh

32 Introduction

33 Studies show that intraspecific trait variation (i.e. variability in traits of conspecific individuals;
34 hereafter ITV) can enable plant species to respond to global changes (Westerband, Funk &
35 Barton, 2021), impact community composition and structure (Whitlock, Grime & Burke, 2010),
36 and govern ecosystem processes (Boege & Dirzo, 2004; Crutsinger et al., 2006; Crutsinger,
37 Souza & Sanders, 2008; Lecerf & Chauvet, 2008). The importance of ITV has been increasingly
38 realized over the years (Violle et al., 2012; Siefert et al., 2015; Funk et al., 2017; Westneat et al.,
39 2019; Westerband, Funk & Barton, 2021), therefore, exploring the causes for ITV is of prime
40 importance, particularly under the current rapid global changes (Westerband, Funk & Barton,
41 2021). Several components including genotypic richness/diversity and phenotypic plasticity
42 triggered by biotic and abiotic environments can drive ITV (Valladares, Gianoli & Gomez,
43 2007). However, biotic components, particularly herbivory, received much less attention than
44 genotypic richness/diversity and abiotic environments (Valladares, Gianoli & Gomez, 2007).

45

46 Whilst herbivores are one of the major drivers for plant trait differentiation globally (Díaz et al.,
47 2007; He & Silliman, 2016), the majority of the studies that document the effects of herbivores
48 on plant traits focus on trait means without considering ITV (e.g. Bullock et al., 2001; Louault et
49 al., 2005; Kahmen & Poschlod, 2008). Limited studies suggest that herbivores may also impact
50 ITV (e.g. Jessen et al., 2020). However, these studies mainly focus on large herbivores. Large
51 and small herbivores are relative. Here we refer to small herbivores as vertebrate herbivores with
52 body mass range from 1 to 10 kg such as hares and geese. Small herbivores sometimes can have
53 stronger impacts on plant communities than large ones especially when their abundance is high

54 (Olofsson et al., 2004). Additionally, small herbivores are usually more selective with forage
55 plants (Olf & Ritchie, 1998). Therefore, small herbivores may also impact ITV, however, we
56 currently lack empirical evidence.

57

58 Small herbivores may impact ITV via multiple non-exclusive processes. First, small herbivores
59 can promote ITV through selective grazing. Studies show that large herbivores generally
60 consume tall plants, thus promoting short plants (Díaz et al., 2007; Evju et al., 2009). This is
61 probably because short plants, which are usually young, are generally more nutritious (e.g.
62 higher protein and lower lignin and cellulose) (Augustine & McNaughton, 1998). Similarly,
63 small herbivores are more likely to consume young (short) plants over old (tall) ones, but some
64 young (short) plants may escape from grazing via association with unpalatable species (Van Der
65 Wal et al., 2000; Kuijper & Bakker, 2008). Thus, small herbivores may promote variation in
66 plant height. Second, small herbivores may impact ITV indirectly through altering genotypic
67 richness and diversity. Increased genotypic richness and diversity can increase ITV (Evans et al.,
68 2016). Studies looking at the effects of large herbivores on genotypic diversity show that large
69 herbivores can increase genotypic diversity by promoting seed transportation (Rico & Wagner,
70 2016) or decrease it by promoting clonal growth (Kleijn & Steinger, 2002). Small herbivores can
71 have similar effects to large ones on many processes such as seed dispersal (Bakker & Olf,
72 2003). Therefore, small herbivores can either increase or decrease genotypic richness and
73 diversity. Third, small herbivores may promote ITV indirectly through altering abiotic
74 heterogeneity (e.g. topographic variation and variation in soil nutrients) via grazing the
75 vegetation at particular spatial scales, trampling, and localized deposition of droppings (Adler,
76 Raff & Lauenroth, 2001). Abiotic heterogeneity usually promotes ITV (Westerband, Funk &

77 Barton, 2021). However, whether small herbivores impact ITV via these processes and the
78 relative importance of them in shaping ITV remains underexplored.

79

80 In the eastern part of the saltmarsh of the island of Schiermonnikoog, hares and geese are the
81 abundant herbivores while large herbivores are absent (Kuijper & Bakker, 2005; Schrama et al.,
82 2015; Chen et al., 2019). A well-calibrated successional gradient is present here (Olf et al.,
83 1997). Hares and geese are more abundant at early successional stages but their abundance
84 decreases at intermediate and late successional stages due to less preferred late successional
85 plants such as *Elytrigia atherica* (synonym *Elymus athericus*) increase in dominance (Kuijper &
86 Bakker, 2005; Schrama et al., 2015; Chen et al., 2019). Although adult plants of *E. atherica* are
87 less preferred, hares and geese considerably graze on its seedling/young plants (Kuijper, Nijhoff
88 & Bakker, 2004; Fokkema et al., 2016). However, short seedlings/young plants may escape from
89 grazing by associating with non-preferred plants such as *Artemisia maritima*. *Elytrigia atherica*
90 mainly reproduces clonally, but sexual reproduction may occur occasionally via windows of
91 opportunity, thus genotypic richness is high in this grass (Bockelmann et al., 2003; Chen, 2020).
92 Hares and geese play a less important role than tidal water in seed dispersal (Chang et al., 2005),
93 therefore, it is unlikely that hares and geese can increase genotypic richness and diversity by
94 dispersing seeds. Instead, hares and geese may decrease genotypic richness and diversity by
95 promoting clonal spread of *E. atherica* (Van Der Graaf, Stahl & Bakker, 2005). Hares and geese
96 may increase topographic variation via trampling (Wijnen, Wal & Bakker, 1999; Elschot et al.,
97 2015), they may also impact sediment accumulation (measured by clay thickness) by trampling
98 and altering vegetation structure (Boorman, Garbutt & Barratt, 1998). Clay thickness is highly
99 correlated with soil total Nitrogen (Olf et al., 1997). Topographic variation and variation in clay

