Migratory birds are threatened by habitat loss and degradation, illegal killings, ineffective conservation policies, knowledge gaps and climate change. These threats are particularly troubling in the Procellariiformes (Aves), one of the most endangered bird groups. For “storm-petrels”, their cryptic breeding behavior, asynchrony between populations, and light pollution pose additional threats that contribute to increased mortality. Markham’s Storm-Petrel (*Hydrobates markhami*), a poorly known migratory species, is a pelagic bird that breeds in dispersed colonies in the Sechura and Atacama Deserts, with asynchronous reproduction between colonies, and is highly affected by artificial lights. Considering its complex conservation scenario and singular breeding, we expected to find narrow habitat distribution conditions, strong geographic genetic structure, and spatially differentiation related to human population activities (e.g. light pollution) and the climate global change. To evaluate these predictions, we analyzed the phylogeography, current and future potential distribution based on mitochondrial gene ND1 and geographic records. The phylogeographic analyses revealed three well-supported clades (i.e. Paracas, Arica, and Salar Grande), and the geographical distribution modeled using an intrinsic conditional model (iCAR) suggests a positive relationship with the mean temperature of the wettest quarter and of the driest quarter, solar radiation, and anthropogenic disturbance. The future predictions under moderate and severe scenarios of global change indicated a drastic distribution area reduction, especially in the southern zone around Tarapacá and Antofagasta in Chile. These suggest a potential loss of unique genetic diversity and the need for conservation actions particularly focused at the edges of the *H. markhami*

distribution.

Living on the edge: genetic structure and geographic distribution in the threatened Markham's Storm-Petrel (*Hydrobates markhami*)

ABSTRACT

Migratory birds are threatened by habitat loss and degradation, illegal killings, ineffective conservation policies, knowledge gaps and climate change. These threats are particularly troubling in the Procellariiformes (Aves), one of the most endangered bird groups. For “storm-petrels” in particular, their cryptic breeding behavior, asynchrony between populations, and light pollution pose additional threats that contribute to increased mortality. Markham’s Storm-Petrel (*Hydrobates markhami*), a poorly known migratory species, is a pelagic bird that breeds in dispersed colonies in the Sechura and Atacama Deserts, with asynchronous reproduction between colonies, and is highly affected by artificial lights. Considering its complex conservation scenario and singular breeding, we expected to find narrow habitat distribution conditions, strong geographic genetic structure, and spatially differentiation related to human population activities (e.g. light pollution) and the climate global change. To evaluate these predictions, we analyzed the phylogeography, current and future potential distribution based on mitochondrial gene ND1 and geographic records. The phylogeographic analyses revealed three well-supported clades (i.e. Paracas, Arica, and Salar Grande), and the geographical distribution modeled using an intrinsic conditional model (iCAR) suggests a positive relationship with the mean temperature of the wettest quarter and of the driest quarter, solar radiation, and anthropogenic disturbance. The future predictions under moderate and severe scenarios of global change indicated a drastic distribution area reduction, especially in the southern zone around Tarapacá and Antofagasta in Chile. These suggest a potential loss of unique genetic diversity and the need for conservation actions particularly focused at the edges of the *H. markhami* distribution.

INTRODUCTION

Seabird populations are threatened by the loss and degradation of breeding and non-breeding habitats, illegal killings, and climate change (Bairlein, 2016; Studds et al., 2017; Wilson et al., 2018; Xu et al., 2019), which have induces steep declines in abundance and distribution at broad scales. This problem is only exacerbated by inefficient conservation policies that do not consider the conservation of breeding sites during the development of investment projects (Syroechkovskiy 2006; de Boer et al., 2011), and major knowledge gaps in many species' basic biology, especially in poor countries and for small-bodied species (Rodriguez et al., 2019). This is particularly troubling on one of the most endangered avian groups, the Procellariiformes (Class Aves) (Croxall et al., 2012), which are disproportionately threatened compared to Aves overall (Rodriguez et al., 2019). For the “storm-petrels” this is not only because of its small size, but also because of its cryptic breeding behavior (i.e., nocturnal colony visits, underground nesting, remote and inaccessible reproduction areas), high mobility that in some cases, prevent their study, management, and conservation (Brooke, 2018), and broad distribution that puts them under different regulations of many national and international jurisdictions and boundaries (Harrison et al., 2018). All these characteristics contribute to a high vulnerability of breeding storm-petrels to anthropogenic disturbances. Additionally, one of the main threats at storm-petrel breeding habitat are light pollution (e.g. Rodríguez et al., 2017). Especially for species with small, restricted breeding grounds near human populations, where light pollution induces high mortality of fledglings (e.g. Gineste et al., 2016).

The Markham's Storm-Petrel (*Hydrobates markhami*) is one of the least known migratory seabirds in the world (Croxall et al., 2012; BirdLife International 2019). However, artificial light from large cities near breeding areas are known to cause mortality from collision

impacts and indirectly from predation by vultures on grounded individuals (Barros et al., 2019). This small pelagic species (21-23 cm) is found mainly in tropical waters of the Pacific Ocean, between 5°N and 29.9°S, and 71°W and 118.02°W (Murphy, 1936; Spear and Ainley, 2007; Howell and Zufelt, 2019). *Hydrobates markhami* is a colonial breeder, with five known dispersed colonies in the Sechura and Atacama Deserts, specifically in saline areas (i.e. salt flats) where they use fissures and cavities found under the surface on the salt flats for nesting, displaying strong philopatry to their natal colonies and nesting sites (Jahncke 1993, 1994, Torres-Mura and Lemus 2013, Schmitt et al. 2015, Barros et al. 2019). The northernmost colony is in Paracas, Peru, where the species breeds in small, dispersed colonies up to 5 km from the sea on the sloping ground (Jahncke, 1993, 1994). The other four colonies are in Chile, located in the Coastal Atacama Desert at up to 50 km inland (Fig. 1; Barros et al., 2019; Medrano et al., 2019). In Chile, the known colonies are (1) Arica, (2) Pampa de la Perdiz, (3) Salar Grande and (4) Salar Navidad (Medrano et al., 2019). Reproduction is asynchronous between colonies (Barros et al., 2019; Medrano et al., 2019). In the northern colonies in Paracas and Arica, most pairs lay eggs between April and August, and chicks hatch asynchronously from July to January with a peak between July and September (Jahncke, 1994; Barros et al., 2019; Medrano et al., 2019). While in the colonies of Pampa Perdiz, Salar Grande and Salar Navidad breeding pairs lay eggs between November and January, and chicks hatch between January and April (Barros et al., 2019; Medrano et al., 2019). The species population size is estimated at 2,305–4,362 breeding pairs in Peru (Jahncke, 1993, 1994) and 55,308–55,733 breeding pairs in Chile (Barros et al., 2019; Medrano et al., 2019). IUCN consider *H. markhami* as Near Threatened (NT; BirdLife International, 2019), but under Chilean classification, this species is categorized as Endangered

