Marine bacteria in the seawater and seafloor are essential parts of Earth's biodiversity, as they are critical participants of the global energy flow and the material cycles. However, their spatial-temporal variations and potential interactions among varied biotopes in artificial habitat are poorly understood. In this study, we profiled the variations of bacterial communities among seasons and areas in the water and sediment of artificial reefs using 16S rRNA gene sequencing, and analyzed the potential interaction patterns among microorganisms. Distinct bacterial community structures in the two biotopes were exhibited. The Shannon diversity and the richness of phyla in the sediment were higher, while the differences among the four seasons were more evident in the water samples. The seasonal variations of bacterial communities in the water were more distinct, while significant variations among four areas were only observed in the sediment. Correlation analysis revealed that nitrite and mud content were the most important factors influencing the abundant OTUs in the water and sediment, respectively. Potential interactions and keystone species were identified based on the three co-occurrence networks. Results showed that the correlations among bacterial communities in the sediment were lower than in the water. Besides, the abundance of the top five abundant species and five keystone species had different changing patterns among four seasons and four areas. These results enriched our understanding of the microbial structures, dynamics, and interactions of microbial communities in artificial habitats, which could provide new insights into planning, constructing and managing these special habitats in the future.

18 **Abstract**

19 Marine bacteria in the seawater and seafloor are essential parts of Earth's biodiversity, as they are
20 critical participants of the global energy flow and the material cycles. However, their spatial-
21 temporal variations and potential interactions among varied biotopes in artificial habitat are
22 poorly understood. In this study, we profiled the variations of bacterial communities among
23 seasons and areas in the water and sediment of artificial reefs using 16S rRNA gene sequencing,
24 and analyzed the potential interaction patterns among microorganisms. Distinct bacterial
25 community structures in the two biotopes were exhibited. The Shannon diversity and the richness
26 of phyla in the sediment were higher, while the differences among the four seasons were more
27 evident in the water samples. The seasonal variations of bacterial communities in the water were
28 more distinct, while significant variations among four areas were only observed in the sediment.
29 Correlation analysis revealed that nitrite and mud content were the most important factors
30 influencing the abundant OTUs in the water and sediment, respectively. Potential interactions and
31 keystone species were identified based on the three co-occurrence networks. Results showed that
32 the correlations among bacterial communities in the sediment were lower than in the water.
33 Besides, the abundance of the top five abundant species and five keystone species had different
34 changing patterns among four seasons and four areas. These results enriched our understanding
35 of the microbial structures, dynamics, and interactions of microbial communities in artificial
36 habitats, which could provide new insights into planning, constructing and managing these
37 special habitats in the future.

40

41 **Introduction**

42 Global marine biodiversity is threatened by habitat degradation, environmental pollution,
43 overexploitation, and other anthropogenic disturbances (Timothy et al., 2006; Pereira et al., 2010;
44 Todd et al., 2019). The decline of global biodiversity has resulted in changes in marine ecosystem
45 structures (Verity et al., 2002). In the coastal waters, habitat loss and degradation are especially
46 tricky problems that must be faced (Jackson et al., 2001; Koldewey et al., 2010). To recover
47 marine habitats that provide feeding, spawning grounds, and shelters, artificial habitats are
48 constructed to support the functions of coastal ecosystems (Janiak and Branson, 2021). Artificial
49 reefs (ARs) offer a series of ecological services like improving marine habitats, increasing fishery
50 resources, and manipulating assemblages of ocean organisms (Seaman and Sprague, 1993; Lima
51 et al., 2019), which is an important form of artificial habitat in marine fisheries. ARs facilitate
52 biological production and enhance fishery resources by creating additional habitats for marine
53 organisms (Ng et al., 2017). At present, ARs have been deployed worldwide by creating different
54 structures related to fishing, scuba diving and coastal recreation (Lima et al., 2019). In China, the
55 practice of deploying ARs to create artificial habitats has been proposed by the government since
56 the 1970s (Sun et al., 2017). The annual investment in ARs is about 100 million dollars in recent
57 years, and its primary purposes are conserving marine environment, enhancing fishery resources,
58 and developing recreational fishing (Yang et al., 2019; Xu et al., 2021). With the increasing
59 attention to ARs, most studies have focused on the behaviors of targeted species (Williams-Grove
60 and Szedlmayer, 2017), designs and engineering (Woo et al., 2014), ecological impacts (Shin et
61 al., 2014), fishery management (Lima et al., 2020) and others (Chen et al., 2013). However, few
62 studies focused on the bacterial community structure in ARs.

63 Microorganisms in marine ecosystems play crucial roles in global biogeochemical processes,
64 such as energy flow, carbon and nutrient cycles (Steele et al., 2011; Sunagawa et al., 2015).
65 Therefore, recognizing that the functions of microbial communities are essential to master the
66 restoration mechanism of artificial habitats. Scientific attempts have been made to isolate and

67 characterize particular microbiomes to explain the ecological roles of artificial habitats in the
68 1990s (Zentgraf et al., 1992). Then, the dynamics of bacterial communities associated with coral
69 reefs (natural habitats) and artificial habitats were compared to verify the ecological effects of
70 two habitats using terminal restriction fragment length polymorphisms (Soka et al., 2011).
71 Nowadays, high-throughput sequencing has dramatically facilitated the understanding of the
72 mechanisms of marine microbial ecology (Langille et al., 2013). Despite great advancements,
73 studies paying attention to the bacterial communities in the water and sediment of ARs are
74 limited. Wang et al. (2019c) assessed the impact of ARs on bacterial communities in the sediment
75 to reveal the changes of microbial structure and functions. Qin et al. (2019) and Zhu et al. (2020)
76 studied the shifts of community dynamics and interaction patterns of the protists in Daya Bay
77 after the deployment of ARs.

78 Microbial community dynamics have been observed at different time scales, from days
79 (Mangot et al., 2013), weeks (Berdjeb et al., 2018), months (Marquardt et al., 2016) to seasons
80 (Genitsaris et al., 2015), and years (Boras et al., 2010). Apart from seasonality, habitats are
81 important factors that influence microbial communities (Sun et al., 2019), especially between
82 water and sediment (Abia et al., 2017; Liu et al., 2018). After profiling the structures and
83 dynamics of microbial communities, co-occurrence network is a powerful tool to uncover the
84 potential ecological interactions among microorganisms (Barberan et al., 2012), and have been
85 applied to obtain a more integrated understanding of microbial communities (Mikhailov et al.,
86 2019; Zhang et al., 2020a).

87 Laoshan Bay is a representative semi-enclosed bay in northern China, with an area of
88 approximately 188 km². Laoshan Bay is an important marine culture area for sea cucumber
89 (*Apostichopus japonicus*) and oyster (*Crassostrea gigas*), and is a stock enhancement area for
90 shrimp and fish species (Sheng et al., 2018). The annual mean seawater temperature is
91 approximately 15°C and has significant seasonal changes (5°C-25°C; Wang et al., 2019b).

92 Fishery resources in Laoshan Bay have decreased rapidly because of habitat degradation and
93 overexploitation. To help reproductive success and support recruitment, two types of ARs were
94 deployed since 2005: (1) rock reefs were deployed with mean volumes of at least 0.04 m³ (weight
95 100 kg); (2) concrete reefs were arranged with principal dimensions of 2 m × 2 m × 2 m.

96 For decades, ARs have been deployed worldwide around coasts to recover marine habitats, and
97 the ecological effects of ARs have been evaluated through periphytons, plankton, benthos, and
98 nekton (Aleksandrov et al., 2002; Scott et al., 2015; Ng et al., 2017; Chen et al., 2019). However,
99 few studies have examined the microbial communities. This study elucidated the bacterial
100 communities in the water and sediment of artificial habitat with two types of ARs using 16S
101 rRNA gene sequencing. The major objectives were: (1) to provide a comprehensive
102 understanding of the bacterial community structures and dynamics in the water and sediment of
103 ARs, (2) to reveal the influence of environmental factors on bacterial communities in the water
104 and sediment, respectively, and (3) to analyze the potential interactions among bacteria and
105 identify the keystone taxa in the ARs.

106

107 **Materials and Methods**

108 **Study sites and sample collection**

109 Triplicate water and sediment samples were collected from Laoshan Bay ARs in January
110 (winter), May (spring), August (summer), and November (autumn), 2020 (Fig. S1). Ninety-six
111 samples from four sampling areas were studied: rock reefs (RR), transition areas (TA), concrete
112 reefs (CR) and adjacent areas (AA). For the water samples, we used a plexiglass to collect 2 L
113 bottom water at every sampling area. For the sediment samples, grab sediment sampler was
114 applied to get about 1 kg surface sediment (0-10 cm) for analysis. Water and sediment samples
115 were stored at a cooler filled with ice and immediately transported back to the laboratory in two
116 hours. The methods for treating samples were followed as previously described in Fang et al.

117 (2021). All field experiment was permitted by “Measures for annual evaluation and
118 reexamination of national marine ranching demonstration areas”, which was promulgated by
119 Ministry of agriculture and rural areas of China.