100 thickness are important factors for the growth and expansion of *E. atherica* in this system (Olf
101 et al., 1997; Nolte et al., 2019). Taken together, hares and geese may increase ITV of *E. atherica*
102 through selective grazing and promoting topographic variation and variation in clay thickness but
103 may decrease ITV by decreasing genotypic richness and diversity.

104

105 To test these hypotheses, we used long-term (22-year) exclosures at the early and intermediate
106 successional stages, where abiotic conditions are relatively similar, but grazing pressure differs
107 markedly (Kuijper & Bakker, 2005; Chen et al., 2019). As ITV is usually strongly driven by
108 processes operating at small spatial scales (Westerband, Funk & Barton, 2021), we, therefore,
109 looked at ITV in local communities (1 m × 1m plots). Specifically, we measured key functional
110 traits of this dominant grass including height, aboveground biomass, flowering (flower or not),
111 specific leaf area, and leaf dry matter content within local communities inside and outside the
112 exclosures. Using structural equation models, we test whether hares and geese impact ITV of *E.*
113 *atherica*, and the relative importance of their direct effects (e.g. selective grazing) and indirect
114 effects (via altering genotypic richness/diversity and abiotic variables) on ITV. We expect that
115 the effects of hares and geese on ITV would be more apparent at the early successional stage
116 (relative to the intermediate one) where grazing pressure was higher.

117

118 **Materials and methods**

119 *Study site*

120 A natural successional gradient is present in the back-barrier saltmarsh of the island of
121 Schiermonnikoog (53°30' N, 6°10' E), the Netherlands. Because this island expands eastward,
122 thus the eastern part of the island is younger relative to the western part (Olf et al., 1997). The
123 western part of the saltmarsh is enclosed for cattle grazing, while the eastern part of it is grazed
124 by wild small herbivores such as spring staging geese, year-round present hares and rabbits.
125 Hares and geese are the most abundant herbivores (Van de Koppel et al., 1996; Van Der Wal,
126 Kunst & Drent, 1998; Van Der Wal et al., 2000; Kuijper & Bakker, 2005; Schrama et al., 2015).
127 Rabbits are very rare. Kuijper and Bakker (2005) found that biomass removed by rabbits in 2000
128 was 6.33% and 0.16% of the total biomass removed by small herbivores at the early and
129 intermediate stage, respectively.

130

131 We used long-term hare and goose exclosures that were initiated in 1994 (details in Chen et al.,
132 2019). We selected exclosures located at the early and intermediate successional stages, which
133 are approximately 2.5 km apart (Fig. 1A). Vegetation succession has undergone around 30 and
134 60 years at the early and intermediate stage, respectively. Age of the vegetation succession was
135 counted from the year of vegetation establishment to 2016. The year of vegetation establishment
136 was determined by checking aerial photographs (Olf et al., 1997). Grazing pressure from hares
137 and geese was much higher at the early stage than the intermediate stage. Grazing pressure was
138 calculated using year-round dropping count in 2000 and 2016 (see Table S1 for more details;
139 Kuijper & Bakker, 2005; Chen et al., 2019; Chen et al., 2019a).

140

141 Hare and goose exclosures (one per each stage) were located in a similar elevation (early stage:
142 1.42 ± 0.004 ; intermediate stage: 1.44 ± 0.004 ; mean \pm 1se; N=24; m+NAP; Normal Amsterdam
143 Water Level). Exclosures (8 m \times 12 m and 6 m \times 8 m at the early and intermediate stages) were
144 made by chicken mesh (mesh width 25 mm) supported by wooden posts every 3.5 m to exclude
145 hare grazing inside the exclosures. Exclosures were around 1 m in height, ropes were suspended
146 on top of the wooden posts to stop geese flying into the exclosures. At the beginning of the
147 exclosure experiment (1995), *E. atherica* rarely occurred (< 2.5 %; percent cover) inside and
148 outside the exclosures at these two stages. Vegetation composition differed in the grazed areas
149 and inside the exclosures in 2016 (Fig.1; also see Table S2 for species composition for the three
150 most abundant species). Specifically, *Artemisia maritima* was the most dominant plant in the
151 grazed area at these two stages, while *E. atherica* was the most dominant plant inside the
152 exclosures.