(EN) due to decreasing population size and extended threats over the breeding colonies (Barros et al., 2019; Medrano et al., 2019).

Currently, the genetic data and species distribution modeling could provide important insights for conservation management of *H. markhami*, by examining the relationship between the environment and the species distribution (Humpries et al., 2012; Field et al., 2020).

Additionally, it is important to include future scenarios in these combined analyses, given that for many threatened species it has been suggested that their distribution under climate change scenarios will experience important changes, due to translocation of habitat optima (Pech et al., 2017; Beaumont et al., 2019; Field et al., 2020) or drastic reductions in habitat suitability (Cianfrani et al., 2018; Borges et al., 2019). Considering its complex conservation scenario and the singular breeding habitat geography between colonies and the strong philopatry in *H.*

markhami (i.e. reproductive isolation and low migration) we expected to find narrow habitat distribution conditions, strong genetic geographic structure, and spatially differentiation related to human population activities (e.g. light pollution) and the climate global change. Under the climate change context, species with unique life history traits are expected to experience more changes in their distribution, which could even lead to loss of genetic diversity (Loarie et al., 2009; Pech et al., 2017). The aims of this study were to: (1) evaluate the phylogeographic structure and genetic diversity distribution across most of *H. markhami* distributional breeding range; (2) evaluate the effect of climatic variables and anthropogenic impact proxies on the *H. markhami* geographic distribution using ecological niche modeling in a Bayesian framework; (3) quantitatively assess the vulnerability to climate change under two representative concentration paths (RCP) of greenhouse gas emissions, which correspond to future climate condition trajectories; and (4) evaluate the effect of migration capacity on the spatial distribution models.

MATERIALS AND METHODS

Phylogenetic analysis

Between November 12, 2018 and December 01, 2019, we collected blood samples from seven specimens of *H. markhami* from Pampa Chaca, Arica (18°70'S, 70°24'W) and 9 specimens from Salar Grande (21°01'55''S, 69°59'13''W) under permits from Servicio Agrícola Ganadero, SAG, of Chilean government (N°5022/2014 and 5742/2016). DNA was extracted from frozen samples following the protocol of Fetzner (1999) using the QIAGEN DNAeasy kit. We amplified the mitochondrial gene NADH dehydrogenase subunit I (ND1), via polymerase chain reaction (PCR). PCR was performed in a total volume of 25 µL containing 12.5 µL Thermo Scientific PCR Master Mix (0.05 U/µL Taq DNA polymerase, reaction buffer, 4 mM MgCl₂, 0.4 mM of each dNTP), 0.2 µM of each primer and 20 ng of template DNA. Amplification was performed using the forward TMET-forward: 5'ACC-AAC-ATT-TTC-GGG-GTA-TGG-G 3' and the reverse primer 16DR-reverse: 5'CTA-CGT-GAT-CTG-AGTT-CAG-ACC-GGA-G 3' (Leaché and Reeder, 2002). The following thermal cycler settings were used to amplify all reactions: 5 min at 94°C followed by 35 cycles of 94°C for 30 s, 55°C for 30 s, and 72°C for 30 s, followed by a final extension of 72°C for 5 min (Sausner et al., 2007). PCR products were sequenced in both directions through automatic sequencing using Macrogen's ABI3730XL (Seoul, South Korea). Sequences were edited using Codon Code Aligner v. 3.0.3 (CodonCode Corporation, www.codoncode.com), and translated into amino acids to corroborate the absence of stop codons. We got a total of eight sequences with high quality for the analysis (MZ768852 to MZ768859; Table S1). Moreover, five ND1 sequences from Paracas breeding site in Cerro Lechuza, Peru (13°8'S, 76°8'W), and one sequence from Chaca in Arica, Chile (18°S, 70°W)

were obtained from Sausner et al., (2017) in GenBank (Table S1). In order to avoid obtaining spurious outcomes resulting from the lost phylogenetic information due to substitution saturation, we tested whether the sequences used were useful for the phylogenetic analysis through Xia's test (Xia et al., 2003) implemented in DAMBE v7 (Xia, 2018). Xia's test is an entropy-based index that estimates a substitution saturation index (Iss) in relation to a critical substitution saturation index (Iss.c), by using a randomization process with confidence intervals (95%). The proportion of invariable sites for this analysis was determined in jModeltest 2 (Darriba et al., 2012). The sequences of *H. markhami* are available in GenBank according to the accession numbers provided in Table S1. As outgroups in the phylogenetic analyses, we used: *H. melania*, *H. microsoma*, *H. tethys*, *H. hornbyi*, *H. leucorhoa* and *H. homochroa*; representatives of Oceanitidae *Oceanites gracilis* and *Fregetta grallaria*; Diomedidae *Thalassarche chrysostoma*, *Thalassarche melanophrys* and *Phoebastria nigripes*; and Procellariidae *Aphrodroma brevirostris* (Table S1.).