120 **Measurements of environmental factors**

121 The temperature (Temp), dissolved oxygen (DO), chlorophyll-a (Chla), sampling depth (Dep),
122 pH and salinity (Sal) of water samples were measured in situ using a YSI PRODSS multi-
123 parameter water quality analyzer (YSI, USA). Transparency (Trans) was obtained by a Secchi
124 disk. The turbidity (Turb) of each area was determined by a Turb 430 IR (Xylem Analytics,
125 Germany). The determination of the total organic carbon (TOC) was performed through a TOC-L
126 series total organic carbon analyzer (Shimadzu, Japan). Eight water environmental factor,
127 including suspended particulate materials (SPM), particulate organic matter (POM), chemical
128 oxygen demand (COD), ammonium ($\text{NH}_4\text{-N}$), nitrate ($\text{NO}_3\text{-N}$), nitrite ($\text{NO}_2\text{-N}$), active silicate
129 (SiO_3) and active phosphate (PO_4) were analyzed under the guidance of GB/T 12763-2007 (State
130 Bureau of Quality and Technical Supervision of China, 2007).

131 For the measurement of sediment characteristics, Mastersizer 3000 (Malvern, UK) was applied
132 to measure the mean particle sizes (Par). Sediment bulk density (BD) was defined as the dry
133 weight of the sediment (drying at 105°C for 72 h) divided by the wet volumes. Water content
134 (WC) was the weight proportion of water in the sediment (drying at 70°C for 72 h). After burning
135 the sediment to ash totally (550°C for 4 h), organic matter content (OM) was obtained. The
136 method for mud content (MC, dry sediment) was following Eleftheriou (2013). As for the salinity
137 (Sal), electrical conductivity (EC) and pH of the sediment, a mixture of sediment and deionized
138 water (2:5, w/v) was used.

139 **DNA extraction, PCR amplification, Illumina MiSeq sequencing and Sequence analysis**

140 Genomic DNA of the whole samples was extracted using the FastDNA[®] SPIN Kit for Soil (MP
141 Biomedicals, Irvine, CA, USA) according to the manufacturer’s instructions. Specifically, the

142 universal primers 338F (5'-ACTCCTACGGGAGGCAGCAG-3') and 806R (5'-
143 GGACTACHVGGGTWTCTAAT-3') were used, which amplified 468 bp in V3-V4
144 hypervariable region of 16S rRNA gene. The procedures of the PCR amplification was based on
145 the manufacturer's instructions and the standard protocols of Majorbio Bio-Pharm Technology
146 Co. Ltd. (Shanghai, China). Raw sequence reads were analyzed using QIIME 1.9 (Caporaso et
147 al., 2010). The detailed processes were all described in Supp. File 1. The sequencing data have
148 been deposited in the National Center for Biotechnology Information (NCBI) Sequence Read
149 Archive database under the accession number PRJNA725051.

150 **Statistical analysis**

151 The number of OTUs and alpha diversity estimators (Shannon, Simpson, Ace, Chao 1 and
152 Good's coverage) were analyzed among four seasons and two habitats. The seasonal and spatial
153 variations of bacterial community compositions were compared by principal coordinate analysis
154 (PCoA) based on the Bray-Curtis distance matrix (Borcard et al., 2011). The effects of the
155 temporal and spatial factors on the bacterial communities were tested using permutation
156 multivariate analysis of variance (PERMANOVA) and analysis of similarity (ANOSIM)
157 (Anderson, 2001; Clarke, 1993). Statistical differences were analyzed using the Kruskal-Wallis
158 test, and the differences were considered significant at $P < 0.05$. The correlations between the
159 most abundant OTUs (relative abundance $> 0.5\%$) and environmental factors, sampling areas
160 were determined by Spearman correlation analysis, and the visualization was achieved by
161 heatmaps (Borcard et al., 2011). The impacts of environmental factors on bacterial communities
162 were evaluated by the Mantel test and partial Mantel test (Smouse et al., 1986). Statistical
163 analyses were conducted in R 4.0.2 using the “*phyloseq*” and “*vegan*” packages (www.r-
164 project.org).

165 The visualization of the three co-occurrence networks was built using Cytoscape 3.8.2
166 (www.cytoscape.org) for the all bacterial communities in the water, sediment and both two

167 habitats. To improve the visibility and sensitivity of the networks, OTUs observed in more than
168 50% of all samples and the mean relative abundance higher than 0.5% were selected. Then, we
169 calculated the Spearman correlations and significances between OTUs in R. Significant edges (P
170 < 0.001) with high correlations ($|r| > 0.8$) were chose to construct the co-occurrence networks.
171 The network topology parameters were calculated using the Analyze Network plugin of
172 Cytoscape to identify the keystone OTUs in the networks (Cheung et al., 2018). Three topology
173 parameters were: (1) degree: the number of edges that a node has; (2) betweenness centrality: the
174 number of shortest paths between any two nodes in the graph passing through a node; (3)
175 closeness centrality: the average distance of a node to any other node. After that, min-max scaling
176 was applied to standardize degree, 1-betweenness centrality, and closeness centrality,
177 respectively. Last, keystone-ness was defined as the average of degree, 1-betweenness centrality,
178 and closeness centrality after min-max scaling was calculated (Berry and Widder, 2014); and the
179 top 10 OTUs with highest scores were identified as the keystone species (Cheung et al., 2018).
180 Jaccard index was applied to analyze the similarities of OTUs among networks (Dmitry et al.,
181 2016).

182

183 **Results**

184 **Bacterial alpha diversities and community compositions**

185 A total of 5,427,513 high-quality bacterial 16S rRNA gene sequences and 17,207 OTUs with
186 97% similarity levels were identified from 96 water and sediment samples. Sediment samples
187 (15,010 OTUs) had higher OTUs than water samples (9,423 OTUs), and 7,226 OTUs were
188 shared between the two habitats. The Good's coverage was over 90% in all samples, indicating
189 the current sequencing depth was sufficient for this study. Alpha diversity indices showed
190 significant variations between the habitats and seasons (Table 1), while there were no differences
191 among four areas. The diversity indices (Shannon, Chao 1 and Ace) of water samples were

192 significantly lower than sediment, while the diversity indices (Simpson and Good's coverage) of
193 water were higher (Table 1). A seasonal pattern of alpha diversity indices (e.g., Shannon) could
194 be observed in the water samples, which varied from 4.09 to 5.16 (Fig. 1). However, no
195 significant seasonal differences were found in the sediment except for the Simpson diversity
196 index (Table 1).

197 Seasonal variations of the abundant phyla in the water were more evident than sediment, but
198 the differences among the four areas were low. The total abundance of the three most abundant
199 phyla was over 74% and around 50% for water and sediment samples, respectively. For the water
200 samples, the three most abundant phyla (> 10%) were Proteobacteria, Cyanobacteria, and
201 Actinobacteria, with mean relative abundances of 42.8%, 18.3% and 13.1%, respectively (Fig. 2).
202 Marked seasonal changes were observed in many bacterial phyla. The phylum Proteobacteria had
203 a relative abundance greater than 56.8% in autumn, while its abundance was 23.6% in summer;
204 the phyla Actinobacteria and Cyanobacteria had the highest abundances in summer (20.9% and
205 29.4%) and the lowest abundances in winter (6.6% and 13.2%). In the sediment, the bacterial
206 community was dominated (> 10%) by the phyla Proteobacteria, Desulfobacterota, and
207 Acidobacteria, which comprised approximately 28.4%, 10.8%, and 10.2% of the relative
208 abundances, respectively (Fig. 2). The relative abundance of the phylum Chloroflexi (mean
209 abundance was 8.6%, ranked 4th) had marked seasonal changes, whose abundance in autumn
210 (12.0%) was twice that in winter (6.7%).

211 **Bacterial community structure**

212 Two different bacterial groups were observed between the water and sediment samples (Fig. 3;
213 Table 2). Significant seasonal differences were both observed for the water and sediment
214 samples, and the bacterial communities in the water samples were more divergent and separated
215 than sediment (Fig. S2). The bacterial communities in the sediment varied among seasons, areas,
216 and their interactions based on PERMANOVA and ANOSIM (Table 2). However, there was no

217 significant difference among the four areas in the water. The Bray-Curtis dissimilarities among
218 four areas had similar seasonal changing trends in the two habitats; and the dissimilarities were
219 highest in autumn and lowest in summer (Fig. 4). The top 39 abundant water OTUs and 24
220 sediment OTUs (> 5‰), which affiliated to six and thirteen bacterial classes, showed varying
221 abundances among four areas (Fig. S3). According to the results of cluster trees, bacterial
222 communities in the areas RR and TA were different from areas CR and AA in the water samples
223 (Fig. S3a); communities in the area CR was separate from other three areas in the sediment (Fig.
224 S3b).

225 **Relationships between abundant OTUs and environmental factors**

226 The relationships among bacterial communities and environmental factors were significant both
227 in the water and sediment samples based on the Mantel test (Table 3, Table S1). For the water
228 samples, NO₂-N ($r = 0.414$) was the most correlating factor in shaping the community; Temp,
229 Trans, PO₄, DO, SiO₃, and COD were significant correlating factors. In the sediment, MC ($r =$
230 0.125) was the only factor that significantly impacted the bacterial community. The relative
231 abundances of the top abundant OTUs were noticeably related to the environmental factors (Fig.
232 5). For the water samples, thirty-three OTUs were significantly correlated with Temp, while only
233 two OTUs were related to Chla (Fig. 5a). For the sediment samples, thirteen OTUs were highly
234 related to EC, and four OTUs were related to WC and OM (Fig. 5b). Also, two bacterial groups
235 were observed that responded to the environmental factors, conversely. For example, class
236 Gammaproteobacteria and class Alphaproteobacteria were divided into two groups for the
237 sediment samples, correspondingly.

