Sauropods are familiar dinosaurs, immediately recognisable by their great size and long necks. However, their necks are much less well known than is often assumed. Surprisingly few complete necks have been described in the literature, and even important specimens such as the Carnegie *Diplodocus* and *Apatosaurus*, and the giant Berlin brachiosaur, in fact have imperfectly known necks. In older specimens, missing bone is often difficult to spot due to over-enthusiastic restoration. Worse still, even those vertebrae that are complete are often badly distorted — for example, in consecutive cervicals of the Carnegie *Diplodocus* CM 84, the aspect ratio of the posterior articular facet of the centrum varies so dramatically that C14 appears 35% broader proportionally than C13. And even in specimens where the cervicodorsal sequence is preserved, it is often difficult or impossible to confidently identify which vertebra is the first dorsal. Widespread incompleteness and distortion are both inevitable due to sauropod anatomy: large size made it almost impossible for whole individuals to be preserved because sediment cannot be deposited quickly enough to cover a giant carcass on land; and distortion of presacral vertebrae is common due to their lightweight hollow construction. This ubiquitous incompleteness and unpredictable distortion compromise attempts to mechanically analyze necks, for example to determine habitual neck posture and range of motion by modelling articulations between vertebrae.

## 9 **Abstract**

10 Sauropods are familiar dinosaurs, immediately recognisable by their great size and long  
11 necks. However, their necks are much less well known than is often assumed. Surprisingly few  
12 complete necks have been described in the literature, and even important specimens such as the  
13 Carnegie *Diplodocus* and *Apatosaurus*, and the giant Berlin brachiosaur, in fact have imperfectly  
14 known necks. In older specimens, missing bone is often difficult to spot due to over-enthusiastic  
15 restoration. Worse still, even those vertebrae that are complete are often badly distorted — for  
16 example, in consecutive cervicals of the Carnegie *Diplodocus* CM 84, the aspect ratio of the  
17 posterior articular facet of the centrum varies so dramatically that C14 appears 35% broader  
18 proportionally than C13. And even in specimens where the cervicodorsal sequence is preserved,  
19 it is often difficult or impossible to confidently identify which vertebra is the first dorsal.  
20 Widespread incompleteness and distortion are both inevitable due to sauropod anatomy: large  
21 size made it almost impossible for whole individuals to be preserved because sediment cannot be  
22 deposited quickly enough to cover a giant carcass on land; and distortion of presacral vertebrae is  
23 common due to their lightweight hollow construction. This ubiquitous incompleteness and  
24 unpredictable distortion compromise attempts to mechanically analyze necks, for example to  
25 determine habitual neck posture and range of motion by modelling articulations between  
26 vertebrae.

## 30 Introduction

31 In a paper on how the long necks of sauropods did not evolve primarily due to sexual  
 32 selection (Taylor et al. 2011), one of the ideas we discussed is that sexual dimorphism between  
 33 the necks of male and female sauropods, expressed as a ratio of neck lengths to shoulder height,  
 34 might be an indicator of sexual selection. Rather despairingly, we wrote (Taylor et al. 2011:4):  
 35 “Available samples of sauropod taxa are unfortunately not large enough to demonstrate bimodal  
 36 distribution of morphological features within any sauropod species.”

37 Sauropod specimens are rarely found in a form complete enough to allow even relatively  
 38 rudimentary measurements to be made — for example, neck length or shoulder height. In fact,  
 39 the problem is more significant than is generally realised. It is not just that we do not have large  
 40 populations of well-preserved sauropod individuals, capable of being subject to statistical  
 41 analyses; even individual complete sauropods are extremely rare. This is true especially of the  
 42 necks, which are composed of large, fragile vertebrae that are prone to disarticulation and  
 43 distortion.