153

154 *Experimental design*

155 We marked an area, ca. 6 m \times 8 m, which corresponds to the smaller size of the exclosures (at
156 the intermediate successional stage), inside and outside the exclosure for both stages in June
157 2017. The distance between the area and the exclosure measured ca. 80 m. We randomly set up 7
158 plots (1m \times 1m) inside these two grazed areas and exclosures (Fig. 1). The distance between
159 these plots ranged from 0.5 m to 9 m. We divided each plot into 25 grids (0.2 m \times 0.2 m). Within
160 each grid, we collected one individual stem of *E. atherica* (with roots), usually in the middle of
161 the grid (Fig. 1). *Elytrigia atherica* did not occur everywhere, particularly not in the grazed area,
162 thus sample size per plot varied from 9 to 25.

163

164 *Trait measurement*

165 We measured traits for individual stems of *E. atherica* in the field. We sampled individual stems
166 without obvious grazing marks. We cut individual stems at the ground level and measured
167 maximum height (cm) from the base to the highest point. We measured the maximum leaf width
168 and length of the first fully grown leaf, usually the third leaf from the top. We also recorded
169 whether individual stems flowered or not. After these measurements, each stem was stored in a
170 paper bag, sealed, labeled, and then put in a self-sealing plastic bag to reduce water loss in
171 tissues. At the end of each day, samples were brought to the lab, we measured fresh biomass of
172 the individual stems and fully-grown leaves. We also measured dried biomass (g) after oven-dry
173 (70 °C) to constant mass (ca. 3 days). Specific leaf area ($\text{mm}^2 \text{mg}^{-1}$) was calculated as (leaf width
174 \times leaf length) / dried leaf biomass. Leaf dry matter content (mg g^{-1}) was calculated as dried leaf
175 biomass / fresh leaf biomass. Note that leaf dry matter content was only measured in 3, 5, 4, and
176 4 plots in the grazed and ungrazed treatment at the early and intermediate stage, respectively.
177 This is because we needed to bring all samples and measure the fresh weight of each leaf sample
178 and the whole plants in the field station. We also need to do this quickly, otherwise, water will be
179 lost in the plant tissues, which may bias estimation of fresh weight. Due to lack of manpower, we
180 measured fresh leaf weight for around half of the randomly selected plots. Also, specific leaf
181 area and leaf dry matter content was not measured in the standard way (Pérez-Harguindeguy et
182 al., 2016), and caution should be taken when comparing our data with other studies. We
183 measured leaf width and length because they are easier to measure in the field. A similar method
184 was also used in a previous study in this system (Veeneklaas et al., 2011). Because we measured

185 leaf width and leaf length for all plots in this way, thus our results are not very likely to be biased
186 by the method used here.

187

188 *Genotyping and genotype richness and diversity*

189 We used oven-dried leaf samples (ca. 2 mg per individual stem) for DNA extraction. We first
190 shredded leaf samples into smaller pieces using tissuelyser. We then extracted DNA from each
191 leaf sample using the CTAB method (Doyle & Doyle, 1987) and stored DNA samples at -20 °C
192 before PCR. We amplified DNA using PCR with fluorescence-labeled primers. We used five
193 microsatellite markers (ECGA89, WMS6, WMS44, WMS2, and ECGA89) originally designed
194 for the other Poaceae species, *Elymus caninus* (Sun, Salomon & Bothmer, 1998) and *Triticum*
195 *aestivum* (Röder et al., 1998). These five markers were used for genotyping *E. atherica* in this
196 system (Bockelmann et al., 2003; Chen 2020). The PCR products from primer ECGA89, WMS6,
197 and WMS44 were pooled together, while the PCR products from WMS2 and ECGA89 were
198 pooled together. Additionally, 1 µL rROX was added in each sample as the internal size standard
199 (Gene Scan™–350 ROX™, Applied Biosystem). We visualized the pooled PCR products
200 using the 3730 DNA analyzer and scored the microsatellite peak patterns (height > 100)
201 manually using GeneMapper. In total, we successfully genotyped 579 individual stems of *E.*
202 *atherica*, but 2 were excluded for further analyses as some trait data measured in the field for
203 these samples were missing.

204

205 *Abiotic variables*

206 We measured clay thickness and topographic variation for each plot (3 replicates). We measured
207 clay thickness using a 2 cm Ø soil corer with tick marks as a proxy for soil total nitrogen (Olf et
208 al., 1997). Previous studies show that clay thickness is strongly positively correlated with soil
209 total nitrogen in this system (e.g. Olf et al., 1997), and is used as a proxy of soil fertility (e.g.
210 Schrama et al., 2017). We measured topography using Trimble R8 (precision for elevation ca. 1
211 cm).

212

213 **Data analysis**

214

215 *Calculating trait means, ITV, topographic variation, and variation in clay thickness*

216 We calculated means for each trait by averaging trait values over 9 -25 individual stems in each
217 plot. We calculated ITV in each trait each plot as the standard deviation /mean. Topographic
218 variation and variation in clay thickness were calculated as standard deviation /mean (over 3
219 samples) of elevation and clay thickness, respectively.