238 **Co-occurrence networks and keystone species**

239 One co-occurrence network containing total bacteria both in the water and sediment, and two
240 networks for the communities in the water and sediment, were constructed to analyze the
241 connections, stability, and complexity of bacterial communities in the ARs (Fig. 6; Fig. S4 and

242 Fig. S5). For the total bacteria network, 185 nodes belonging to 18 phyla and 6,832 edges were
243 detected. A complete distinction of nodes from water and sediment samples formed two modules
244 (Fig. 6a). The most abundant OTUs (top five OTUs with highest abundance) in the network were
245 OTU18562 (Firmicutes), OTU18460 (Cyanobacteria), OTU10090 (Proteobacteria), OTU17592
246 (Proteobacteria), and OTU18751 (Actinobacteria). Four OTUs mainly from water samples
247 exhibited seasonal variations in their abundances; OTU10090 was from sediment samples, which
248 had no seasonal change (Fig. 7a). Differences of five abundant OTUs among four areas were not
249 significant except OTU18562 (Fig. 8a). The bacterial network for the water samples comprised
250 189 nodes belonging to 15 phyla, while only 1,772 edges were observed (Fig. S4). OTU18562
251 (Firmicutes), OTU14763 (Cyanobacteria), OTU17592 (Proteobacteria), OTU18751
252 (Actinobacteriota), and OTU18053 (Proteobacteria) had the highest abundances in the network.
253 Similar seasonal changes of OTU18562 and OTU17592 in abundance were observed, and the
254 other three OTUs showed similar trends (Fig. 7b). OTU18562 showed a most apparent difference
255 among four areas compared with other four abundant OTUs (Fig. 8b). For the sediment bacterial
256 network, 274 nodes belonging to 24 phyla and 1,166 edges were observed (Fig. S5). The top five
257 most abundant OTUs in this network were OTU10090 (Proteobacteria), OTU3621
258 (Desulfobacterota), OTU13814 (Myxococcota), OTU13137 (Desulfobacterota), and OTU6550
259 (Chloroflexi). The seasonal variations of the five OTUs were not evident (Fig. 7c), and
260 OTU10090 showed lower abundances in areas RR and CR than in TA and AA (Fig. 8c).

261 The top keystone OTUs with relative abundances higher than 1‰ were identified as the
262 keystone taxa in the co-occurrence networks. In the total bacterial co-occurrence network, the top
263 10 keystone OTUs were affiliated to five phyla, Myxococcota, Proteobacteria,
264 Gemmatimonadota, Chloroflexi and Actinobacteriota (Table S2a). The keystone OTU with
265 highest keystone-ness was OTU13814 (Myxococcota, keystone-ness = 0.840), which ranked 15
266 among all OTUs with a relative abundance of 12.3‰; the abundance of OTU12321

267 (Proteobacteria, keystone = 0.836) ranked 150 with a relative abundance of 1.8‰. There was
268 no significant seasonal abundance variation for the top five keystone OTUs except OTU13814,
269 and no evident differences among the four areas were found (Fig. S6a, S7a). For the water
270 network, the top 10 keystone OTUs included members of the phyla Bacteroidota, Proteobacteria,
271 Desulfobacterota, Gemmatimonadota and Acidobacteriota (Table S2a). The top two keystone
272 OTUs (OTU525 and OTU7969) had abundances of 2.3‰ (ranked 90) and 1.4‰ (ranked 123),
273 respectively. Similar seasonal trends of the abundance for the top five keystone OTUs were
274 observed, which showed higher abundance in spring and autumn (Fig. S6b). For the sediment
275 network, the top 10 keystone OTUs belonged to three phyla, Proteobacteria, Firmicutes and
276 Chloroflexi (Table S2c). OTU6991 (abundance 2.3‰, ranked 114) and OTU3902 (abundance
277 8.8‰, ranked 24) were the only two keystone OTU with keystone greater than 0.7. The
278 changing patterns among the four seasons and four areas for keystone OTU17592, OTU16870,
279 and OTU17616 were consistent (Fig. S6c and Fig. S7c).

280

281 **Discussion**

282 **Bacterial community characteristics in the water and sediment of ARs**

283 The distributions of the marine bacterial communities were highly of indigenous and specific,
284 while the abundant taxa that represented in the communities were analogous (Pommier et al.,
285 2007). In this study, Proteobacteria, Cyanobacteria, and Actinobacteria were the most abundant
286 phyla, with a total relative abundance of 74% in the water samples (Fig. 2), which was consistent
287 with previous studies in coastal waters (Lee and Eom, 2016; Ye et al., 2016). For the differences
288 of bacterial communities between habitats, sixteen shared phyla were observed between the water
289 and sediment, and five phyla among sixteen phyla had higher relative abundances in the water
290 than those in the sediment. The absolute predominance of the phylum Proteobacteria in the water
291 samples may be the main reason. Because of the higher abundance of Proteobacteria (42.8%) in

292 the water samples, significantly restricting the population size of the other bacterial phyla (e.g.,
293 Sun et al., 2019). Higher diversities of the bacterial communities were observed in the sediment
294 than water (Fig. 1; Table 1), which was in accordance with the results of Feng et al. (2009) and
295 Abia et al. (2017). Some reasonable assumptions were proposed. Ye et al. (2009) stated that
296 sediments within aquatic environments formed more complex environments, which resulted in
297 more prosperous bacterial communities; Perkins et al. (2014) noted that sediment provided
298 shelters for bacteria, which helped to defend against the impacts of predation and sunlight; Liu et
299 al. (2018) explained that lower concentration of suspended sediment in the water would lead to
300 lower microbial diversity.

301 The heatmap of the abundant OTUs with four areas revealed that bacterial abundance in RR
302 was inconsistent with other areas, especially in the sediment (Fig. S3). Many studies showed that
303 the diet preference of *A. japonicus* can change the microbial communities in the sediment (e.g.,
304 Zhao et al., 2020). Thus, we assumed that the aquaculture activities of *A. japonicus* in RR might
305 result in these distinctions. Besides, rock reefs were deployed more intensive than concrete reefs,
306 changing the substrate and flow field surrounding ARs more significantly (e.g. Tang et al., 2022),
307 which might impact the bacterial communities strongly. As for the differences of bacterial
308 abundance among four areas, some inconsistencies were observed. For instance, OTU1283
309 (Actinobacteriota) showed significantly higher abundance in RR and CR than that in TA and AA,
310 which suggested that it favored ARs. The phylum Actinobacteria plays important roles in
311 mineralizing organic matter in marine sediment (Bell et al., 1998), indicating that the organic
312 matter content in the ARs was higher than that in non-intervened areas. OTU7413 (family
313 Rhodobacteraceae) was regarded as an important food resource for *A. japonicus* (Zhao et al.,
314 2020), which showed a lower abundance in RR than other three areas.

315 As for the beta diversity among the four areas, the highest and lowest beta diversities were
316 found in autumn and summer, respectively (Fig. 4). Some current studies highlighted that high

317 beta diversity of bacterial communities in a particular season was a response to environmental
318 heterogeneity (Fournier et al., 2020). While some studies addressed that the Bray-Curtis
319 dissimilarities among microbial communities did not significantly correlated with environmental
320 factors such as temperature and salinity (Balzano et al., 2015). These opposite conclusions may
321 result from the differences in spatial and temporal scales (Hatosy et al., 2013).

322 **Seasonal dynamics of bacterial communities in ARs**

323 Marine bacterioplankton exhibit pronounced seasonal succession patterns worldwide (Bunse and
324 Pinhassi, 2017), and follow with the changes of temperature, chlorophyll-a, and other nutrients
325 (Mohapatra et al., 2020; Pinhassi et al., 2006). In this study, seasonal changes in the relative
326 abundances of diversity indices, abundant species and community structures were observed. The
327 seasonal variations of α diversity between water and sediment were inconsistent (Fig. 1). In the
328 water samples, a more considerable fluctuation of α diversity was observed, and had the highest
329 Shannon diversity in spring. Similar seasonal patterns in the Shannon diversity have been
330 observed in other seawaters (Piwosz et al., 2018; Zhu et al., 2020). Previous studies indicated that
331 sudden decrease of microbial plankton communities in winter and new growing season in spring
332 preceding the spring bloom (Espinoza-González et al., 2012; Figueiras et al., 2020) could
333 promote these seasonal patterns. Therefore, higher diversity in spring can be explained by the
334 intrinsically high growth rate of bacterioplankton (Agawin et al., 2000). However, no significant
335 differences of bacterial diversity in the sediment were detected. Marine sediment is characterized
336 as a habitat type with high biodiversity, complicated community structures and spatial
337 heterogeneity (Brandt et al., 2016). The bacterial communities in the sediment had wider niche
338 ranges and sufficient nutrients, which helped maintain and facilitate prosperous diversities (Shu
339 et al., 2020).

340 The abundance of the abundant phyla also showed conspicuous varieties (Fig. 2). For the water
341 samples, our results showed that Actinobacteria had the highest abundance in summer, when the

342 salinity was lowest because of higher precipitation level. Shen et al. (2018) confirmed that
343 Actinobacteria is sensitive to the change of salinity. Meantime, the peak abundance of
344 Cyanobacteria occurred in summer. Martin et al. (2017) also stated that the autotrophic
345 Cyanobacterium, *Synechococcus* exhibited higher abundances during monsoons. For the
346 sediment samples, the seasonal variations of the abundant bacteria were not significant compared
347 with water samples. For instance, Chloroflexi was the most abundant in autumn. Chloroflexi is
348 regarded as having anaerobic and heterotrophic lifestyles, which are positively related to organic
349 matters (Wilms et al., 2006). In autumn, the seaweed cultivation in the adjacent sea could
350 probably explain their higher abundances of Chloroflexi.