44 The consequent incompleteness of known sauropod necks, and the ubiquitous distortion of the  
 45 elements that are available, has negative consequences for taxonomic work (since we are  
 46 frequently unable to compare overlapping elements of different specimens), phylogenetic  
 47 analysis (due to loss of character data), developmental studies (as we are frequently unable to  
 48 determine for example how pneumatic features vary along the neck in patterns mimicking  
 49 ontogeny), biomechanical function (since we do not have sufficiently precise joint anatomy to  
 50 accurately model neutral posture or range of motion) and ecological impact (using neck length as  
 51 a proxy for feeding behaviour). While these problems are appreciated by seasoned campaigners,  
 52 they are less well understood by newcomers to the field and to those whose specialisms are in  
 53 adjacent fields such as extant animal anatomy, especially as most people’s initial impressions of

54 sauropod are formed by large and apparently complete mounted specimens in public galleries.

55 In this paper I will first show that even the best-preserved and best-known sauropod  
56 specimens mostly have necks that are incomplete, then show that distortion of what cervical  
57 vertebrae we do have is ubiquitous and unpredictable, and finally explore the implications of this  
58 on what we can know of how these necks behaved in life.

## 95 **Incompleteness**

96 A truly complete neck would consist of all vertebrae, each of them individually complete.  
 97 Unfortunately, it is rarely possible to tell from published descriptions whether a given neck is  
 98 complete in this sense: necks are sometimes described superficially as “complete” when all that  
 99 is meant is that some portion of each vertebra is preserved. In the cases of necks that are  
 100 described in detail, it is almost always apparent that a “complete” neck is complete only in this  
 101 limited sense: for example, in the *Cathetosaurus lewisi* holotype BYU 9047, McIntosh et al.  
 102 (1996:76) note that although all 12 cervicals are present, “10–12, particularly 12, have suffered  
 103 such severe damage that it is impossible to restore them”. For the purposes of this paper, then we  
 104 use “complete” in the unsatisfactory sense that at least a good part of each vertebra is present.

105 The determination of completeness of necks is also hindered by the problem that for many  
 106 species we do not know how many vertebrae would constitute a complete neck. When necks are  
 107 not found in articulation but a probably complete set of cervicals is found scattered, the  
 108 possibility that additional vertebrae were present in life cannot be discounted. The mode of  
 109 preservation can vary wildly with disarticulated necks, giving us a greater or lesser degree of  
 110 confidence that all vertebrae are present. At one end of the spectrum, vertebrae may be scattered  
 111 around, and intermixed with those of other species or even other individuals of the species, as  
 112 with the numerous cervical vertebrae included in the *Camrasaurus specimen* complex AMNH  
 113 5761/5761a and assigned somewhat arbitrarily to three sequences (Osborn and Mook 1921:plates  
 114 LXVII–LXIX). In happier cases, such as that of the *Qijianglong guokr* holotype QJGPM 1001,  
 115 partial sequences are articulated (in this case C2–11) and other cervicals closely associated.  
 116 However, even a neck found in articulation may be impossible to evaluate as to its completeness,  
 117 as with *Lavocatisaurus agrioensis* (see below).

118 With these caveats in mind, I now survey the known complete and nearly-complete sauropod  
 119 necks.

## 120 **Catalogue of complete necks**

121 Unambiguously complete necks are known from published accounts of only a few sauropod  
 122 specimens. In chronological order of description, the following specimens were found with their  
 123 necks complete and articulated, and have been adequately described:

- 124 • CM 11338, a referred specimen of *Camarasaurus lentus* described by Gilmore (1925).  
 125 This is a juvenile specimen, and thus does not fully represent the adult morphology.  
 126 (McIntosh et al. 1996:76 claim that this specimen is the holotype, but this is not correct:  
 127 YPM 1910 is the holotype — see below.)
- 128 • CM 3018, the holotype of *Apatosaurus louisae*, described by Gilmore (1936). The neck  
 129 was separated from the torso but articulated from C1–C15, though the last three cervicals  
 130 were badly crushed: see below for details.