220

221 *Calculating genotypic richness, genotypic diversity, and genetic differentiation*

222 To calculate genotype richness and diversity per plot, we first calculated pairwise genetic
223 distance using Dice dissimilarity from the R package ade4 (Dray & Dufour, 2015) based on the
224 presence/absence matrix of 42 allele bands from those five markers. We then assigned genotypes
225 based on dice dissimilarity, using the function “assignClones” from the R package polysat
226 (Lindsay, Clark & Clark, 2018). We calculated genotypic richness as the number of unique
227 genotypes detected divided by the number of individual stems genotyped for each plot.
228 Genotypic diversity — taking into account the abundance of different genotypes—was

229 calculated using the function “genotypeDiversity” with the index of “Shannon” from the package
230 polysat (Lindsay, Clark & Clark, 2018). Because small herbivores may select for some particular
231 genotypes that are more resistant or tolerant to herbivore grazing (Kotanen & Bergelson, 2000),
232 which may also impact traits. We explored genetic differentiation using principal coordinates
233 analysis (PCoA) from the R package ade4 (Dray & Dufour, 2015). We looked at genetic
234 differentiation at the treatment level, that is, grazed and ungrazed across plots at each stage,
235 result can be found in Fig. S1.

236

237 *Effects of small herbivores on trait means and ITV*

238 Although our focus is on ITV, to compare whether the effects of small herbivores on ITV are
239 stronger than trait means, we also looked at the effects of small herbivores on trait means. We
240 use analysis of variance, function “lm”, to look at the effects of small herbivores on means and
241 ITV of each trait at the early and intermediate successional stage, separately. We checked
242 residuals for each model, in all cases, models fitted the data reasonably well.

243

244 *Direct and indirect effects of small herbivores on ITV*

245 We estimated the direct, indirect effects through altering genotypic richness and diversity,
246 indirect effects through altering abiotic variables, and total effects (sum of direct and indirect
247 effects) of small herbivores on ITV. We estimated these effects in each trait at each successional
248 stage based on the standardized path coefficients using structural equation models from the R
249 package “lavaan” (Rosseel, 2012). Grazing (0: ungrazed, 1: grazed), genotypic richness,
250 genotypic diversity, topographic variation, and variation in clay thickness were included in the
251 models. Note that genotypic diversity was not included for ITV at the early stage, as it was

252 significantly correlated with genotypic richness (variance inflation factor > 4). See online
253 supporting text for an example of a structural equation model for ITV in height at the
254 intermediate stage and calculation of the direct and indirect effects. Note that leaf dry matter
255 content was not evaluated in structural equation models due to limited sample size. Effects are
256 significant when $p \leq 0.05$, while marginally significant when $p > 0.05$ and $p < 0.1$. Data analysis was
257 performed in R3.5.3 (R Core Team 2020).

258

259 **Results**

260 *Effects of small herbivores on trait means and ITV*

261 At the early successional stage, small herbivores significantly decreased means in height,
262 aboveground biomass, and flowering of *E. atherica*, but had no effects on means in specific leaf
263 area and leaf dry matter content. Also, small herbivores significantly increased ITV in flowering
264 and marginally increased ITV in height, but had no effects on ITV in other traits. At the
265 intermediate successional stage, small herbivores significantly decreased means in all traits
266 except for leaf dry matter content. However, small herbivores had no effects on ITV in all traits
267 (Fig. 2; see Table S3 for test statistics).

268

269 *Direct and indirect effects of small herbivores on ITV*

270 The structural equation model reveals that overall (summing up the direct and indirect effects),
271 small herbivores tended to promoted ITV in height and flowering, but not in other traits at the
272 early successional stage. Overall, small herbivores tended to promoted ITV in height, but not in
273 other traits at the intermediate stage. Moreover, these positive overall effects of small herbivores
274 on ITV in height and flowering were mainly attributable to their direct effects. Although the

275 overall effects of small herbivores on ITV in aboveground biomass and specific leaf area were
276 not significant, small herbivores also directly significantly impacted ITV in these two traits at the
277 early successional stage (Fig 3; see Table 1 for standardized path coefficient estimated from
278 SEM for the direct, indirect, and total effects of small herbivores on ITV).

279

280 At the early stage, small herbivores did not have significant effects on genotypic richness and
281 diversity, but genotypic richness decreased ITV in flowering. At the intermediate stage, small
282 herbivores did not have significant effects on genotypic richness, but significantly reduced
283 genotypic diversity. However, genotypic richness and diversity did not impact ITV in any traits
284 (Fig. 3).

285

286 Small herbivores did not impact topographic variation and variation in clay thickness at both
287 stages. However, these variations significantly increased ITV in all traits at the early stage except
288 that the effects of topographic variation on ITV in flowering were not significant, their effects
289 were less apparent at the intermediate stage (Fig. 3).

290

291 **Discussion**

292

293 In this study, using long-term exclosures, in combination with field observations and genetic
294 analyses, we explored ITV of a dominant clonal grass (*Elytrigia atherica*) and the direct and
295 indirect effects of small herbivores on ITV. We found that, at the early successional stage, small
296 herbivores promoted ITV in height and flowering of this grass. At the intermediate stage, small
297 herbivores marginally promoted ITV in height. Moreover, small herbivores promoted ITV

298 mainly through direct effects (e.g. selective grazing) but not through altering genotypic
299 richness/diversity or topographic variation and variation in clay thickness.