351 Marked seasonality of bacterial community compositions in the water was widely observed.
352 Shu et al. (2020) found distinct seasonal patterns of core and non-core bacterial communities in
353 an urban river; Mohapatra et al. (2020) discovered that seasonal variations of environmental
354 drivers highly impacted the bacterial communities. However, the seasonal variations of microbial
355 community compositions in the sediment were controversial. We observed significant seasonal
356 changes of bacterial communities at OTU level (Table 2), while some similar studies have
357 presented different conclusions. Liu et al. (2015) revealed noticeable seasonal variations of
358 bacteria community because of environmental heterogeneity; Palit and Das (2020) reported a
359 comparatively low seasonal fluctuation of sediment bacterial communities in part of sampling
360 sites based on the culture-dependent method; Ming et al. (2021) indicated that no marked
361 seasonal difference was observed among the bacterial community compositions. Different
362 temporal and spatial scales may cause these inconsistent results, and more follow-up studies are
363 suggested.

364 **Environmental characteristics and bacterial communities**

365 Environmental factors significantly affected bacterial communities, such as nitrite, temperature in
366 the water (Fadeev et al., 2018; Zorz et al., 2019) and mud content in the sediment (Lee et al.,

2020). In the present study, the Mantel test revealed that nitrite, temperature, and transparency significantly correlated with the communities in the water, while mud content was the only related factor in the sediment (Table 3). Although N and P are limiting factors of eutrophication, they are important nutrients affecting the proliferation of bacteria (Huang et al., 2017). Our results revealed that dissolved inorganic nitrogen ($\text{NO}_3\text{-N}$, $\text{NH}_4\text{-N}$, $\text{NO}_2\text{-N}$) was correlated with many abundant OTUs (Fig. 5a). Water temperature is an important factor that governs microbial growth and activity (Margesin, 2009), and thirty-three abundant OTUs were significantly related to temperature. Light intensity could also shape different microbial communities (Davies and Evison, 1991), and our studies confirmed that the correlation between transparency and the bacterial communities was significant. Different electrical conductivity levels can influence bacteria (Silverman and Munoz, 1975), which was in accordance with the results that the abundances of thirteen dominant OTUs were affected by EC. Mud content was a vital factor influencing microorganisms from sediment, higher content could offer more nutrition substrates, which was meaningful to support greater microbial biomass (Wei et al., 2014).

381 **Co-occurrence networks and keystone species of bacterial communities in ARs**

382 Although the physical and chemical properties between water and sediment were fundamentally
383 different, the microbial communities are connected through the sedimentation of organic matters
384 (Lucie et al., 2011). To reveal the potential interactions among the bacterial communities in two
385 habitats, co-occurrence networks were used to promote our understanding of the microbiomes in
386 marine ecosystems (Berry and Widder, 2014). Species similarity between the water and sediment
387 networks was low (Jaccard = 11.8%), and the similarity between the water network and total
388 bacterial network (33.1%) was equal to that between the sediment network and total bacterial
389 network (31.5%). These results indicated that habitats significantly affected the compositions of
390 microorganisms in the co-occurrence networks, which was consistent with Zhang et al. (2020a).

391 A total of 47 OTUs were simultaneously observed in the three networks, and some played
392 important roles in ecosystems. For instance, family Woeseiaceae (OTU10090) covers a broad
393 physiological spectrum (Mußmann et al., 2017), which may promote plant survival by
394 participating in nitrogen and carbon cycling (Zhang et al., 2020b); family Methylophilaceae
395 (OTU3417) was reported as an important host related to antibiotic resistance and metal resistance
396 (Zhang et al., 2021). Significant seasonality of the top five abundant OTUs for the networks was
397 exhibited, while the dissimilarities of their abundance among the four areas were relatively low
398 (Fig. 7 and Fig. 8). OTU18562 (family Planococcaceae) was the most abundant OTU in the total
399 network and water network, which showed evident temporal and spatial differences,
400 concurrently. OTU18562 affiliates to family Planococcaceae, which was correlated with the
401 decomposition of fertilizers (Suzuki et al., 2021). OTU17592 (family Moraxellaceae) had higher
402 abundance in RR and CR than in TA and AA in the total network and water network, indicating
403 positive relationships between OTU17592 and ARs existed. OTU18751 (family Microtrichales),
404 which showed the highest abundance in summer and lowest abundance in spring, played crucial
405 roles in hydrolyzing and utilizing complex organic matters (Li et al., 2021).

406 Keystone species are highly connected taxa in networks that play vital roles in maintaining
407 microbial community structures (Faust and Raes, 2012). The top ten keystone OTUs in the three
408 co-occurrence networks were significantly different. As reported, differences of key microbial
409 groups at ARs and open waters have also been studied (Zhu et al., 2020). The ranks of relative
410 abundance for the top ten keystone OTUs in the three network were low (Table S2). Two factors
411 could explain this phenomenon. On the one hand, it was suggested that abundant bacteria
412 contribute mostly to the biogeochemical cycles, while rare microbiomes might act to stabilize the
413 community (Shade et al., 2014; Genitsaris et al., 2015). Moreover, rare species may be disturbed
414 by the rapid changes of the environment (Shade et al., 2014). On the other hand, rare taxa could
415 considerably increase in abundance to respond the environmental disturbances; and these

416 dynamics may be the reasons for their greater contributions to microbial communities (Caron and
417 Countway, 2009).

418 In general, relative to the important functions of keystone species in the community, the
419 discovery of these species evidently falls behind (Palit et al., 2020), which leads to a limited
420 understanding of microbial ecology. The abundance of the top five keystone OTUs in the water
421 network all showed similar seasonal variations (Fig. S6b), suggesting keystone species were
422 more consistent in response to the changes of environmental conditions than abundant species
423 (Fig. 7b). OTU525 belongs to family Flavobacteriaceae, which were reported as important
424 bacterial populations associated with algal blooms closely (Pavlovska et al., 2021). What's more,
425 the seasonality of the top five keystone OTUs in the sediment network was also significant (Fig.
426 S6c). Three keystone OTUs (OTU17592, OTU16870 and OTU17616) in the sediment network
427 had significantly higher abundance in RR than in other three areas (Fig. S7c), showing their
428 positive relationships with the deployment of rock reefs. These three keystone OTUs all affiliate
429 to order Pseudomonadales, class Gammaproteobacteria. As reported by Eswaran and
430 Khandeparker (2019), Pseudomonadales participated in mediating the degradation of
431 carbohydrates by producing β -Glucosidases in a tropical estuarine environment. Some other
432 keystone OTUs are also crucial in the particular ecological process. For instance, the abundance
433 of OTU7413 (family Rhodobacteraceae) ranked 137th in the water network (Table S2b), which
434 was regarded as the key member of the initial microbial biofilm in coastal seawater (Hila et al.,
435 2013). OTU11572 and OTU8614 belong to family Thermoanaerobaculaceae, may play crucial
436 roles in nitrogen transformation in water (Wang et al., 2019a).

437

438 **Conclusions**

439 In the present study, we simultaneously profiled the temporal and spatial variabilities and
440 potential interaction patterns of bacterial communities in the water and sediment of ARs for the

441 first time. Seasonal variations of bacterial community compositions were observed in the two
442 habitats, while spatial changes were only detected in the sediment. Bacterial communities in the
443 rock reef area were significantly different with other three areas, which indicating the deployment
444 of ARs impacted the bacterial communities in sediment. The potential correlations among
445 bacterial communities in the sediment were lowest in the three networks, suggesting less niche
446 overlap existed. The abundant and keystone species in the networks showed discordant variations
447 among four seasons and four areas, revealing that two types of species played different ecological
448 functions. As important artificial habitats in marine fisheries, our discoveries about ARs are
449 crucial to better comprehend the mechanisms of microbial ecology in artificial habitats, to
450 promote restoration efficiency, to improve biodiversity, and to recover the marine environment.
451 Particularly, marine microbial loops are comprehensive networks containing bacteria, archaea,
452 and eukaryotes, and further studies are suggested to reveal the interactions among these
453 microbiomes in artificial habitats.

454

455 **Acknowledgements**

456 This study was funded by the Project of Investigation of Fishery Resource of Marine Ranching
457 from the Department of Agriculture and Rural Affairs of Shandong Province. We thank all
458 scientific staff and crew members of Qingdao Longpan Company for their assistance in the
459 surveys.

Figure 1

Seasonal change of Shannon diversity (mean \pm SD) of bacterial communities in the two habitats of artificial reefs.

Means with different letter (lowercase letters for water samples, capital letters for sediment samples) are significantly different with P value < 0.05 .