- 131 • CCG V 20401, the *Mamenchisaurus hochuanensis* holotype, described by Young and  
132 Zhao (1972). Each vertebra is broken in half at mid-length, with the posterior part of each  
133 adhering to the anterior part of the its successor; and all the vertebrae are badly crushed in  
134 an oblique plane.
- 135 • ZDM T5402, a *Shunosaurus lii* referred specimen, described in Chinese by Zhang  
136 (1988), with English figure captions. Their figure 22 depicts the atlas. Unlike the  
137 holotype T5401, this specimen is mature.
- 138 • BYU 9047, the *Cathetosaurus lewisi* holotype, described by Jensen (1988). (Jensen  
139 incorrectly gives the specimen number as BYU 974.) This specimen was redescribed, and  
140 the species referred to *Camarasaurus*, by McIntosh et al. (1996). Although all 12  
141 cervicals are present, “10–12, particularly 12, have suffered such severe damage that it is  
142 impossible to restore them” (McIntosh et al. 1996:76).
- 143 • MACN-N 15, the holotype of *Amargasaurus cazau* MACN-N 15, described by Salgado  
144 and Bonaparte (1991) who described “22 presacral vertebrae articulated with each other  
145 and attached to the skull and sacrum, relatively complete” (Salgado and Bonaparte  
146 1991:335, translated).
- 147 • ZDM 0083, the holotype of *Mamenchisaurus youngi*, described in Chinese by Ouyang  
148 and Ye (2002) with English figure captions. Their figure 14 depicts the atlas and axis.
- 149 • MUCPv-323, the holotype of *Futalognkosaurus dukei*, initially described by Calvo et al.  
150 2007a and redescribed by Calvo et al. 2007b. The neck was found in two articulated  
151 sections which fit together without needing additional vertebrae in between (Jorge O.  
152 Calvo, pers. comm., 2021).
- 153 • SSV12001, the holotype of *Xinjiangtitan shanshanensis*, described by Zhang et al. (2018).  
154 The original description of this specimen by Wu et al. 2013 included only the last two  
155 cervicals, which were the only ones that had been excavated at that time.

156 A few additional specimens are known to have complete and articulated necks, but have not  
157 yet been described:

- 158 • USNM 13786, a referred subadult specimen of *Camarasaurus lentus* recently mounted at  
159 the Smithsonian. The specimen “was almost completely buried before the sinews had  
160 allowed the bones to separate” (letter from Earl Douglass to William J. Holland, 22  
161 August 1918), and photographs kindly supplied by Andrew Moore show that the atlas  
162 was preserved.
- 163 • MNBH TIG3, the holotype of *Jobaria tiguidensis*. Sereno et al. (1999:1343) assert that  
164 this species has 12 cervicals in all and say “One articulated neck was preserved in a fully  
165 dorsiflexed, C-shaped posture”. Paul C. Sereno (pers. comm., 2021) confirms that the  
166 articulated neck is MNBH TIG3
- 167 • SMA 002, referred to *Camarasaurus* sp. Tschopp et al. (2016), in a description of its feet,  
168 say that this specimen “lacks only the vomers, the splenial bones, the distal end of the  
169 tail, and one terminal phalanx of the right pes. The bones are preserved in three  
170 dimensions and in almost perfect articulation”.
- 171 • MAU-Pv-LI-595, the “La Invernada” Titanosaur. Filippi et al. (2016) give a very brief  
172 account in an abstract. Filippi (pers. comm, 2021) says that the entire preserved specimen  
173 was articulated.
- 174 • MAU-Pv-AC-01, an unnamed titanosaur mentioned in abstracts by Calvo et al. (1997)  
175 and Coria and Salgado (1999). The specimen was found in perfect articulation from skull

176 down to the last caudal vertebrae (Rodolfo A. Coria, pers. comm., 2021).

177 The first cervical (the atlas) in sauropods is very different in form from the other vertebrae,  
178 and small and fragile. Consequently it is easily lost. Some further specimens have necks that are  
179 complete and articulated from C2 (the axis) backwards:

