

Pore size is a critical parameter for obtaining sustained protein release from electrochemically synthesized mesoporous silicon microparticles

Ester E. Pastor, Elaine Reguera-Nuñez, Eugenia Matveeva, Marcos Garcia-Fuentes

Mesoporous silicon has become a material of high interest for drug delivery due to its outstanding internal surface area and inherent biodegradability. We have previously reported the preparation of mesoporous silicon microparticles (MS-MPs) synthesized by an advantageous electrochemical method, and showed that due to their inner structure they can adsorb proteins in amounts exceeding the mass of the carrier itself. Protein release from these MS-MPs showed low burst effect and fast delivery kinetics with complete release in a few hours. In this work, we explored if tailoring the size of the inner pores of the particles would retard the protein release process. To address this hypothesis, three new MS-MPs prototypes were prepared by electrochemical synthesis, and the resulting carriers were characterized for morphology, particle size, and pore structure. All MS-MP prototypes had 90 μm mean particle size, but depending on the current density applied for synthesis, pore size changed between 5 and 13 nm. The model protein α -chymotrypsinogen was loaded into MS-MPs by adsorption and solvent evaporation. In the subsequent release experiments, no burst release of the protein was detected for any prototype. However, prototypes with larger pores (>10 nm) reached 100% release in 24-48 h, whereas prototypes with small mesopores (<6 nm) still retained most of their cargo after 96 h. MS-MPs with ~ 6 nm pores were loaded with the osteogenic factor BMP7, and sustained release of this protein for up to two weeks was achieved. In conclusion, our results confirm that tailoring pore size can modify protein release from MS-MPs, and that prototypes with potential therapeutic utility for regional delivery of osteogenic factors can be prepared by convenient techniques.

15 **ABSTRACT**

16

17 Mesoporous silicon has become a material of high interest for drug delivery due to its
18 outstanding internal surface area and inherent biodegradability. We have previously reported the
19 preparation of mesoporous silicon microparticles (MS-MPs) synthesized by an advantageous
20 electrochemical method, and showed that due to their inner structure they can adsorb proteins in
21 amounts exceeding the mass of the carrier itself. Protein release from these MS-MPs showed low
22 burst effect and fast delivery kinetics with complete release in a few hours. In this work, we
23 explored if tailoring the size of the inner pores of the particles would retard the protein release
24 process. To address this hypothesis, three new MS-MPs prototypes were prepared by
25 electrochemical synthesis, and the resulting carriers were characterized for morphology, particle
26 size, and pore structure. All MS-MP prototypes had 90 μm mean particle size, but depending on
27 the current density applied for synthesis, pore size changed between 5 and 13 nm. The model
28 protein α -chymotrypsinogen was loaded into MS-MPs by adsorption and solvent evaporation. In
29 the subsequent release experiments, no burst release of the protein was detected for any
30 prototype. However, prototypes with larger pores (>10 nm) reached 100% release in 24-48 h,
31 whereas prototypes with small mesopores (<6 nm) still retained most of their cargo after 96 h.
32 MS-MPs with ~ 6 nm pores were loaded with the osteogenic factor BMP7, and sustained release
33 of this protein for up to two weeks was achieved. In conclusion, our results confirm that tailoring
34 pore size can modify protein release from MS-MPs, and that prototypes with potential
35 therapeutic utility for regional delivery of osteogenic factors can be prepared by convenient
36 techniques.

42 1. INTRODUCTION

43

44 Mesoporous silicon (MS)-based materials are currently investigated in a variety of systems for
45 drug delivery and tissue engineering applications (Anglin et al., 2008; Santos, 2014). Their main
46 advantage lies on their outstanding surface area arising from the fine mesoporous structure that
47 allows remarkable drug loadings to be achieved just by plain adsorption (Prestidge et al., 2008).