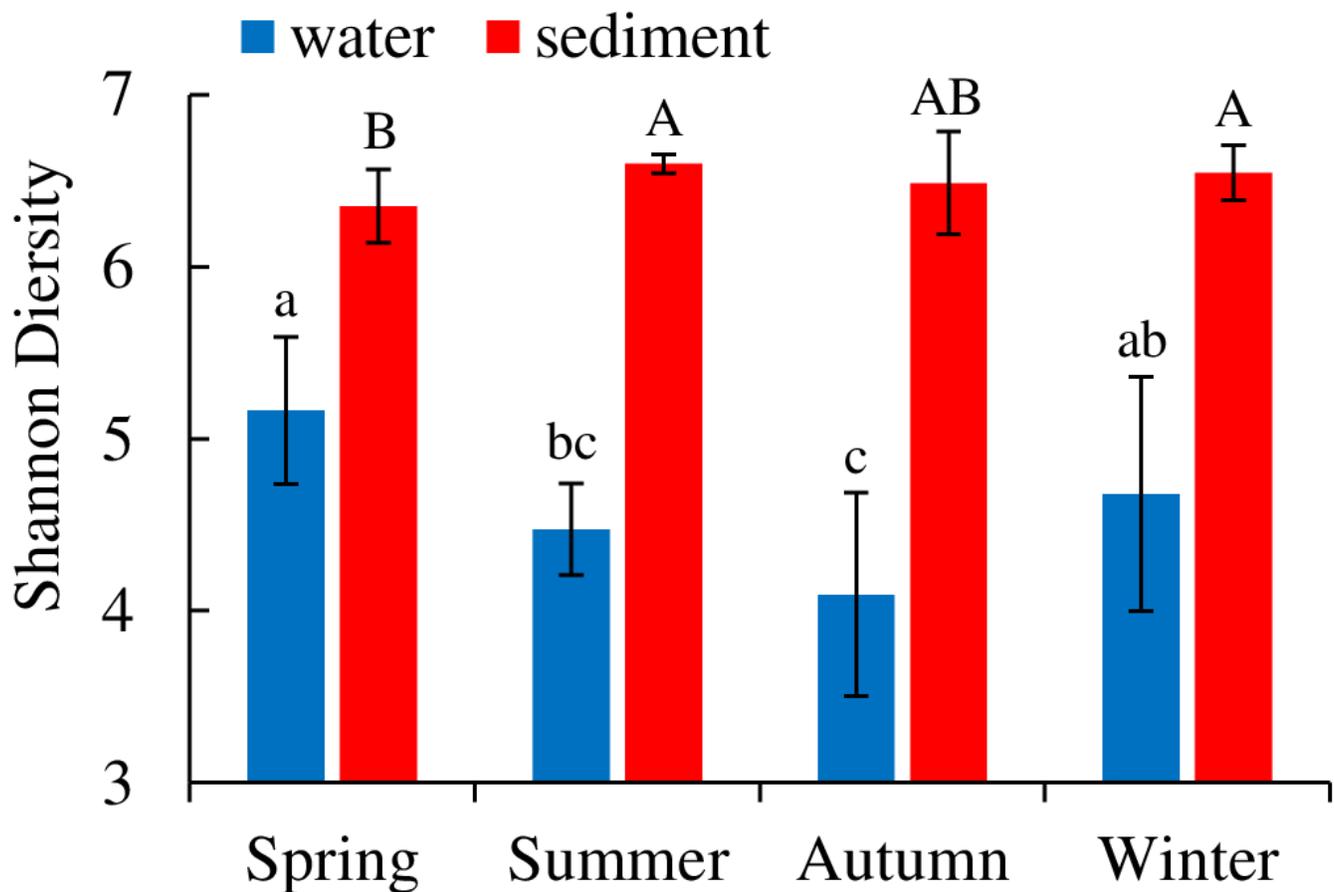

Figure 2

Relative abundance of bacterial communities at phylum levels in the two habitats and four seasons of artificial reefs.

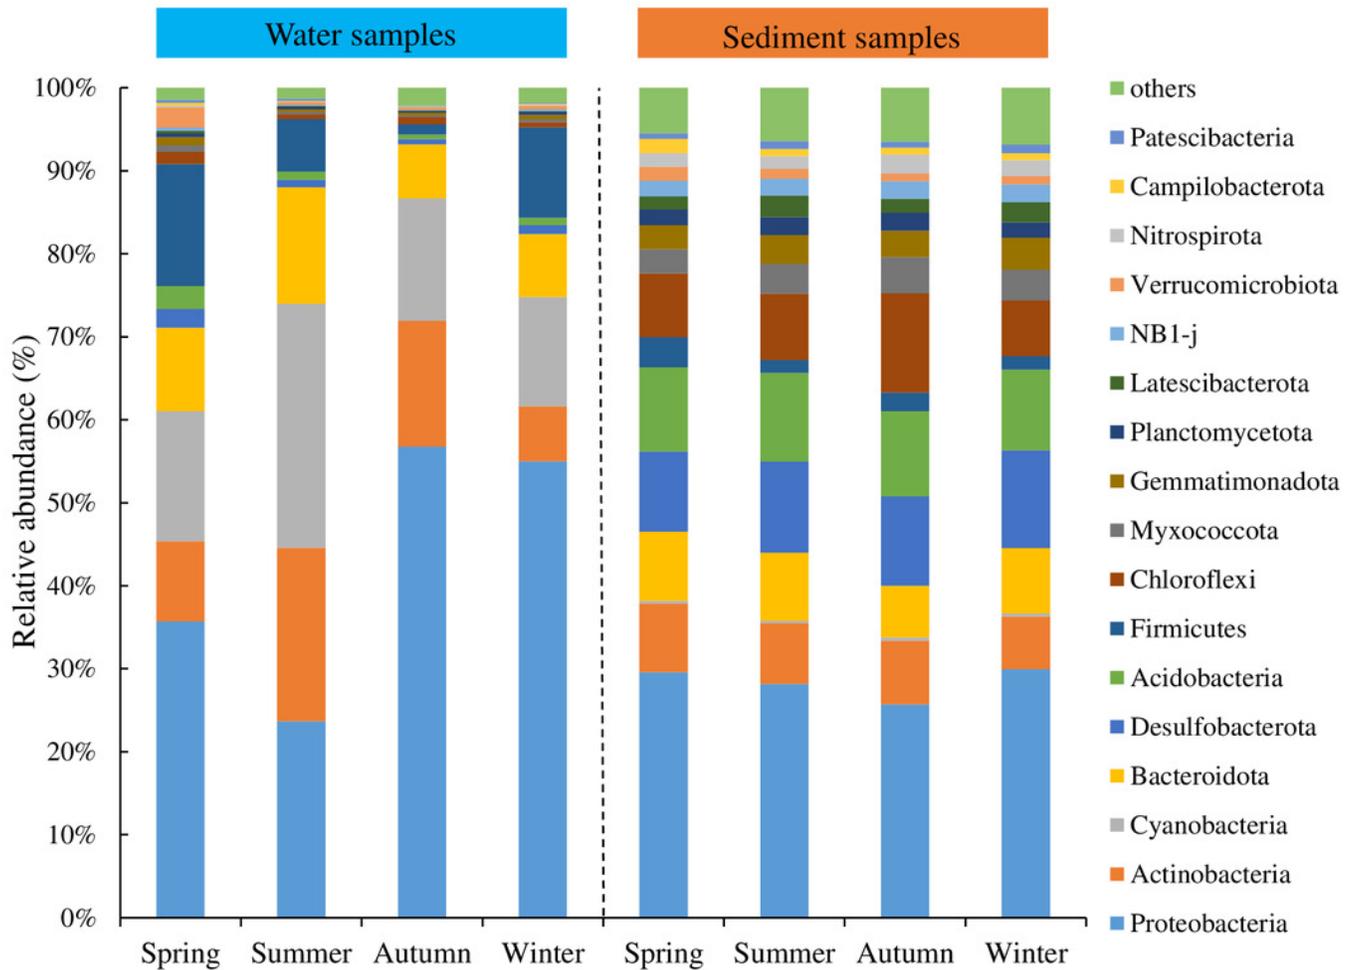

Figure 3

Principal coordinates analysis (PCoA) plots of bacterial communities in the water and sediment of artificial reefs.

R: the test statistical significance of analysis of similarities (ANOSIM); *P*: statistical significance value at $\alpha = 0.05$ level.

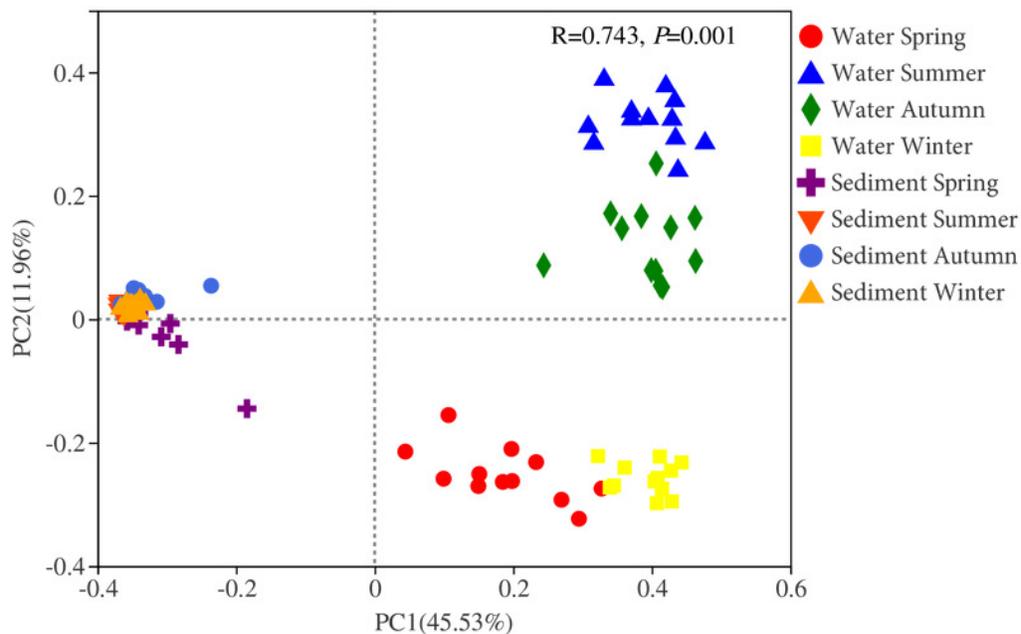

Figure 4

Seasonal variations of bacterial communities among samples in the water and sediment using Bray-Curtis dissimilarity.