Data were analyzed as previously described in Norambuena et al., (2018), we used both Bayesian inference (BI) and maximum likelihood (ML) approaches for phylogenetic reconstruction. We conducted Bayesian analyses using BEAST v. 1.10.4 program (Drummond et al., 2012), using 'Yule speciation process' for the tree prior to consider the effect of divergent sequences on outgroups (Drummond et al., 2012). We identified the best-fit nucleotide substitution model using jModeltest 2 (Darriba et al., 2012), which indicated HKY+ Γ as the best-fit model for ND1 using BIC and AICc criterion. We ran all analyses for 100 million generations, and we sampled every 1,000 steps; the first 25% of the data was discarded as burn-in. The convergence of MCMC analysis was examined visually in Tracer v1.6 (Rambaut and Drummond, 2009).

ML analyses were conducted in RAxML v8 (Stamatakis, 2014) using the multiple inference strategy. We ran 1,000 independent inferences and 1,000 bootstrap replicates with the same nucleotide substitution model settings as for the Bayesian analysis. Support values from 1,000 bootstrap replicates were annotated on the tree with the highest likelihood. .

We also inferred a haplotype network as previously described in Norambuena et al., (2018) by using the “median joining network” algorithm in Network 4.610 (Bandelt et al., 1999), which is based on the sum of weighted differences (i.e. Hamming distance) between sequences. Ambiguities within the network were solved according to the criteria of Crandall and Templeton (1993). Finally, for each geographic area (i.e. Paracas, Arica and Salar Grande) retrieved by phylogenetic analysis, we calculated in DnaSP v.5 (Librado and Rozas, 2009) the number of polymorphic sites (S), haplotype diversity (H) and nucleotide diversity (π).

Occurrence data and climate variables

Hydrobates markhami occurrence data were obtained during 12 expeditions (see Barros et al., 2019 for details), literature from the Peruvian colonies (e.g. Jahncke 1993, 1994; Torres-Mura and Lemus, 2013), and electronic databases (eBird, 2020). We obtained a total of 972 georeferenced records that were later reduced to 75 data cleaning (Supplemental Data S1). All the final records correspond to confirmed and potential nests on breeding sites (Jahncke 1993, 1994; Barros et al., 2019). To reduce spatial autocorrelation that usually results from sampling areas with a high density of locality points (clusters of points), we spatially filtered locality data to allow a minimum distance of 1 kilometer between any two points.

The climatic variables were obtained from Wordclim version 2.1 with 2.5 minutes spatial resolution (Fick and Hijmans, 2017). Additionally, we obtained environmental variables such as

ultraviolet radiation (Beckmann et al., 2014), elevation, wind (Fick and Hijmans, 2017) and topographic roughness (Amatulli et al., 2018). As anthropogenic impact proxies, we used the databases of Human footprint (Venter et al., 2016), artificial lights (Falchi et al., 2016) and human population (CIESIN, 2016). We selected the variables that were used in the models through an exploratory analysis which resulted in strongly correlated variables to be eliminated. We used the variance inflation factor (VIF) to evaluate the collinearity among predictors, where VIF greater than 10 is a signal that the model has collinearity problems (Quinn and Keough, 2002). Our analyzes showed that four variables have a VIF <3 and four variables have a VIF between 4 and 9, which are below the threshold (VIF <10) (See Fig. S1 and Table S2). Finally, eight uncorrelated variables were used to perform the species distribution models (SDMs): Min Temperature of Coldest Month, Temperature Annual Range, Mean Temperature of Wettest Quarter, Mean Temperature of Driest Quarter, Human footprint, artificial lights, solar radiation, and wind (see Table S2).

Species distribution modelling (SDM)

The geographical distribution of *H. markhami* was modeled using an intrinsic conditional model (iCAR). We assume that the response variable Z_i is a binary variable that represents the presence (1) or absence (0) of *H. markhami*. This approach explicitly considers spatial autocorrelation (Latimer et al., 2006) to adjust an ecological process where the presence/absence of the species is explained by the suitability of the habitat (Vieilledent et al., 2014), where:

$$Z_i \sim \text{Bernoulli}(\pi_i)$$

$$\text{logit}(\pi_i) = X_i\beta + \rho_j(i)$$

X_i = matrix of covariates, β = vector of the regression coefficients, ρ represents the random spatial effect of the observation i in cell j , and the logit link is used to model the relationship between π_i , the covariates and spatial effect. Models were built using the package “hSDM” (Vieilledent, 2019) in the software R (Core Team 2019). Uninformative priors centered at zero with a fixed large variance of 100 were used for all parameters involved in both ecological and observation processes, while a uniform distribution was used for the variance of the spatial effects (Pennino et al., 2017). We chose the model which had the lowest Deviance Information Criterion (DIC) (Spiegelhalter et al., 2002), where lower values of DIC represent the best compromise between fit and estimated number of parameters.

Geographical projection to the future scenarios

To model the geographic distribution into the future, we selected two representative concentration paths (RCP) of greenhouse gases, which correspond to future climate conditions trajectories of greenhouse gases adopted by the IPCC (Stocker et al., 2013). RCPs span the range of the year 2100 radiative forcing, i.e. from 2.6 to 8.5 W/m² (van Vuuren et al., 2011). An RCP 2.6 was selected as the scenario for an extremely low forcing level and 8.5 as an extremely high baseline emission scenario. Three global climate models (GCMs); CCCMA, CSIRO and MIROC were evaluated for the year and 2080. The climatic projections were obtained from the portal <http://www.ccafs-climate.org/> (Navarro et al., 2020). We explored 32 GCMs projections through the GCM compareR application (Fajardo et al. 2020). CCMA, CSIRO represent models where low precipitation and high temperature are represented, while MIROC is a more conservative model and closest to the study area’s average (e.g., Alarcón & Cavieres, 2015; Lazo-Cancino et al., 2020). In the future projections of the SDMs, we only use the variables min temperature of

the coldest month, temperature annual range, mean temperature of the wettest quarter, and mean temperature of the driest quarter. The variables for Human footprint, artificial lights, radiation and wind were not included since there are no future predictions for these variables.