300

301 *Effects of small herbivores on trait means and ITV*

302 Our results suggest that small herbivores can impact both means and variations in functional
303 traits of *E. atherica*, but their effects differed in different traits. At the early stage, we found that
304 small herbivores strongly impacted means in three traits measured (height, aboveground
305 biomass, and flowering) and they strongly promoted ITV in two traits (height and flowering). At
306 the intermediate stage, small herbivores impacted means in four traits (height, aboveground
307 biomass, flowering, and specific leaf area) and they marginally promoted ITV in one trait
308 (height; Fig. 2). This suggests that trait means and variations may be driven by different
309 processes. Moreover, we only observed ITV in height and flowering may be because these two
310 traits have higher plasticity than other traits, and traits with a higher level of plasticity also show
311 higher ITV (Givnish, 2002). Further, the effects of small herbivores on trait means (relative to
312 ITV) were less dependent on grazing pressure. This may be due to that the preferred plant, *F.*
313 *rubra*, was more abundant in the grazed area at the early successional stage (ca. 3 times relative
314 to that of the intermediate successional stage). Thus, small herbivores (although more abundant)
315 may graze more on *F. rubra* rather than *E. atherica*. At the intermediate stage, the abundance of
316 *F. rubra* decreased, while the abundance of *E. atherica* increased in the grazed area (ca. 5 times
317 relative to that of the early successional stage), thus small herbivores (less abundant) may also
318 substantially grazed on less preferred *E. atherica*. Therefore, overall, the effects of small
319 herbivores on trait means were similar at these two stages. Meanwhile, non-preferred species (*A.*

320 *maritima*) was more abundant in the grazed area at the early successional stage (ca. 2 times
321 relative to that of the intermediate successional stage; see Table S2 for more detailed percent
322 cover of these species), which may facilitate young/short *E. atherica* escape from herbivore
323 grazing. Therefore, ITV was more apparent at the early successional stage than the intermediate
324 one. Previous studies in this system have shown that hares and geese are the important drivers
325 for plant community composition and structure along this successional gradient (Olf et al.,
326 1997; Kuijper & Bakker, 2005; Chen et al., 2019). Here, extending the current knowledge, we
327 show that small herbivores may also impact trait means and variations, which in turn may impact
328 community composition and structure (Whitlock, Grime & Burke, 2010).

329

330 *Direct and indirect effects of small herbivores on ITV*

331 As we hypothesized, the direct effects of small herbivores through selective grazing increased
332 ITV. This is not only true for height and flowering but also for aboveground biomass and
333 specific leaf area, despite the overall effects of small herbivores on aboveground biomass and
334 specific leaf area were not significant. As explained in the previous paragraph, the direct effects
335 of small herbivores may be mediated by community composition especially the proportion of
336 preferred and non-preferred plants. Herz et al. (2017) found that local neighborhood diversity
337 can explain a large amount of ITV in German meadows and pastures, possibly through increased
338 plant-plant interactions (e.g. competition). In this study, plant diversity was higher in the grazed
339 than the ungrazed plots at both successional stages after 22-year grazing (Table S2). Thus, higher
340 plant diversity may also contribute to increased ITV in height under grazing at both successional
341 stages. Future studies/experiments looking at the effects of herbivores on ITV in plant

342 communities with the same composition are needed to fully separate the effects of selective
343 grazing from the effects of neighboring plants.

344

345 We found that small herbivores did not impact genotype richness and diversity of *E. atherica* at
346 the early successional stage but decreased genotypic diversity at the intermediate stage. A
347 previous study in the west part of this saltmarsh found that cattle grazing does not impact
348 genotype richness and diversity of this grass, but cattle grazing alters its morphological traits in
349 the field such as decreasing height and leaf width (Veeneklaas et al., 2011). Here, we found that
350 genotypic richness and diversity generally had no significant effects on ITV. Possibly because
351 microsatellite markers are selectively neutral, thus they do not control gene expression for the
352 traits measured here. A low correlation between variation in morphological traits and DNA
353 markers was also reported before (Kolliker et al., 1998). Additionally, we found genetic
354 differentiation of *E. atherica* in the grazed and ungrazed areas at the early successional stage, but
355 not at the intermediate successional stage (Fig. S1), however, more data (presumably from more
356 exclosures) are needed to consolidate this result. Thus, the observed trait changes (at both
357 successional stages) may not be associated with genetic changes in *E. atherica*. Taken together,
358 plasticity induced by herbivore grazing may play a major role in trait changes (both in means and
359 variations).