Means with different letter (lowercase letters for water samples, capital letters for sediment samples) are significantly different with P value < 0.05 .

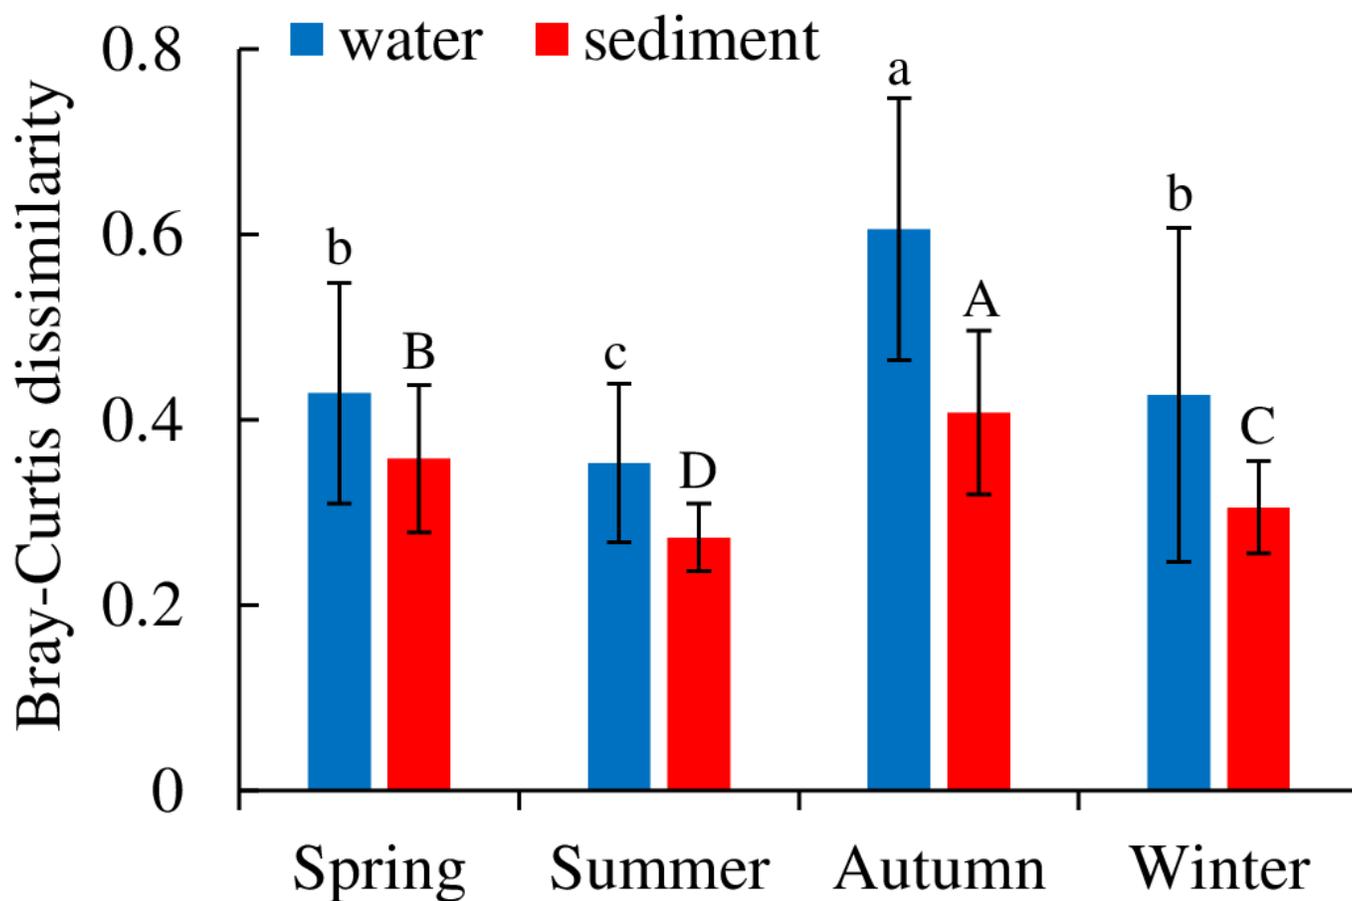

Figure 5

Heatmap of top abundant OTUs of bacterial communities with environmental factors in the (a) water and (b) sediment of artificial reefs.

The cluster trees were analyzed to show the similarity of OTUs using Bray-Curtis distance. Asterisks represent significant correlations between bacterial OTUs and environmental factors at the following α levels: * = 0.05, ** = 0.01, *** = 0.001. Environmental factors: temperature (Temp); transparency (Trans); chemical oxygen demand (COD); active silicate (SiO_3); suspended particulate materials (SPM); total organic carbon (TOC); ammonium ($\text{NH}_4\text{-N}$); depth (Dep); chlorophyll-a (Chla); dissolved oxygen (DO); nitrite ($\text{NO}_2\text{-N}$); turbidity (Turb); active phosphate (PO_4); electrical conductivity (EC); water content (WC); salinity (Sal); mean particle sizes (Par); organic matter content (OM); sediment bulk density (BD); mud content (MC).