- 180 • MB.R.4886, the holotype of *Dicraeosaurus hansemanni*, described by Janensch (1929),  
181 has a neck that complete and well preserved from C2 to C12 (the last cervical). Janensch  
182 referred to this as “specimen m” and writes “It was found articulated from the 19th  
183 caudal vertebra to the 9th cervical vertebra inclusive. The proximal part of the neck from  
184 the 8th cervical vertebra up to the axis was bent ventrally and lay at right angles to the  
185 distal part of the neck.” (Janensch 1929:41).
- 186 • PMU 233, the holotype of *Euhelopus zdanskyi*, described by Wiman (1929) as “exemplar  
187 a” and redescribed by Wilson and Upchurch (2009).
- 188 • ZDM T5401, the subadult holotype of *Shunosaurus lii*, described in Chinese by Zhang et al.  
189 1984. The quarry map (Zhang et al. 1984:figure 1) suggests that the atlas is missing.
- 190 • MCT 1487-R, informally known as “DGM Series A”, described by Powell (2003).  
191 Gomani (2005:9) summarises as “12 cervical vertebrae, except the atlas, preserved in  
192 articulation with three proximal dorsal vertebrae”.
- 193 • GCP-CV-4229, the holotype of *Spinophorosaurus nigerensis*, described by Remes et al.  
194 (2009). This species is known from two specimens, of which the holotype was found in  
195 very good condition and well articulated from C2 to C13, the last cervical (Figure 1). The  
196 atlas seems to be missing (Kristian Remes, pers. comm., 2021; Ralf Kosma, pers. comm.,  
197 2021).

198 One other sauropod is complete from the first cervical, but probably not to the last:

- 199 • MOZ-Pv1232, the holotype of *Lavocatisaurus agrioensis*, described by Canudo et al.  
200 (2018). This is complete from C1–C11. Canudo’s guess is that this is the complete neck  
201 (Jose I. Canudo, pers. comm, 2021), but the specimen doesn’t demand that conclusion  
202 and no known eusauropod is definitively known to have fewer than 12 cervicals.  
203 However, Upchurch (pers. comm., 2021) notes that the dicraeosaurid neosauropod  
204 *Amargasaurus* has 22 presacral vertebrae in total, and difficulties in locating the  
205 cervicodorsal junction (see below) make it impossible to state confidently whether it had  
206 12 or only 11 cervicals, so caution is warranted here.

207 Other sauropod specimens have necks that are complete and articulated from further back in  
208 the cervical sequence:

- 209 • YPM 1910, the holotype of *Camarasaurus lentus*, a mounted specimen described by Lull  
210 (1930). The neck is complete from C2 or C3, Lull was uncertain which. (It should be  
211 possible to clear that up by re-examining the specimen in light of what has subsequently  
212 become known about *Camarasaurus lentus*, but this work has not yet been done.)
- 213 • SMA 0004, *Kaatedocus siberi*, described by Tschopp and Mateus (2012). Cervicals 3–14  
214 are preserved.
- 215 • AODF 888 (informally “Judy”), probably referable to *Diamantinasaurus*, briefly  
216 described by Poropat et al. (2019). Preserved from C3 or maybe C4. “One posterior  
217 cervical (XIII or XIV) found several metres from articulated series, but appears to slot  
218 nicely into the gap between the articulated cervical series and the unprepared thoracic

219 section, which might include at least one additional cervical (XIV or XV)” (Poropat, pers.  
220 comm. 2021).

221 Several necks are probably nearly complete, but it is not possible to know due to their not  
222 being found in articulation:

- 223 • CM 84, the holotype of *Diplodocus carnegii*, described by Hatcher (1901). C2–C15 are  
224 preserved, though not all in articulation; C11 may be an intrusion: see below for details.
- 225 • ZDM T5701, the holotype of *Omeisaurus tianfuensis*, described by He et al. (1988). The  
226 neck was not articulated (He et al. 1988:figure 1), and was missing “two elements or so”  
227 (He et al. 1988:120).
- 228 • QJGPM 1001, the holotype of *Qijianglong guokr*, described by Xing et al. (2015). On  
229 page 8, the authors say “The axis to the 11th cervical vertebra were fully articulated in  
230 the quarry. The atlas intercentrum and the 12th–17th cervical vertebrae were closely  
231 associated with the series.”
- 232 • MNBH TIG9, a referred specimen of *Jobaria tiguidensis*. Wilson (2012:103) writes that  
233 this specimen “includes a partially articulated series of 19 vertebrae starting from the axis  
234 and extending through the mid-dorsal vertebrae.”
- 235 • MNBH TIG6, another referred specimen of *Jobaria tiguidensis*, which has not been  
236 mentioned in the literature. Paul C. Sereno (pers. comm., 2021) says that it is “a subadult  
237 partial skeleton with excellent neck” and that “the sequence was articulated from C2–11.  
238 Most of the ribs were attached as well.”