To quantify geographic distribution changes under future climate change scenarios, we compared the current model with future projected models. Each model was converted from a continuous output to a binary classification (presence/absence) using the threshold that maximizes the sum of sensitivity and specificity (max SSS) (Liu et al., 2013). Then the areas gained, lost, no occupancy, and no change in the future were estimated. We calculated the estimated areas in square kilometers using the South American Albers Equal Area Conic projection. We used SDMtoolbox module (Brown, 2014) implemented in ArcGIS 10.4.1 (ESRI, 2015) to calculate the areas of expansion range, contraction range, and the distribution without change between present and future models.

Migration constraints

Since the SDMs are static in nature and do not consider the species dispersal ability, biotic interactions, or population dynamics (Zurell et al., 2009, 2016; Engler et al., 2012), these do not allow predicting the effect of climate change on the distribution of species in a realistic way. Therefore, in our models, we consider limitations to the dispersion of *H. markhami* in the projections, through the “Migclim” approximation (Engler et al., 2009; Engler et al., 2012). This method explicitly includes the dispersal of a species, potential propagule production, geographic barriers, short-distance dispersal capacity (SDD) and probability for long-distance dispersal (LDD) (Engler et al., 2012). We performed the analyzes using the habitat suitability models predicted by iCAR for the years 2030, 2050 and 2080. Because not all the parameters required

by the algorithm are known, we opted to consider a model with barriers to dispersion, using three thresholds (300, 500 and 700), where habitat suitability scales from 0 to 1000, and the values below the threshold are considered absences and above the threshold they are considered presences. These thresholds allow the classification of suitable or unsuitable habitat, where cells with habitat suitability \geq threshold are considered as suitable, values $<$ threshold unsuitable. We do not consider long-distance dispersion since *H. markhami* is highly philopatric (see results). To set the spatial barriers for future dispersion we consider the Human Footprint as a “strong” barrier, given the sensitivity of this species to human activity. The analyzes were performed for the three global climate models (GCMs); CCCMA, CSIRO and MIROC. We compare the results of each Migclim run selecting the best and worst simulated scenario, as follow: for the best scenario, we consider one with the highest number of occupied cells, the smallest number of absent cells at the end of the dispersion process, and the largest number of cells that could be used in the case of "unlimited dispersal" and "non-dispersal"; and the opposite conditions was considered as the worst scenario. The analyzes were performed in the MigClim 1.6 package (Engler et al., 2013). All simulations for each GCMs and RCP are detailed in Table S3.

RESULTS

Genetic population structure

Sequences of 955 bp in length for the ND1 locus were obtained and the result of Xia’s test suggests low saturation, as the critical index of substitution saturation value (Iss.c = 0.819) were significantly higher than the observed index of substitution saturation values (Iss = 0.514; $p < 0.0001$), therefore, the sequences were deemed suitable for performing phylogenetic analyses. Four haplotypes were identified defined by 17 polymorphic sites. The ML and BI trees based on

ND1 sequences showed identical topologies (Fig. 1A). Both trees inferred that the *H. markhami* is monophyletic and composed of three well-supported clades (posterior probability pp of 0.9-1.0 and ML bootstrap support of 100). The three clades are geographically structured, with one clade represented by Paracas individuals, the other by Arica, and the third by Salar Grande individuals (Fig. 1A). The only geographic incongruence was in the Paracas clade where a sample from Arica was the sister of all the Paracas individuals that are monophyletic with a 0.9 of pp (Fig. 1A).

The ND1 haplotype network revealed the same three major clades recovered from the BI and ML phylogenies (Fig. 1B). Overall haplotype diversity for the ND1 gene was 0.747 ± 0.004 and overall nucleotide diversity was 0.028. The clade of Paracas had the highest haplotype diversity and the clade of Arica had the highest nucleotide diversity, while the clade of Salar Grande had the lowest values and was represented by one exclusive haplotype.

Present and future geographic distribution

The *H. markhami* distribution was mainly driven by min temperature of the coldest month (Bio 6), temperature annual range (Bio 7), mean temperature of the wettest quarter (Bio 8), mean temperature of the driest quarter (Bio 9), Human footprint (HFP), and radiation (Table 1). Positive relationships were found between Bio 8, Bio 9, HFP, radiation and the occurrence of *H. markhami*, and negative relationship with the variables Bio 6 and Bio 7 (Table 1, Fig. S1). The highest median posterior probability of the presence of *H. markhami* occurs around the region of Paracas (Peru), and in a continuous area from the southern coast of Arequipa region in Peru to Antofagasta region in Chile (Fig. 2A). The spatial effect, that is, a model without considering the environmental predictors, showed to be strong for almost the entire modeled distribution range of

the species (Fig. 2B). By 2080, the distribution predicted considering less severe scenarios (i.e., RCP 2.6) and severe (RCP 8.5) showed that expansion areas geographic range were greater than the areas of contraction geographic range (Fig. 3 and Fig. 4) (See Table S3 and Fig. S2). The MIROC model (RCP 2.6) was the only case where there would be a greater contraction of the geographic range predicted in the future (Table S3). In all models and Representative Concentration Pathway, a high no-occupancy geographic area is predicted, that is, areas currently not occupied by the species and that are not expected to be occupied in the future. Similarly, a significant area of no-change is predicted, that is, areas currently occupied by the species and expected to remain occupied in the future (See Table S3 and Figs. S2-5).

The habitat changes predicted by the simulations indicate two highly contrasting simulations (Table 2). The first one indicating a low impact on the distribution of the species in a future scenario for the GCMs model MIROC (RCP 2.6) with a high number of pixels that would be colonized at the beginning and end of the simulation, though, there are also numerous areas to the south of their known distribution that would not be colonized (pink pixels) (Fig. 5A, Table 2); The second, being the worst case scenario for *H. markhami* (Fig. 5B, Table 2), where the CCMA model (RCP 8.5) indicated a low number of occupied and colonized pixels at the end of the simulation, reducing the number of areas that are suitable in the present and that would also be suitable in the future (red pixels). The remaining simulations by GCMs and RCP support previous results and are shown in Figs. S2-4 of the supplementary materials.