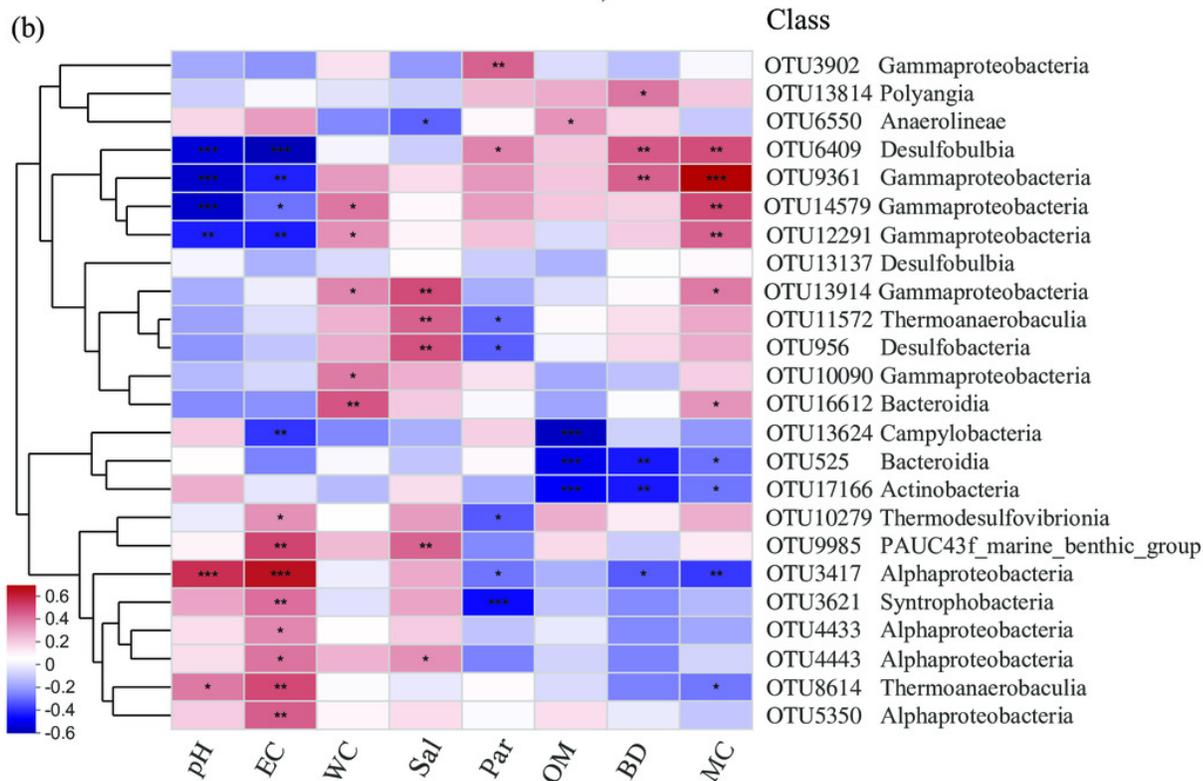

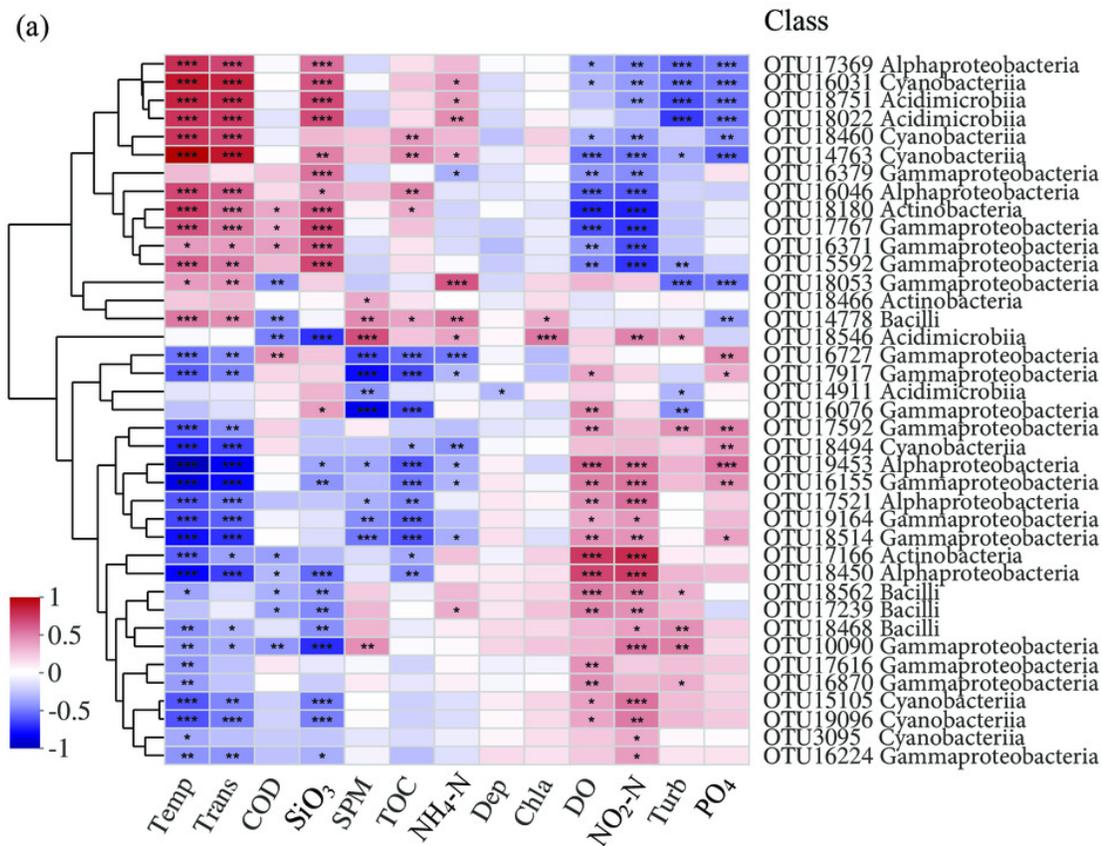

Figure 6

Co-occurrence networks built from abundant bacterial OTUs in the water and sediment of artificial reefs.

Nodes are colored at (a) habitats and (b) phylum levels. Edges with $|r| \geq 0.8$ and $P \leq 0.001$ are shown in the networks. Positive and negative lines are represented by solid lines and dotted lines, respectively.

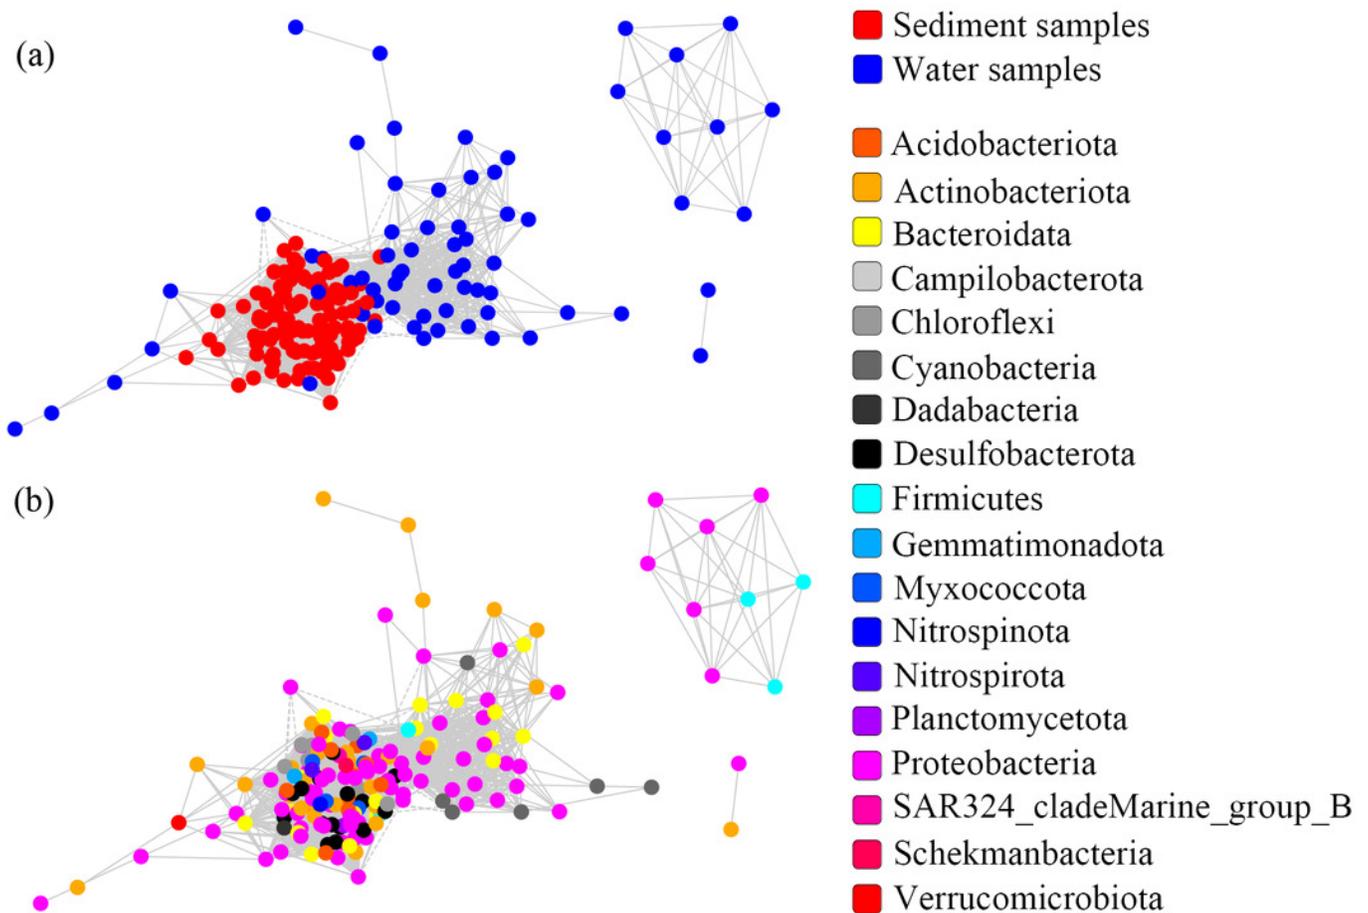

Figure 7

Seasonal changes of the relative abundance for the top five abundant OTUs of the co-occurrence networks in the (a) water and sediment, (b) water and (c) sediment of artificial reefs.

Four seasons: spring (SPR); summer (SUM); autumn (AUT); winter (WIN).