48 MS is also biocompatible (Canham 1995; Godin et al., 2008; Salonen et al., 2008), and degrades
49 in the body to silicates (SiO_2) (Canham 1995; Salonen et al., 2008; Pastor et al., 2009) that are
50 eliminated by renal excretion (Poplewell et al., 1998). Silicates have FDA GRAS status, and

51 even safety margins for silica nanoparticles administered intravenously start to be established
52 (Yu et al., 2013). Inspired by these properties, researchers have investigated silicon-based

53 carriers in a variety of formats (i.e. scaffolds, microparticles, nanoparticles, etc.) for delivering
54 hydrophobic and hydrophilic drugs (Anglin et al., 2008; Prestidge et al., 2008; Salonen et al.,
55 2008). MS-based materials have also been proposed for delivering drug-loaded nanoparticles
56 within the concept of multistage delivery vehicles (Tasciotti et al., 2008).

57 Devices composed of a crystalline mesoporous silicon matrix are alternatives to silica
58 mesoporous structures (Kresge et al., 1992), but unlike those, they do not require a mesophase
59 template removal for their preparation. Mesoporous silicon can be prepared by stain-etching or
60 electrochemical anodizing of silicon. Both methods result in suitable mesoporous

61 (nanostructured) materials, but the stain-etching method is less controlled with respect to pore
62 homogeneity, and often leaves an untreated crystalline silicon core inside the particles. Medical
63 materials prepared from stain-etched mesoporous silicon should be additionally checked for
64 complete removal of toxic nitric oxide residues. The electrochemical method for MS production
65 is therefore more medical-friendly, and recently its scalability has been considerably improved
66 (Makushok, Matveyeva & Pastor, 2012).

67 The desired nanostructure of MS fabricated by electrochemical methods can be easily achieved
68 by a simple tuning of the preparation conditions, first of all, the applied current density. Even
69 though these inner nanostructure parameters (pore size, overall porosity, particle size, etc.) are
70 important for MS silicon drug carriers, they cannot assure by themselves optimal drug payloads.
71 The interaction between the drug and the carrier surface needs also to be engineered, and thus the
72 surface modification and functionalization of MS nanostructures has been extensively studied in
73 recent years (Jarvis, Barnes & Prestidge, 2011; 2012; Barnes, Jarvis & Prestidge, 2013). Among
74 different techniques, a simple oxidation is frequently performed that converts the outer surfaces
75 of crystalline mesoporous silicon to a mesoporous silica replica (Kresge et al., 1992).

76 In a previous publication from our group, MS microparticles (MS-MPs) with an average pore
77 size of 35 nm were prepared by an electrochemical method and stabilized by thermal oxidation.
78 These MS-MPs were successfully loaded by absorption equilibrium with two model proteins,
79 insulin and bovine serum albumin BSA (Pastor et al., 2011). Although these proteins were
80 released from a vehicle in a controlled manner, the process was fast (~80-100% release in less
81 than 2 h), and consequently only suitable for some applications such as mucosal drug delivery.
82 Previous studies with hydrogels (Peppas et al., 2000), solid polymers (Sandor et al., 2001), and
83 other mesoporous materials (Santos, Radin & Ducheyne, 1999) have shown that modulation of

84 the inner nanostructure of the carrier can change the kinetics of drug release. We proposed that
85 similar principles should apply for controlling the release of proteins from electrochemically
86 synthesized MS-MPs. To address this hypothesis, we prepared MS-MPs with different pore sizes
87 and explored how changes in inner nanostructure can influence the release of loaded proteins.
88 This study was performed initially with the model protein α -chymotrypsinogen (aCT); then,
89 considering the bioactivity of MS materials for orthopedic regeneration (Canham, Reeves &
90 Newey, 1999; Pastor et al., 2007; Sun et al., 2007), we loaded a protein of therapeutic interest for
91 this application, bone morphogenetic protein-7 (BMP7).