239 **Note.** The *Jobaria tiguidensis* individuals previously had specimen numbers beginning MNN,  
240 but the Musée National du Niger changed its name to Musée National Boubou Hama and the  
241 specimen numbers have changed with it.

242 The breakdown of these complete and near-complete necks is interesting (Figure 2). Non-  
243 neosauropods are relatively well represented, both inside and outside of Mamenchisauridae —  
244 although it is unfortunate many of these specimens are not well described in English: two of  
245 the ten are of *Jobaria*, for which the cursory summary of Sereno et al. (1999) remains the only  
246 published description, and some of the Chinese sauropods are described only in Chinese.

247 Diplodocoids are surprisingly poorly represented, with only a single specimen in each of  
248 Dicraeosauridae and Diplodocidae that is complete. Brachiosaurids have absolutely no  
249 representation — see below on how unconvincing the neck of *Giraffatitan* is. More advanced  
250 titanosauriforms are better represented, but there is still only one with a complete neck,  
251 *Futalognkosaurus dukei*. By contrast, the single genus *Camarasaurus* is very well represented,  
252 with five specimens of which four are fully complete (though only two of those have been  
253 described). Probably this does not indicate a taxon-specific taphonomic signal, but follows from  
254 the sheer abundance of *Camarasaurus* specimens — an abundance likely influenced by over-  
255 lumping of multiple rather different species into a single genus.

256 It is surprising, though, that the second and third best represented sauropods in museums,  
257 *Diplodocus* and *Apatosaurus*, are both barely represented in terms of complete necks. And while  
258 the number of complete and nearly-complete necks among somphospondyls, including  
259 titanosaurs, is encouraging, it is disappointing that so many of them are not yet described.

260 At the time of writing, the Paleobiology Database (<https://paleobiodb.org/>) lists more than 270  
261 sauropod species. The nine unambiguously complete and articulated necks therefore represent

262 only one in 30 known sauropod species — and recall that even these are mostly “complete” only  
 263 in the weak sense of preserving some part of each cervical vertebra.

264 As best we can tell, only one sauropod species, *Camarasaurus lentus*, is known from more  
 265 than a single complete neck. Of the two individuals, CM 11338 is a juvenile and USNM 13786 is  
 266 a subadult, so the mature morphology is unknown. If we allow necks missing the atlas, then there  
 267 are also two individuals of *Shunosaurus lii*: ZDM T5401, the subadult holotype, which is  
 268 missing its atlas; and ZDM T5402, an adult referred specimen whose neck is complete. (These  
 269 specimens have not been described in English.) With sample sizes this small, it is not possible  
 270 even in principle to determine whether there is a bimodal distribution in the length of any  
 271 sauropod’s neck.

272 Several well-known sauropod specimens are often thought of as having complete, undamaged  
 273 necks, but in each case the truth is less clear. I now discuss three important specimens.

### 274 ***Diplodocus carnegii* CM 84**

275 The Carnegie *Diplodocus* is one of the most recognised dinosaurs in the world: not only is the  
 276 original specimen, CM 84, on display as a mounted skeleton in the Carnegie Museum in  
 277 Pittsburgh, but casts are displayed in many other major museums (e.g. the Natural History  
 278 Museum in London, the Museum für Naturkunde Berlin and the Muséum National d’Histoire  
 279 Naturelle in Paris.) The neck appears complete in these mounted skeletons, with fifteen cervical  
 280 vertebrae, and is illustrated as such by Hatcher (1901: plate 8); Figure 3. However, the situation  
 281 is not as clear as it appears in these exhibits.