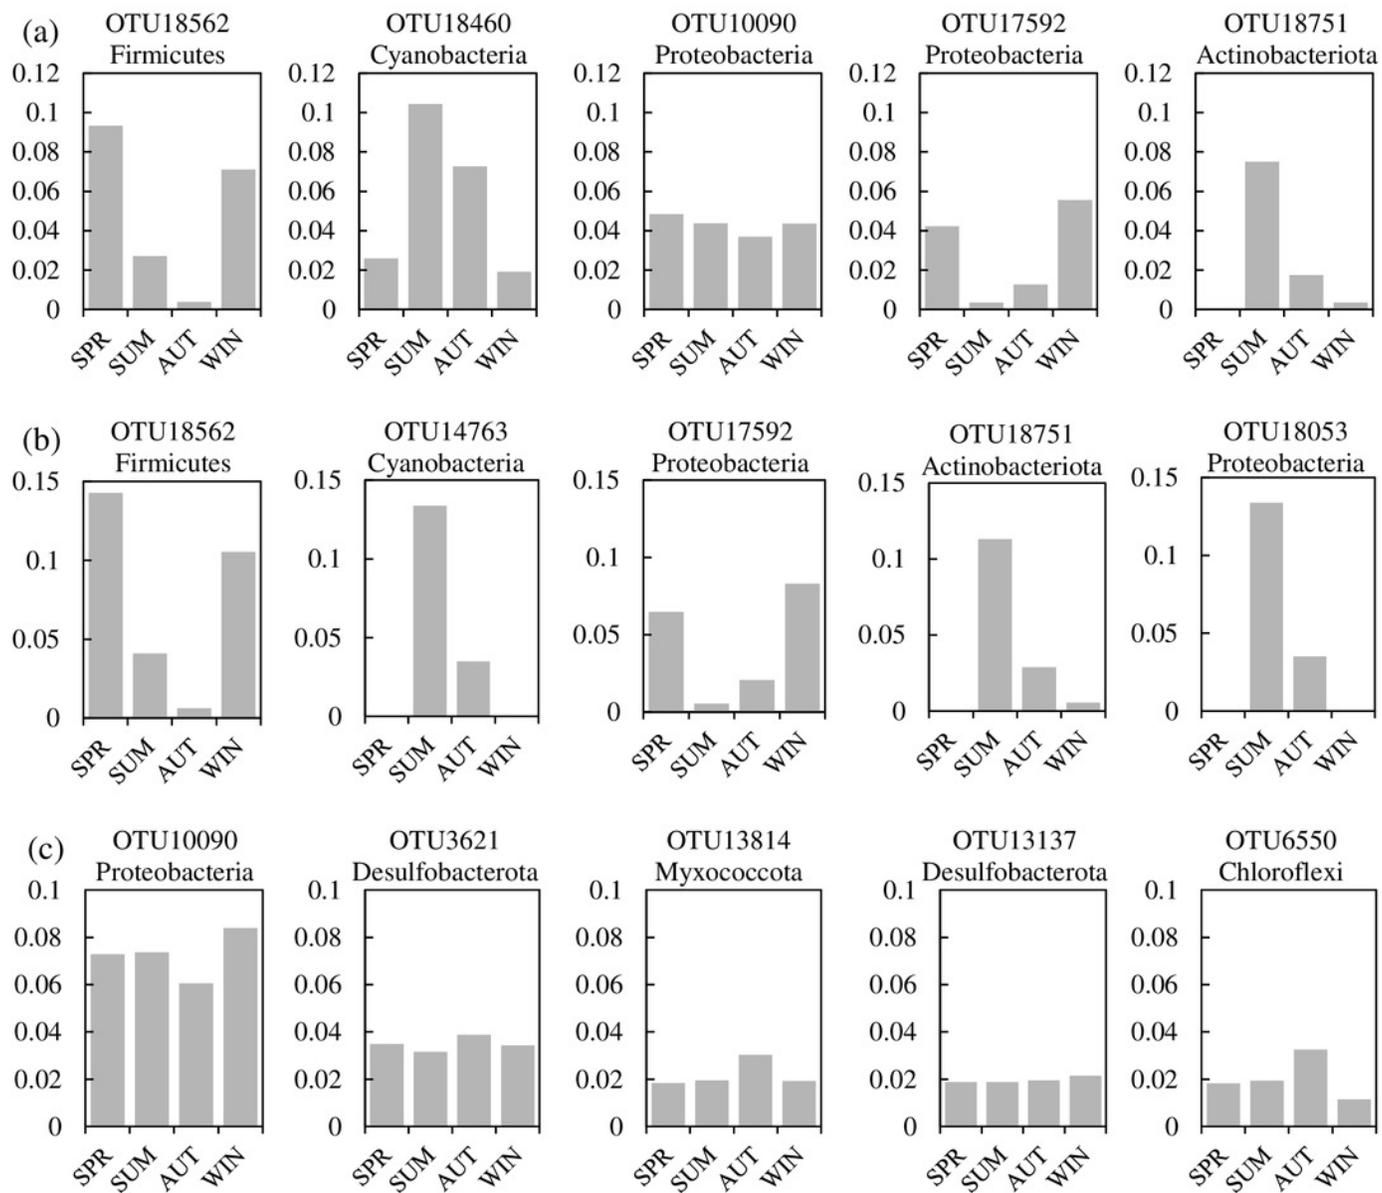

Figure 8

Variations of the relative abundance for the top five abundant OTUs among four sampling areas of the co-occurrence networks in the (a) water and sediment, (b) water and (c) sediment of artificial reefs (ARs).

Four sampling areas in ARs: rock reefs (RR), transition areas (TA), concrete reefs (CR) and adjacent areas (AA).

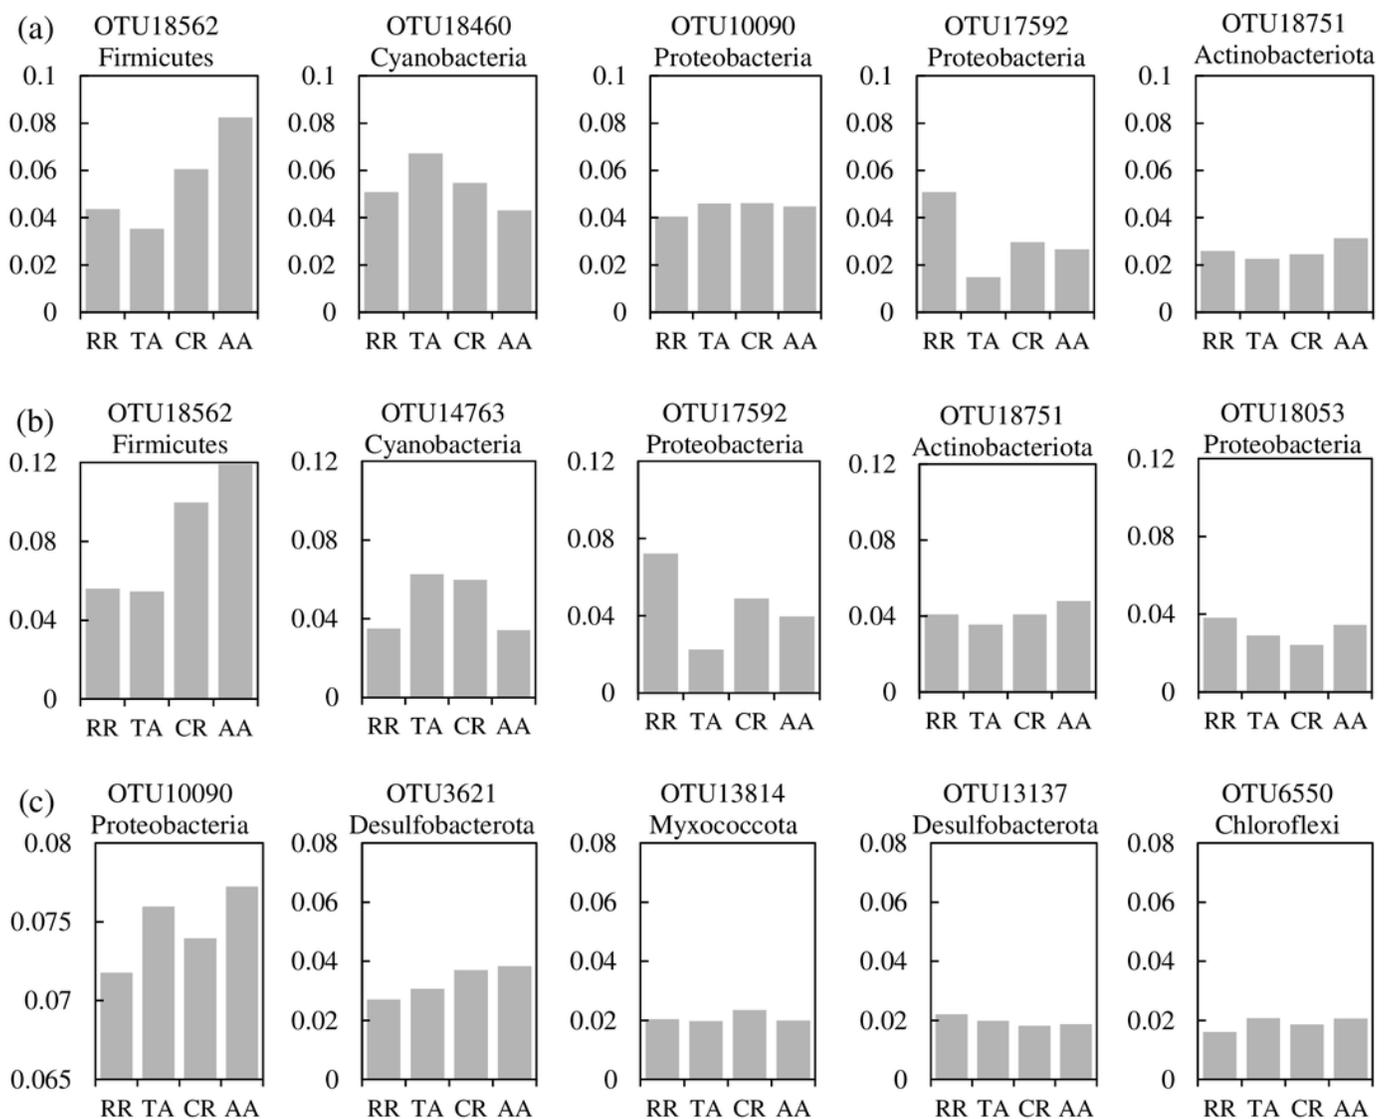

Table 1 (on next page)

Number of OTUs and alpha diversity indices in the water and sediment of artificial reefs for four seasons.

Seasonality *P*: statistical difference among four seasons; Water-Sediment *P*: statistical difference between water and sediment samples. Significant difference was at $\alpha = 0.05$ level.

1

Season	OTUs		Shannon		Simpson		Ace		Chao 1		Coverage

Table 2 (on next page)

The effects of habitat, season and site on bacterial communities (OTU level) based on PERMANOVA and ANOSIM. Interaction effects were only calculated by PERMANOVA.

F: the test statistical significance of Permutational multivariate analysis of variance

(PERMANOVA); *R*: the test statistical significance of analysis of similarities (ANOSIM); *P*:

statistical significance value at $\alpha = 0.05$ level.

1

Habitat	Effect	PERMANOVA		ANOSIM	
		<i>F</i>	<i>P</i>	<i>R</i>	<i>P</i>