92

93 **2. MATERIALS AND METHODS**

94

95 *2.1. Materials*

96 Boron doped silicon with different resistivity, 0.01–0.02 and 10–20 $\Omega \cdot \text{cm}$, was purchased from Si
97 Materials (Germany); wafer diameter was 100.0 ± 0.5 mm and thickness of 525 ± 25 μm ($\text{pI} = 2$ –
98 3.5). Fluoric acid (HF) (48 %) was purchased from Riedel de Haën (Germany) and ethanol
99 (96%) from Panreac (Spain). Synthetic air (N_2 with 21% of O_2) was provided from AbelloLinde
100 S.A. (Spain). Avidin-peroxidase conjugate, α -chymotrypsinogen A (aCT) from bovine pancreas
101 ($\text{pI} = 9.5$; $\text{Mw} = 25.7$ kDa), and 2,2'-azino-bis(3-ethylbenzthiazoline-6-sulfonic acid) were
102 obtained from Sigma Aldrich (Spain). Recombinant human Bone Morphogenetic Protein-7
103 (BMP7) ($\text{pI} = 8.1$; $\text{Mw} = 28.8$ kDa), polyclonal antibody rabbit anti-human BMP7, and
104 biotinylated polyclonal antibody rabbit anti-human BMP7 were purchased from PeproTech
105 (UK). All other solvents and chemicals used were high-grade purity.

106

107 2.2. Preparation of mesoporous silicon microparticles (MS-MPs)

108 MS-MPs were obtained by an electrochemical method similar to that previously described by us
109 (Pastor et al., 2009). The main difference was the use of a 1:1 HF:Ethanol electrolyte, and special
110 cyclic regimes with etch-stops in order to improve the homogeneity of pore sizes distribution
111 along with the in-depth etching (Bychto et al., 2008). A constant current step (40 or 60 mA/cm²
112 for 5-10 s) was followed by an etch-stop step (no current applied for 2-5 s) in cyclic periods.
113 After obtaining a MS layer of ~150 μm thickness, the electrochemical process was stopped, and
114 the Si wafer was washed thoroughly with distilled water, dried, and the porous material was
115 scratched from the remaining Si substrate. The obtained MS was subjected to a thermal oxidation
116 under a flow of synthetic air for 1 hour at 500 or 650 °C (Programat P200 equipped with a
117 vacuum pump VP3 and gas inlet, Ivoclar-Vivadent, Inc., US). To reduce the particle size to the
118 micrometer scale, the MS material was milled and sieved in cascade. The fraction between 75
119 and 100 μm was selected for further studies. Henceforth, this fraction is referred to as MS-MPs.
120 The preparation conditions for the three different MS-MP prototypes studied in this work are
121 summarized in Table 1. For example, prototype B was prepared from Si wafer of 0.01-0.02
122 Ω·cm resistivity, under a current density of 40 mA/cm² applied for 10 s, and then interrupted by
123 a 2 s interval of zero current (etch-stop). This regime was cyclically repeated for a few hours
124 until the 150 μm porous layer was grown. After recollecting the porous material, the material
125 was thermally oxidized at 650 for one hour.

126

127 2.3. Characterization of MS-MPs

128 The porosity of the porous silicon materials was determined gravimetrically by comparing the
129 mass of the silicon wafer before and after anodizing as previously described (Pastor et al., 2011).

130 Particle sizes were analyzed with a Mastersizer 2000 (Malvern Instruments, UK). MS-MPs
131 morphology was visualized by high resolution Scanning Electron Microscopy (SEM, Hitachi
132 S4500, Japan). Additionally, the Brunauer- Emmett-Teller (BET) surface area of the MS-MPs
133 was determined by N₂ adsorption–desorption isotherms (Micrometrics ASAP 2020 V3.04H,
134 Micromeritics France S.A., France). Pore size was calculated from the same N₂ adsorption data,
135 by the Barroett-Joyner-Halenda (BJH) method.

136

137 *2.4. Protein loading*

138 Protein loading was carried out by solvent evaporation (Prestidge et al., 2008). Briefly, 20 µL of
139 the model protein aCT (3 mg/mL) or BMP7 (5 µg/mL) in aqueous solutions were added to a
140 fixed amount of MS-MPs (1 mg). The samples were gently vortexed for 10 seconds, and then
141 incubated under mild agitation at 37 °C until total evaporation of solvent was reached and all
142 amounts of proteins incorporated into the MS-MPs (about 7 hours). The theoretical protein
143 loadings were: 60 µg/mg of MS-MPs for aCT, and 0.1 µg/mg of MS-MPs for BMP7. Loaded
144 MS-MPs were freeze-dried and stored at -20 °C until use.