282 Holland (1900:816), in the first published account of the Carnegie *Diplodocus*, assigned to  
 283 this specimen only eleven cervicals, noting (on p. 817) that:

284 The cervicals were for the most part interarticulated, all lying in such position as to  
 285 show the serial order [...] Eleven are found in the specimen at the Carnegie Museum,  
 286 atlas and axis being as yet undiscovered.

287 Allowing for the missing atlas and axis, Holland concluded only that the cervical count was  
 288 “at least 13”.

289 However, Hatcher (1900:828–829) corrected this count later the same year:

290 About 45 feet (14 meters) of the vertebral column is preserved in our specimen.  
 291 When discovered the vertebrae did not lie in a connected and unbroken series, yet  
 292 there can be little doubt that they all pertain to the same individual [...]   
 293 Unfortunately no diagram was made, at the time of exhuming the remains, showing  
 294 the relative position of each of the vertebrae in the quarry [...] Early last spring, at  
 295 the request of the writer, Mr. W. H. Reed (who assisted in unearthing the skeleton),  
 296 while again on the ground, made a diagram of the quarry, showing the relative  
 297 positions, as he remembered them, of the various bones of the skeleton.

298 Despite this uncertainty, Hatcher asserted (p. 828–829):

299 “In all 41 vertebrae are represented, including 14 cervicals (all but the atlas) [...]   
 300 Assuming that no vertebrae are missing from our series the vertebral formula of  
 301 *Diplodocus* should now be written as follows: Cervicals, 15 [...] The number of  
 302 cervical vertebrae in *Diplodocus* is definitely fixed at at least 15.”

303 Hatcher's 1900 paper is unsatisfactory in that it gives no reason for his revision of the cervical  
304 count. Hatcher also hedged by leaving open the possibility of there being more than 15 cervicals.  
305 The lack of a reliable quarry map is unfortunate.

306 In his subsequent monograph, Hatcher (1901:4) expanded on the completeness and condition  
307 of the material as follows (emphasis added):

308 [Diplodocus carnegii holotype CM 84] has been entirely freed from the matrix and is  
309 found to consist of [appendicular material and] forty-one vertebrae divided as  
310 follows: fourteen cervicals including the axis, eleven dorsals, four sacrals, and twelve  
311 caudals. These vertebrae are for the most part fairly complete, though unfortunately  
312 the sacrals and **anterior cervicals are more or less injured**. This series of forty-one  
313 vertebrae are believed to pertain to one individual and to form an unbroken series  
314 from the axis to the twelfth caudal, although as was shown in a previous paper, **there**  
315 **is some evidence that there are perhaps one or more interruptions in the series**  
316 **and that one or more vertebrae are missing**. On the other hand, as will appear  
317 later, **it is not entirely impossible that at least one vertebra of this supposed**  
318 **series pertains to a second individual** belonging perhaps to a distinct genus.

319 Hatcher (1901:11) went on to quote a statement from A. S. Coggeshall, who had assisted in  
320 the excavation, explaining in more detail how the elements of the neck were discovered:

321 [The] last (fifteenth) cervical was considerably removed from the succeeding dorsals  
322 and less so from the preceding cervicals. Commencing with the next vertebra  
323 (cervical fourteen), the direction of the entire cervical series was altered so that it lay  
324 with its axis almost at right angles to that of the dorsal series. The cervicals extended  
325 in an almost straight line from the fourteenth to the fifth, but there was a considerable  
326 gap between cervicals eleven and ten, while the axis and cervicals three, four and  
327 five were doubled back under the succeeding vertebrae.

328 This account almost explains why Holland underestimated the number of cervicals: the  
329 anteriormost four, lying under more posterior cervicals, had not yet been found. However, if ten  
330 cervicals (C6–C15) had been found and the atlas and axis were both missing, Holland  
331 (1900:816) would surely have stated “Ten are found in the specimen at the Carnegie Museum,  
332 atlas and axis being as yet undiscovered” rather than eleven. Some mystery remains: perhaps  
333 Holland was aware of one of the anteriormost four preserved cervicals.