Discussion

Genetic population structure

The phylogeny and haplotype network supported three main lineages within *H. markhami*, showing a clear geographic structure associated to breeding areas in Paracas, Arica and Salar Grande. The shared haplotype between Paracas and Arica suggests some degree of connectivity between both areas (gene flow), however, we cannot discard that could be due to incomplete lineage sorting. This result is coherent with the fact that the northern colonies (Paracas and Arica) share breeding phenology, with most pairs laying eggs between April and August, and chicks hatching from July to January (Jahnke, 1994; Barros et al., 2019; Medrano et al., 2019). On the other hand, the differentiated haplotype from Salar Grande shares breeding phenology with Pampa Perdiz and Salar Navidad, with pairs laying eggs between November and January, and chicks hatching between January and April (Barros et al., 2019; Medrano et al., 2019). This fact supports the importance of breeding phenologies as a key factor in explaining microevolutionary processes in the *Hydrobates* genus. For example, for the *H. castro* species complex, the occurrence of two different phenologies (hot and cold season) has been described as a relevant mechanism for sympatric speciation (Monteiro and Furnes, 1998; Friesen et al., 2007). This strong degree of geographic structure has been documented previously in Peruvian diving-petrel and two Patagonian shag species that breed in colonies along the coasts of Peru, Chile and Argentina (Calderón et al., 2014; Cristofari et al., 2019). However, to test the relevance of the gene flow hypothesis requires additional samples improve our preliminary result about geographic structured pattern and active dispersion between Paracas and Arica.

The biological association between breeding phenologies in *H. markhami* and saline areas produce strong philopatry to their natal colonies and nesting sites (Jahncke, 1993, 1994; Torres-Mura and Lemus, 2013; Schmitt et al., 2015; Barros et al., 2019). A large number of studies have now documented that all *Hydrobates* species of South America use salt flats/saltpetre deposits in

the coastal deserts of Sechura and Atacama to nest (Jahncke 1993, 1994; Bernal et al., 2006; Ayala et al., 2007; Torres-Mura and Lemus, 2013; Barros et al., 2019; Medrano et al., 2019), and even some *Oceanites* storm-petrels (Oceanitidae family) have been found using the same areas for nesting (Barros et al., 2020).

Geographic distribution

Under conservative and more severe climate change scenarios, our models suggest moderate reductions and strong reduction of the distribution of *H. markhami*, respectively, which agree with the idea that species with specialist reproductive habitat (e.g. breeding phenology associated with saline areas) are especially sensitive to the effects of rapid climate-change (Loarie et al., 2009), because of the constraints imposed by this specific requirement for breeding sites (i.e. niche conservatism). To date, after multiple expeditions searching for breeding sites, they have only found *H. markhami* breeding in this specific environment (Barros et al. 2019, Medrano et al. 2020). But considering that some petrels are able to use cavities in other substrates, such as soft soil and man-made burrows (Podolsky & Kress 1989, Bolton et al. 2004), we do not rule out the capability of nest substrate plasticity.

The most impacted area of *H. markhami* distribution will be its current southern edge between the Tarapacá and Antofagasta regions in Chile. Moreover, this is also the most affected area by light contamination (see Barros et al., 2019), considering that 11.41% (2.269 MW) of the electrical power of Chile is generated in this area and large cities dependent on mining-related economy (e.g. Iquique and Antofagasta) continue to grow. The future reduction in the distribution of *H. markhami* may be even more severe than suggested by our models, given that we were not able to include a prediction of human footprint in the models.

According to our results, the predicted future habitat range of *H. markhami* is likely to be negatively affected by future climate change and will concentrate on the central portion of its present distribution (i.e. around the Arica area). The first response of species to climate change under GCMs MIROC RCP 2.6 scenario would be the colonization of areas around present distribution, but under CCMA model (RCP 8.5) this colonization considerably decreased. In both scenarios the southern distribution would not be colonized and suitable in the future (MigClim simulation, Fig. 5). The MigClim simulations also suggest the loss of some areas in Southern Peru and in the south of Arica colony. Unlike species with greater mobility or fewer restrictions on reproductive habitat, that shift their distributions moving poleward and to higher elevations (Chen et al., 2011; Pecl et al., 2017), the limited distribution of salt flats/saltpetre deposits (Sáez et al., 2012) -key habitat for *H. markhami* nesting- will affect the responses of this species to climate change. This, added to the small population of *H. markhami* (Barros et al., 2019), would constrain its distribution range change by limiting its colonizing capability, and thus increasing its extinction risk.

Most research on the response of seabird to climate change has been studies considering at-sea distribution (e.g. Wolf et al., 2010; Humpries et al., 2012). However, for seabirds such as *H. markhami*, the individuals at the breeding colonies could be affected by the warming of air temperature, that in severe cases could cause mortality due to overheating and physiological stress (Sydeman et al., 2012). These last conditions, related to an increase of temperature, could be particularly important in the breeding habitat of *H. markhami* in the Sechura and Atacama Deserts. In fact, it is expected that seabird species will respond differentially to climate change according to many different factors, including life history characteristics, diet, range, and abundance (Furness and Tasker, 2000; Sydeman et al., 2012). So, while some seabirds may fare

well in warming oceans, others may become locally, regionally, or perhaps even globally extinct (e.g. Kitaysky and Golubova, 2000; Jenouvrier et al., 2009; Wolf et al., 2010; Lewison et al., 2012).

CONCLUSIONS

Overall, our results of *H. markhami* can be useful for the design of conservation policies, considering that the planning of protected areas and management should be focused on areas with higher or unique genetic diversity (Midgley et al., 2003; Ayebare et al., 2018). In *H. markhami*, the extinction of any local population could mean a loss of unique genetic diversity. The southern portion of the *H. markhami* distribution (Tarapacá and Antofagasta) are the most vulnerable areas according to our results and do not have any type of legal protection today. The only breeding area partially protected is Paracas in Perú (Jahncke, 1993; 1994). This provides a complex conservation scenario for this species, especially considering the future consequences of climate change. Finally, considering the complex conservation scenario, singular breeding habits, its narrow habitat distribution conditions, preliminary evidence of genetic geographic structure, and spatial differentiation related to human population activities (e.g. light pollution and climate global change); we highlight the urgent need for increased cooperation and governance between the Peruvian and Chilean wildlife technical units, and the protection of their breeding sites in the center and south of their distribution, given that the local extinctions occur closer to the border or core range depending on local and regional environmental factors intermingled with human impacts (Cowlshaw et al., 2009; Boakes et al., 2018).