145

146 *2.5. In vitro release studies*

147 Samples comprising 1 mg of MS-MPs loaded with aCT or BMP7 were incubated with 500 µL of
148 PBS (USP 38-NF 33, pH 7.4) under agitation (100 rpm, Heidolf, Titramax 1000, Germany) at
149 37 °C (Heidolf, Inkubator 1000, Germany). At scheduled time points, release samples were
150 collected, and centrifuged at 7000 RCF for 10 min at 4 °C (Beckman Coulter, Microfuge 22R).
151 The amounts of aCT in supernatants were determined by the bicinchoninic acid method (Micro
152 BCA protein Assay Kit, Pierce Biotechnology Inc., USA), and those of BMP7 by ELISA, as

153 previously reported by us (Reguera-Nuñez et al., 2014). Amounts of released protein are
154 expressed as percentage of a total protein mass added at the loading stage since the whole mass
155 was considered as absorbed upon solvent evaporation.

156

157

158

159 **3. RESULTS AND DISCUSSION**

160

161 *3.1 Characterization of different MS-MPs carriers*

162 Mesoporous silicon microparticles (MS-MPs) were prepared by electrochemical etching,
163 thermal stabilization, and milling to reduce the particle sizes. The resulting powder was sorted
164 by sieving. The particles of the selected fraction (i.e. the MS-MPs) were irregular in shape, but
165 homogeneous in size (Fig. 1A). All the MS-MPs prototypes generated showed a normal
166 distribution of sizes with a mean value around 90 μm (Figure 1B). This normal particle
167 distribution contrasted with our previous data where the particle distribution was log-normal
168 (Pastor et al., 2011); this might be related to the different particle fractions selected on each
169 work (90 μm vs 33 μm mean size, respectively). The mesoporous structure of MS-MPs
170 observed by high resolution SEM (Fig. 1C) revealed the regular and homogeneous pores
171 propagated along a single direction, as it is common for electrochemically prepared MS. The
172 SEM analysis, however, might not reveal the smallest pores of the materials due their well-
173 known resolution limits.

174 The inner structure for three different MS-MP prototypes (A-C) prepared under the conditions
175 summarized in Table 1 was characterized by N_2 adsorption-desorption experiments (Fig. 1D).

176 The data revealed very high specific surface areas for prototypes A and B ($>200 \text{ m}^2/\text{g}$), but even
177 more for prototype C ($350 \text{ m}^2/\text{g}$) (Table 2). The porosity of all samples was high ($>50\%$), and
178 the mean pore diameter was $\sim 12 \text{ nm}$ for prototypes A and B, and $\sim 6 \text{ nm}$ for prototype C. These
179 pore sizes were significantly smaller than MS-MPs prepared in our previous work (Pastor et al.,
180 2011), a result of the different preparation conditions. Due to their tighter internal structure, we
181 expected that the MS-MPs obtained in this work would be more suitable for the sustained
182 release of proteins.

183 Due to the limited number of prototypes studied and the important difference in parameters
184 observed, it is difficult to draw unequivocal conclusions on the relationships between the MS-
185 MPs preparation parameters (Table 1) and the resulting carrier properties (Table 2). Still, under
186 the tested preparation conditions, there is a positive correlation between the current density and
187 the specific surface area. Also, an inverse correlation between the applied current density and the
188 mean pore diameter can be noted, although the doping level of Si wafer might play a dominant
189 role in this correlation. Globally, the study confirms the possibility to prepare MS-MPs with
190 controllable mesoporous inner structures by the electrochemical method.

191

192 *3.2. Protein loading in MS-MPs*

193 After characterization of the different MS-MP prototypes, we characterized how these systems
194 are capable of loading and releasing two proteins, aCT and BMP7. The zymogen aCT was
195 selected as a model protein for screening studies since it has very similar physicochemical
196 properties (pI and Mw) to BMP7 (see data on section 2.1), and we have previously observed
197 good correlation between encapsulation of both proteins (Reguera-Nuñez et al., 2014). ACT is a
198 zymogen physiologically activated by gut's endopeptidases, and does not activate under the

199 conditions of the loading procedures and release tests applied in this work. For protein loading in
200 this work we decided to work under forcing conditions, and we evaporated a protein solution in
201 the presence of the MS-MPs at 37°C. This method has the main advantage of forcing protein
202 encapsulation, which can be assumed to be close to 100%. Because MS-MPs cannot be degraded
203 without harming the loaded protein, we were unable to quantify the loaded proteins. However,
204 from the final release point of our release studies (see 3.3 and 3.4), we can conclude that > 75%
205 of aCT was loaded in all preparations, and >60% of BMP7.