334 Coggeshall's description is somewhat corroborated by Reed's quarry map, which is included  
335 as Plate 1 of Hatcher's (1901) monograph (Figure 4). However, the map is in some respects at  
336 odds with the description: for example, it shows all 13 vertebrae C2–C14 in a single straight line  
337 rather than indicating that C2–C5 were doubled back; and it shows gaps both between C10 and  
338 C11 (as stated), and also between C11 and C12 (not mentioned in the text).

339 Regarding the vertebra that might pertain to “a second individual belonging perhaps to a  
340 distinct genus”, Hatcher (1901:22) explained: “*Eleventh Cervical*.—This vertebra is so unlike  
341 either the immediately preceding or succeeding vertebrae that if it had been found isolated it  
342 would have been unhesitatingly referred to a different genus. Mr. Coggeshall, however, assures  
343 me that it was interlocked with the succeeding, or twelfth cervical.” Yet, as noted, the quarry  
344 map suggests that there was some distance between C11 and C12, perhaps invalidating  
345 Coggeshall's assertion. It is to be lamented that both the map and the description were created

346 some time after the excavation actually took place, by which time memories had evidently  
347 become unreliable.

348 In conclusion, *Diplodocus carnegii* most likely had fifteen cervicals, but may have had more  
349 (if some vertebrae were not recovered), or maybe fewer (if C11 was misassigned). Furthermore,  
350 the anterior cervicals are damaged in a way that is not at all apparent from Hatcher's drawings  
351 (plate III) or photographs (plate IV) because they were restored before these illustrations were  
352 prepared. As Hatcher (1901:23) noted, "The work of freeing these vertebrae from the matrix and  
353 restoring them was for the most part done during my absence in the field. Unfortunately no  
354 drawings or photographs were taken prior to the process of restoring with colored plaster." (In  
355 the early 20th Century, it was routine to restore damaged fossils in ways that completely  
356 obscured the degree of damage: see Figure 5.)

### 357 *Apatosaurus louisae* CM 3018

358 *Apatosaurus louisae* is the best known species of *Apatosaurus*, since its holotype CM 3018 is  
359 much more complete and better preserved than that of the type species *A. ajax* (YPM 1680), or  
360 that of the closely related *Brontosaurus excelsus* (YPM 1980).

361 The specimen was collected by Earl Douglass in 1909 and 1910, from what was then known  
362 as the Carnegie Museum Dinosaur Quarry near Jensen, Utah, and is now Dinosaur National  
363 Monument. It was mounted for exhibition in 1913, and somewhat belatedly named the type of a  
364 new species in a brief initial description by Holland (1915). He noted that "the specimen consists  
365 of a series of vertebrae, complete from the atlas to nearly the end of the tail" and appendicular  
366 material; but also that "the cervical vertebrae had been separated from the dorsals and shifted,  
367 but the entire series was found articulated in regular order" (p. 143). (Holland's description also  
368 mentioned that "a skull, which judging by its location, belongs to the specimen, was found  
369 within eleven feet of the atlas. It does not differ greatly in form from the skull which belongs to  
370 *Diplodocus*". Had Holland stuck to his guns, *Apatosaurus* could have been restored with its  
371 correct skull 63 years before Berman and McIntosh (1978) corrected Marsh's long-standing and  
372 influential misapprehension that it had a *Camarasaurus*-like skull.)

373 Holland stated (p. 144) that he had "in preparation a large monographic paper relating to the  
374 genus, based in part upon [CM 3018]". However, completion was long delayed, and Holland  
375 died in 1932 before it was ready to be published. It was eventually brought to completion by  
376 Gilmore (1936) and it is from this monograph that the species is primarily known.