ACKNOWLEDGEMENTS

404 We thank Fernando Medrano for his comments on drafts of the manuscript. We thank the ‘ROC’
 405 volunteers that assisted the research and conservation project of Atacama storm-petrels. We
 406 thank American Bird Conservancy (ABC) (Grant #B2016-04 and #1854A) for funding and
 407 advise for our fieldwork from 2016–2020 and the Mohammed Bin Zayed Fund and the Packard
 408 Foundation, for funding our fieldwork in 2017 through ABC. HVN was funded by FONDECYT-
 409 POSTDOCTORADO 3190618 and CEH by the FONDECYT 1170815 and 1201506 grants. RR
 410 was supported by Millennium Institute of Oceanography (IMO), University of Concepción,
 411 Concepción, Chile. We thank an anonymous reviewer and Marcelo Rivadeneira for revisions to
 412 the manuscript.

Figure 1

Map of the phylogeographic structure of *Hydrobates markhami*

Map of the phylogeographic structure of *Hydrobates markhami* showing: (A) the mtDNA ND1 Bayesian Inference (BI) and Maximum Likelihood (ML) phylogeny and the distribution of the three main clades (Upper node values represent BI posterior probabilities and down nodes values represent ML bootstrap values). (B) Haplotype network and each locality; the scale represents the sample size for each locality. At the bottom is the map with the breeding sites used for the genetics analysis. Out-groups on phylogeny are not shown. Photograph of *H. markhami*: courtesy of Fernando Díaz Segovia.

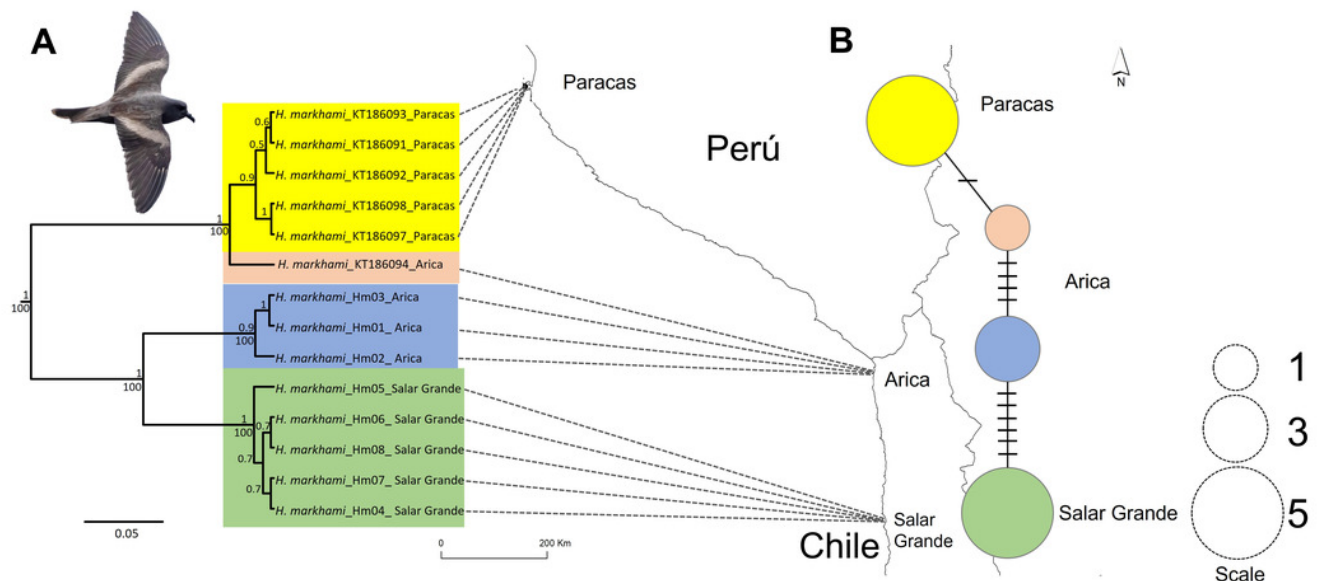

Figure 2

A) Median of the posterior probability of the presence of the *Hydrobates markhami*, B) Spatial effect (the spatial component represents the intrinsic spatial variability of the data without variables).