206 When using this loading method, the mechanisms that drive protein loading would be capillary
207 forces and adsorption from a continually concentrating solution (Karlsson et al., 2003). Other
208 possible mechanisms would be electrostatic interactions; after thermal oxidation the MS-MPs
209 surface bears a negative charge as the silicon oxides cover the entire porous network (Zangoie,
210 Bjorklund & Arwin, 1998). This might affect the loading and release of cationic proteins such as
211 aCT and BMP7. Under the tested conditions, the final protein payloads per mg of the carrier
212 were 60 µg for aCT and 0.1 µg for BMP7.

213

214 3.3 Pore size can control the release of a model protein (aCT) from MS-MPs

215 The release of loaded aCT from the three MS-MPs prototypes was analyzed *in vitro* (PBS,
216 37°C). No burst release was observed for any of the tested prototypes, suggesting that most
217 protein is inside the pores and not adsorbed on the outer MS-MP surface (Fig. 2A). This
218 behavior is in agreement with our previous study on insulin and BSA, where despite of a faster
219 release (<2 h), only a moderate burst effect was observed (~30%) (Pastor et al., 2011). In the
220 present work, the burst effect was drastically reduced, presumably because of lower pore size of

221 carriers, and because of the different procedures for protein loading (solvent evaporation vs.
222 adsorption equilibrium).

223 The MS-MPs investigated in this work were able to control protein release for longer periods of
224 time than the carriers previously reported by us (Pastor et al., 2011): for prototypes A and B a
225 ~100% release was achieved in 30-40 h after incubation at 37°C in PBS. Prototype C showed
226 even more sustained kinetics with high retention of aCT still after 96 h (Fig. 2A). However,
227 after 2-weeks, sample C had released a $77.2\% \pm 4.2$ (n=3) of the loaded aCT. The slower
228 release should be associated with the nanostructure of the carriers, mainly to their pore size.
229 Mean pore size was <15 nm for all prototypes studied here, and 33 nm in our previous work.
230 Prototype C possesses pores with a mean size of ~6 nm, half of those of prototypes A and B,
231 and similar to the radius of gyration of aCT, 1.76 nm (Perkins et al., 1993). As observed in other
232 systems (Santos, Radin & Ducheyne, 1999; Peppas et al., 2000; Sandor et al., 2001), when the
233 drug's radius of gyration is about the size of pores in the matrix, diffusion might be hindered,
234 and more sustained release kinetics achieved. When comparing the different prototypes studied
235 in this work, particle inner structure seems to be the critical factor modulating different release
236 kinetics.

237 When comparing the performance of the MS-MP prototypes from this work with those of our
238 previous work (Pastor et al., 2011), two additional factors need to be considered. First, the
239 effect of the chemical differences of the proteins tested. Insulin and BSA, used before, both bear
240 negative charges in PBS, and therefore, their attachment to MS-MPs surfaced by adsorption
241 should be driven mostly by hydrophobic interactions. On the other hand, aCT is positive in PBS,
242 and therefore, ionic interactions with the silicon oxide on the surface of MS-MPs can be
243 important to explain protein adsorption/desorption. Another parameter that could have some

244 limited influence on protein release is the average particle dimensions, which was 33 μm in our
245 previous work, and is 90 μm here (Pastor et al., 2011). Particle dimension will influence the
246 diffusion length within the carrier for the protein. Recently, a new production method yielding
247 planar mesoporous silicon microparticles with a controlled thicknesses, porosity and pore sizes
248 has been reported (Makushok, Matveyeva & Pastor, 2012). This new kind of materials might be
249 interesting for release mechanism studies since their lateral dimensions, perpendicular to the
250 pore axis, will play no important role in the release process.