360

361 In contrast, we found no effects of small herbivores on topographic variation and variation in
362 clay thickness within plots. These abiotic variations may be primarily induced by flooding and
363 inundation, which may overrule the effects of small herbivores in salt marshes. However,

364 variations in these two abiotic variables had substantial positive impacts on ITV particularly at
365 the early stage. Abiotic environment may be more heterogenous at the early stage because this
366 stage has more frequent sediment deposition than the intermediate stage (Schrama, Berg & Olf, 2012). A previous study conducted in the western part of this saltmarsh also found that
367 topographic variation at the small spatial scales (0.1 m² and 10 m²) is positively correlated with
368 species richness and cattle grazing additionally increased species richness (Ruifrok et al., 2014).
369 Thus, abiotic variations, even at very small spatial scales, may play an important role in
370 promoting ITV and altering other plant community properties.
371

372

373 *Long-term exclosures*

374 Although we used 22-year old herbivore exclosures, our data cannot answer whether duration of
375 herbivore grazing impacts ITV, as we only collected data for one year. To our knowledge, no
376 studies have compared the effects of short- and long-term grazing on ITV. Didiano et al. (2014)
377 found that tolerance to rabbit grazing decreased as the age of the exclosures increased in *F.*
378 *rubra*, the most abundant plant in Silwood Park, England. Therefore, grazing duration may also
379 impact ITV.

380

381 **Conclusion**

382 Our results yield substantial insight into (1) small herbivores may not only impact means but also
383 ITV in some key functional traits of a dominant grass (*E.atherica*); (2) small herbivores
384 impacted ITV mainly through plasticity induced by selective grazing but not through altering

385 genotypic richness/diversity and abiotic variations. However, topographic variation and variation
386 in clay thickness may contribute to ITV. Small herbivore populations are changing rapidly due to
387 human actions. For instance, populations of European brown hares have declined dramatically
388 due to land-use changes (Smith, Jennings & Harris, 2005), while populations of geese are rapidly
389 increasing globally (Menu, Gauthier & Reed, 2002). These changes in small herbivore
390 populations could thus impact their effects on ITV, which may have consequences for saltmarsh
391 plants to respond to global changes.

Figure 1

Sampling location and scheme

Location for the 22-year exclosures at the early and intermediate successional stage in the saltmarsh of the island of Schiermonnikoog. Pictures of the exclosures at the early and intermediate successional stages are shown. Sampling plots (1× 1 m) within an exclosure and sampling scheme for individuals of *Elytrigia atherica* within a 1× 1 m plot are shown. We followed the same sampling scheme for each plot. *Elytrigia atherica* did not always occur within each grid, thus sample size varied for each plot. Sampling plots and scheme were similar outside the exclosures (in the grazed area) at both successional stages. Number of hares and geese indicate the abundance of small herbivores such that the early successional stage had higher grazing pressure (indicated by two hares and two geese) relative to the intermediate stage (indicated by one hare and one goose). Note, only the map of the saltmarsh, but not exclosures and sampling plots, is projected according to its actual size

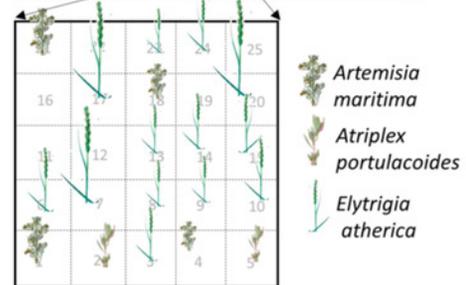

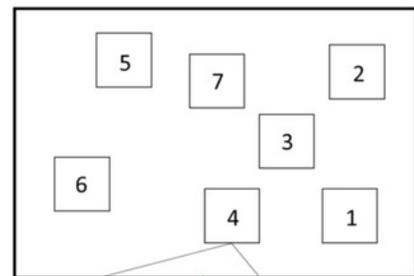

Figure 2

Means and variations in functional traits of individual stems of *Elytrigia atherica* in the grazed and ungrazed plots at the early and intermediate stages.

Traits include height (cm), aboveground biomass (g), flower frequency, and specific leaf area ($\text{cm}^2 \text{g}^{-1}$), leaf dry matter content (g g^{-1}). Dots are the means, error bars show 1 se. Asterisks indicate significant levels: * $P < 0.1$; ** $P < 0.05$; *** $P < 0.001$. See Table S3 for test statistics.