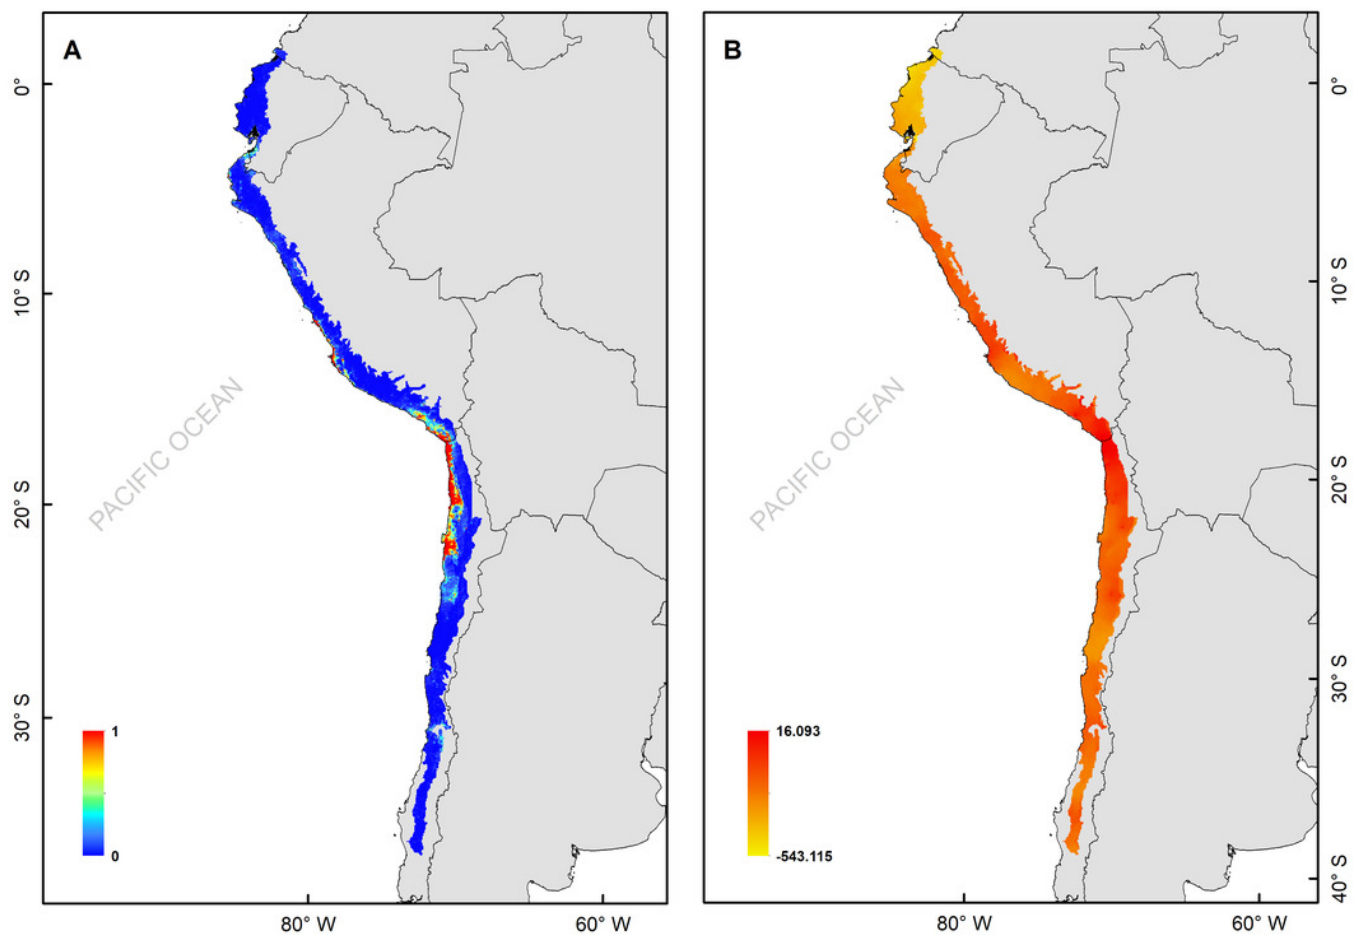

Figure 3

Habitat suitability maps for future climatic conditions predicted for 2080 under a RCP 2.6 (benign scenario).

A) Map of habitat suitability under GCMs CCCMA B) Map of habitat suitability under GCMs CSIRO, and C) Map of habitat suitability under GCMs MIROC.