251

252 *3.4 MS-MPs can achieve a 2-week sustained release of antigenically active BMP7*

253 Based on promising data obtained with aCT protein, we tested MS-MP prototype C for the
254 controlled release of a therapeutic protein: BMP7. This protein is approved by FDA and other
255 regulatory agencies for orthopedic applications (OP-1 Putty and OP-1 Implant, Stryker, US),
256 and it is delivered through a collagen sponge with limited controlled release properties. This
257 limited controlled release has been linked to most of the treatment undesirable effects (Lane,
258 2001). MS-MPs were loaded with BMP7 as described in section 3.2, and the release kinetics of
259 the protein was analyzed. Consistently with the data obtained with aCT, a 2-week sustained
260 release was achieved (Fig. 2B). Once again, the release kinetics was characterized by low burst
261 (<10%), and by a sustained release profile for at least 14 days. Maximum release observed over
262 the experiment (28 days) was ~70%. Noteworthy, the quantification of BMP7 in the supernatant
263 was performed by ELISA, and thus, it guarantees the presence of the protein in its antigenically-
264 active form upon release. While antigenic activity is not a final proof of biological activity,
265 previous studies from our group using the same ELISA kit have found a relation between

266 antigenic BMP7 and bioactive protein in a glioblastoma cancer stem cell model (Reguera-
267 Nuñez et al., 2014).

268 The release profile was fitted to zero-order, first-order, Higuchi and to the Kosmeyer-Peppas
269 models (Wizard - Statistics, Visualization, Data Analysis, Predictive Modeling, version 1.4,
270 Evan Miller[©], US). Fitting to the first-order and Higuchi models was adequate ($p < 0.008$ and
271 $p < 0.002$, respectively), but the best fit was achieved with the Kosmeyer-Peppas model (BMP
272 released% = $10.4 \cdot t \text{ (days)}^{0.64}$, $p < 0.001$). The Kosmeyer-Peppas model is effective to describe
273 release systems where release kinetics might depend on several factors. The diffusional
274 exponent ($n = 0.64$) indicates a process of anomalous diffusion (Korsmeyer et al., 1983; Peppas,
275 1985).

276 The similarities between aCT and BMP7 release kinetics reflect their similar physicochemical
277 properties. Indeed, BMP7 has a radius of gyration ~ 3.5 nm (by analogy with other BMPs,
278 (Berry et al., 2006)) just slightly larger than aCT. It has also a basic isoelectric point (8.1) close
279 to that of aCT (9.5). These similarities result in consistent profiles for both proteins, and suggest
280 the robustness of the delivery technology.

281 In summary, we have achieved sustained release of BMP7 for at least two weeks by using
282 electrochemically synthesized MS-MPs. A preparation technology for the whole therapeutic
283 system is convenient, since both components, protein solution and pre-formed empty MS-MPs,
284 can be integrated together in an extemporaneous process. Due to the recently reported
285 osteointegration properties of the MS-MP carrier itself (Sun et al., 2007), one of the immediate
286 promising applications of this system would be in the bone regeneration area.

287

288 **4. CONCLUSIONS**

289

290 Mesoporous silicon microparticles with controlled inner structure (pore size) can be prepared by
291 an electrochemical method, and loaded with proteins by simple adsorption and solvent
292 evaporation. Under optimized electrochemical conditions these microparticles present a
293 nanostructure with pore sizes below 10 nm, and this small pore size is critical to provide
294 sustained release over several days for proteins . The medical potential of the electrochemically
295 synthesized mesoporous silicon microparticles is suggested by the two weeks sustained release
296 profile of the osteogenic factor BMP7.

Table 1 (on next page)

Table 1

Table 1 - Preparation conditions for different mesoporous silicon prototypes synthesized by the electrochemical method under special cyclic regimes with etch-stop (zero current) applied after each anodizing interval. Three different prototypes (A-C) were prepared and tested in this study, differing in silicon wafer resistivity, current densities, etch-stop times, and thermal oxidation temperatures.

Prototype	Si wafer resistivity (Ωcm)	Current density (mA/cm ²)/ anodizing time (s)	Etch stop time (s)	Oxidation temperature ($^{\circ}\text{C}$)
A	0.01-0.02	40 / 5	5	500
B	0.01-0.02	40 / 10	2	650
C	10-20	60 / 5	2	550