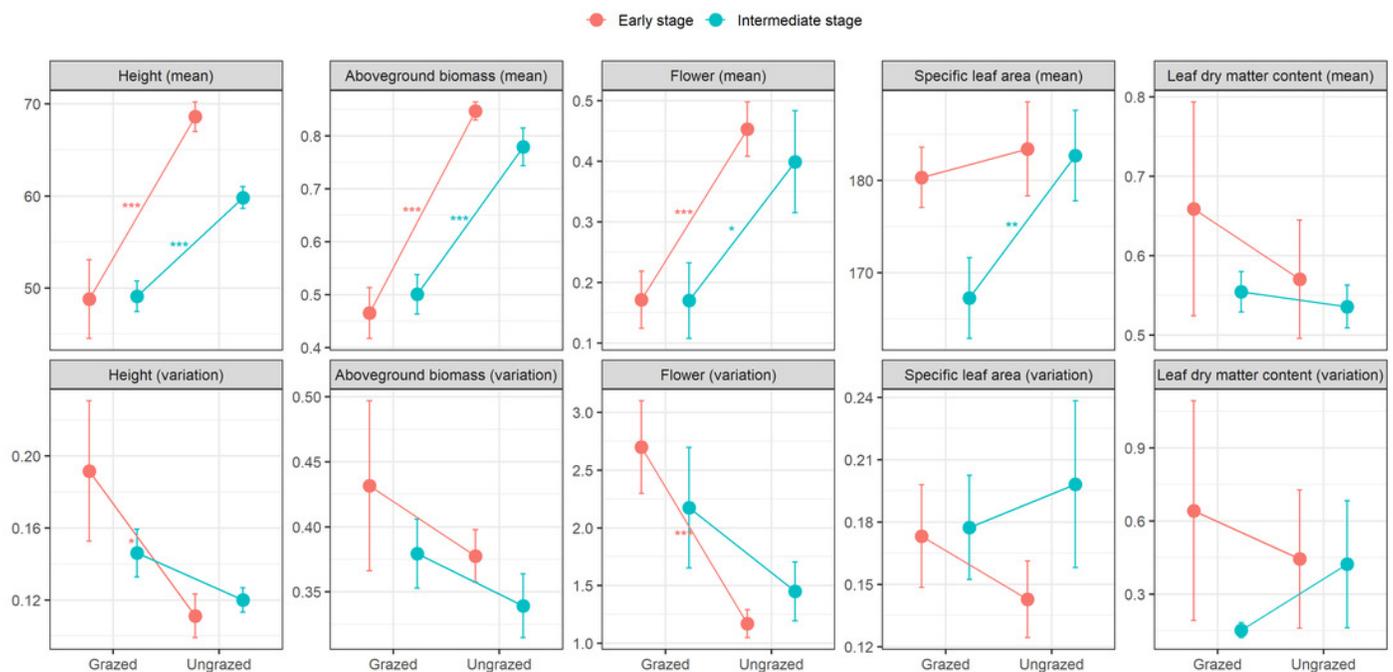

Figure 3

Intraspecific trait variation (ITV) of the dominant grass *Elytrigia atherica* and the direct and indirect effects of small herbivores on ITV in local communities at the early (A-D) and intermediate stage (E-G).

The direct effects, indirect effects through genotypes, indirect effects through abiotic variations, and total effects of small herbivores on ITV in each trait are summarized in Table

1. Model fit the data well (for all models at the early successional stage: $\chi^2 = 4.409$, $df=3$, $N=14$, $p>0.05$; for all models at the intermediate stage: $\chi^2 = 6.559$, $df=6$, $N=14$, $p>0.05$). Variance explained for clay thickness (variation), topographic variation, and genotypic richness for models at the early successional stage are 0.024, 0.008, and 0.056, respectively. Variance explained for clay thickness (variation), topographic variation, genotypic richness, and genotype diversity for models at the intermediate successional stage are 0.079, 0.045, 0.016, and 0.289, respectively. Number of hares and geese indicate the abundance of small herbivores such that the early successional stage had higher grazing pressure (indicated by two hares and two geese) relative to the intermediate stage (indicated by one hare and one goose). Boxes are measured variables. Arrows denote unidirectional relationships among variables. Blue arrows are significant positive relationships, red arrows are significant negative relationships, and grey arrows show non-significant relationships. The width of the arrows indicates the strength of the pathways. The values on the arrows denote standardized path coefficients. Asterisks indicate significant paths: * $P<0.1$; ** $P<0.05$; *** $P<0.001$.