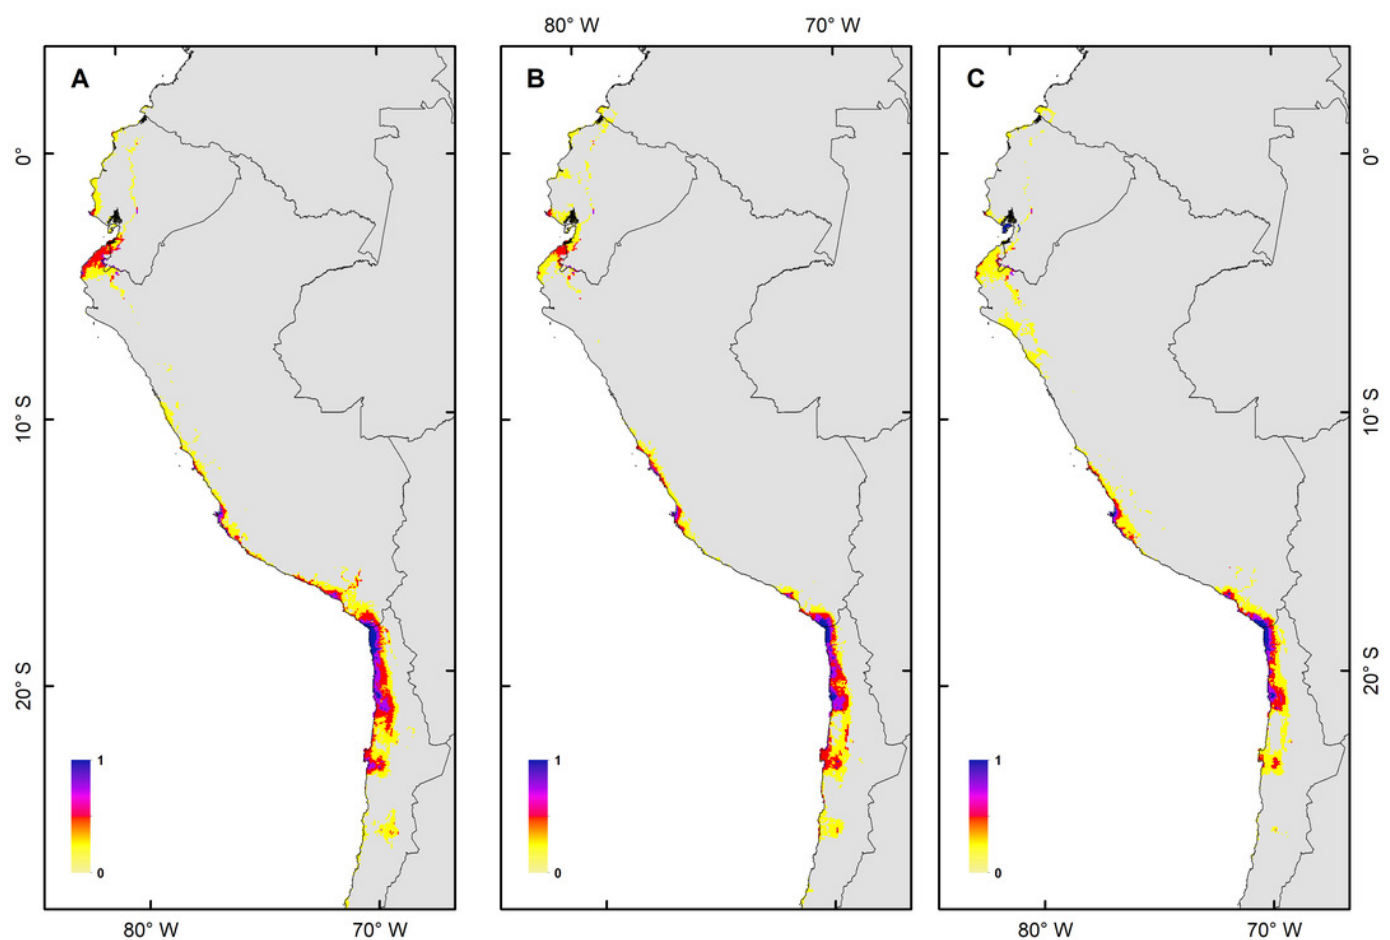

Figure 4

Habitat suitability maps for future climatic conditions predicted for 2080 under a RCP 8.5 (hard stage).

A) Map of habitat suitability under GCMs CCCMA, B) Map of habitat suitability under GCMs CSIRO, and C) Map of habitat suitability under GCMs MIROC.

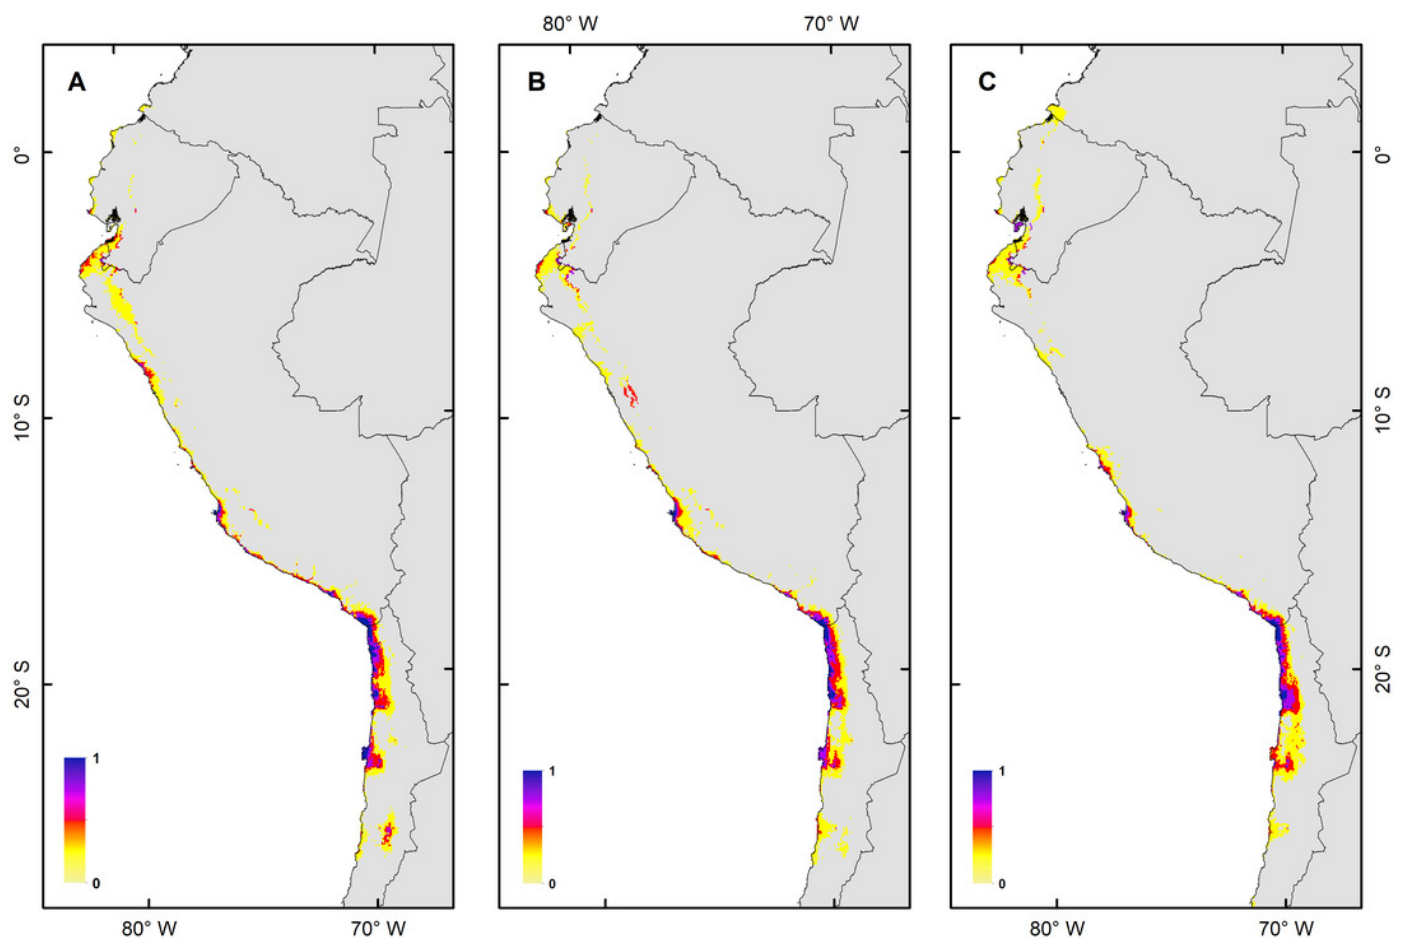

Figure 5

MIGCLIM output map Dispersal restricted future distribution of *Hydrobates markhami*, under two RCP.

A) Simulation for model MIROC (RCP 2.6). B) Simulation for model CCCMA (RCP 8.5).