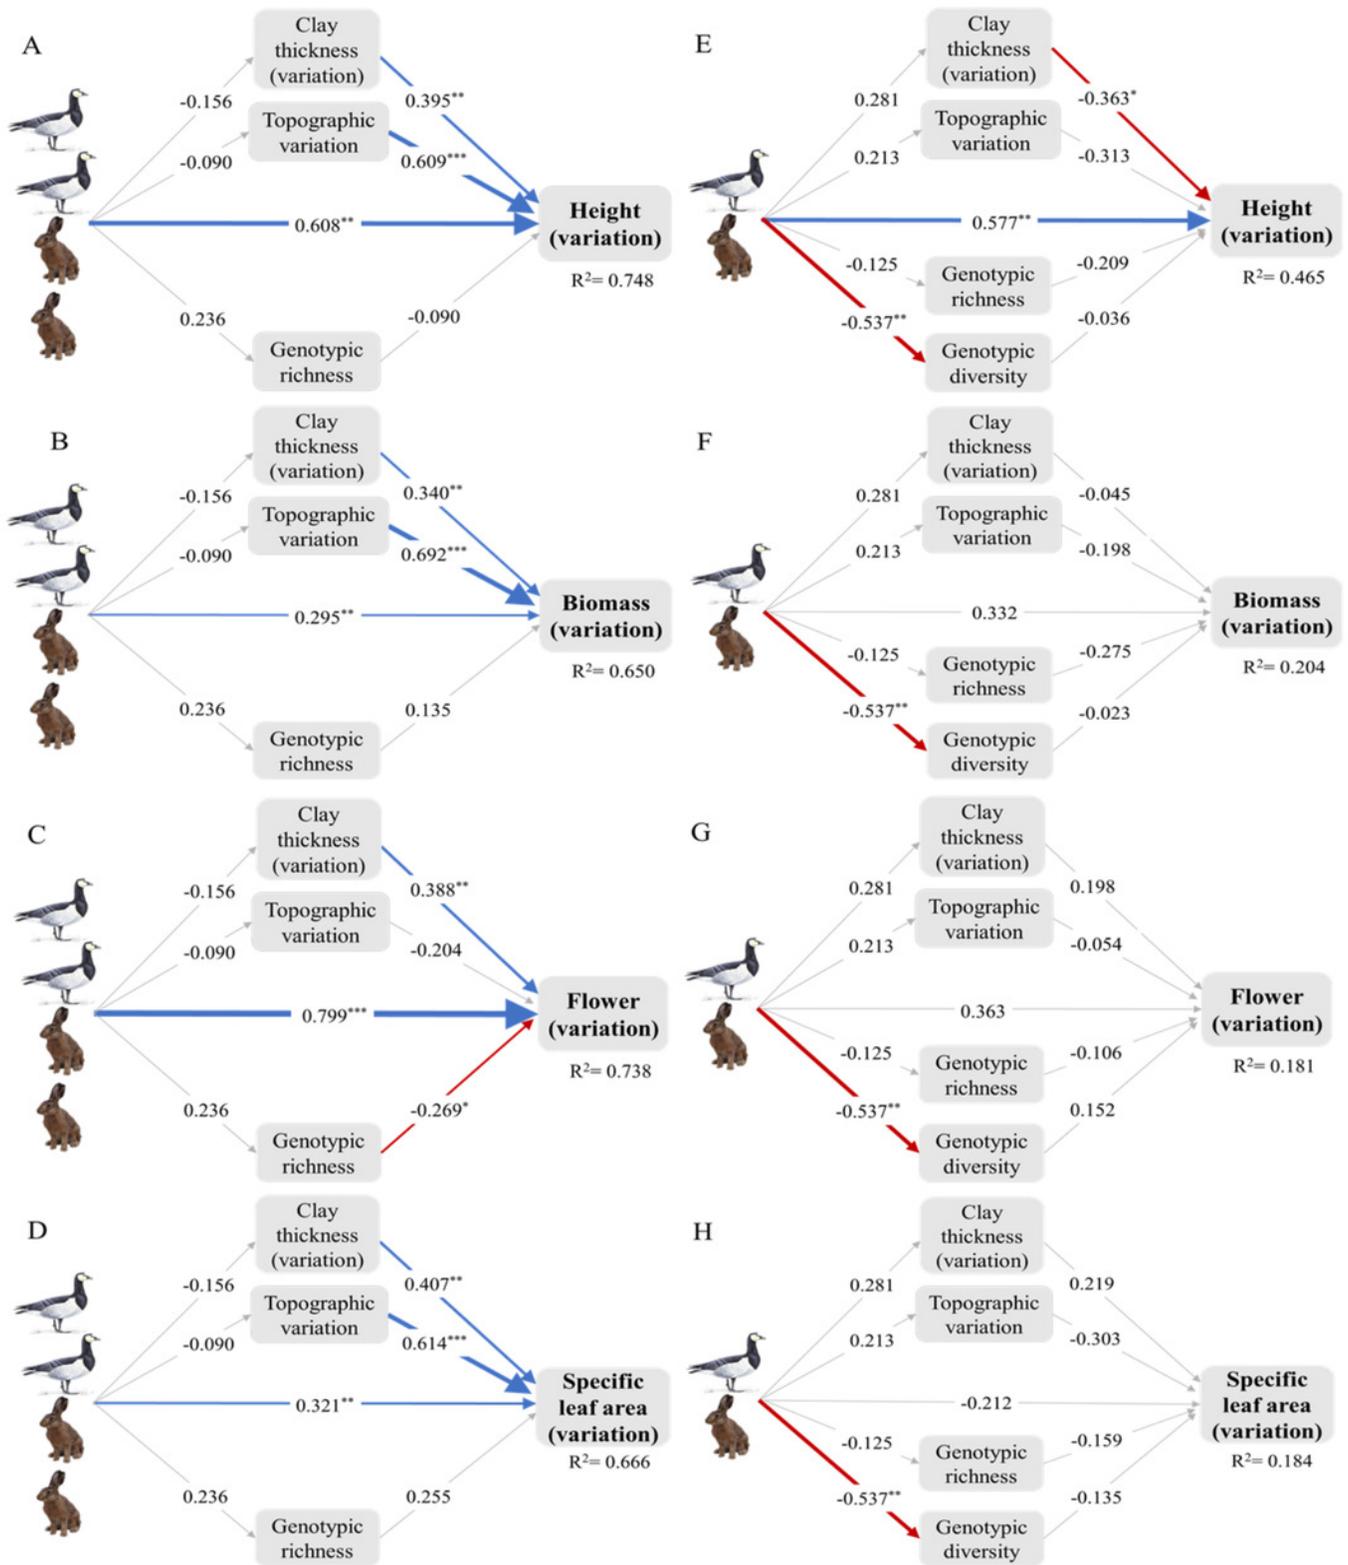

Table 1 (on next page)

Direct and indirect effects of hares and geese on intraspecific trait variation (ITV) of *Elytrigia atherica* at the early and intermediate successional stages.

See online supporting text for an example of how these data were calculated and how significance was determined using lavaan SEM. Asterisks indicate significant effects: * $P < 0.1$; ** $P < 0.05$; *** $P < 0.001$.