377 Gilmore's monograph explains that all is not as it seems in the neck of his specimen. He notes  
378 (p. 191) that "there was some distortion due to the compression to which [the cervicals] had been  
379 subject, but this has been largely corrected during preparation" — a questionable decision, as it  
380 means that the shapes of the vertebrae as originally found are now lost, and cannot be subjected  
381 to more modern retrodeformation techniques (e.g. Tschopp et al. 2013). He continues "Cervicals  
382 thirteen, fourteen, and fifteen, however, were so badly crushed that it was thought best to replace  
383 them in the mounted skeleton by plaster restorations of these vertebrae", although he does claim  
384 that "they are, however, sufficiently well preserved so that most of their important characteristics  
385 can be determined". The caption to Gilmore's plate XXIV reads "Cervical vertebrae of  
386 *Apatosaurus louisae*. Type, No. 3018 [...] Cervicals 13, 14 and 15 have been much restored  
387 from badly crushed originals, and should be used with caution." It is also evident from this plate  
388 that most of C5 is also missing, although this is not acknowledged in the text. As noted by  
389 Upchurch (2000), the poor condition of the posterior cervical vertebrae, and their replacement by

390 plaster models in the mounted skeleton, compromise the validity of biomechanical modelling  
391 based on this specimen, such as that of Stevens and Parrish (1999).

392 In conclusion, while the articulation of the cervical sequence of CM 3018 leaves little doubt  
393 that all cervicals are present and in the correct order, the crucial posterior cervicals are largely  
394 uninformative.

### 395 ***Giraffatitan brancai* MB.R.2181**

396 This specimen is the paralectotype of *Giraffatitan brancai* (= “*Brachiosaurus*” *brancai*).  
397 Much of the material is incorporated in the mounted skeleton in the atrium of the Museum für  
398 Naturkunde Berlin, which remains the largest substantially real mounted skeleton of a terrestrial  
399 animal anywhere in the world. (There are larger mounts of sauropods, such as the skeletons of  
400 *Patagotitan* at the AMNH and FMNH, but these are casts and sculptures, not real material.)  
401 While most of the material of the Berlin brachiosaur mount is real fossil bones, the presacral  
402 vertebrae are too heavy and fragile to mount: instead, high quality sculptures are used, and the  
403 vertebrae themselves are held in collections.

404 The presacrals in the mount are based on real bones that are from two specimens — the  
405 lectotype MB.R.2180 (formerly known as SI) and the paralectotype MB.R.2181 (formerly SII).  
406 The former includes cervicals 2–7, an assignment that can be accepted with some confidence if  
407 the vertebrae indeed form a sequence because the axis, C2, in sauropods is very distinctive,  
408 having a completely different anterior articular surface from all the subsequent cervicals (see e.g.  
409 Janensch 1950:figs. 9–16, cf. figs. 17–48.) MB.R.2181 includes cervicals assigned by Janensch  
410 to positions 3–13 (although almost all of them are damaged, some very severely).

411 However, the two individuals MB.R.2180 and MB.R.2181 were found together in a single  
412 quarry (designated Quarry S). Bones of the two individuals were jumbled up together, with little  
413 articulation, as shown in the quarry map, redrawn by Heinrich (1999: figure 16; Figure 6) from  
414 an original drawn in the field by Werner Janensch. Any reconstruction — or even assignment of  
415 individual vertebrae to one specimen or the other — must be considered provisional.

416 I have previously suggested (Taylor 2009:800–801) that the distinctively high-spined dorsal  
417 vertebra usually considered the fourth of MB.R.2181 may not actually belong to that specimen,  
418 or even that taxon. Instead, this unusually tall vertebra may belong to an animal more closely  
419 resembling the Tendaguru titanosauriform briefly described by Migeod (1931) and which I plan  
420 to redescribe (Taylor 2005, Taylor in prep). If this vertebra is indeed not part of MB.R.2181 then  
421 the most likely inference is that it is part of MB.R.2180. This would be unfortunate if these two  
422 specimens were indeed representatives of different taxa. The smaller and less complete  
423 MB.R.2180, rather than the larger, more complete and better known MB.R.2181, is the lectotype  
424 (Janensch 1935–1936). Therefore, the ICZN rules dictate that the name *Giraffatitan brancai*  
425 would adhere to MB.R.2180, and that a new name would be required for the better-known  
426 MB.R.2181. Since this species was thought until relatively recently to be a species of the North  
427 American genus *Brachiosaurus* (see Taylor 2009), a further reassignment would mean that this  
428 charismatic and iconic specimen would become known by a third different name in not much  
429 more than a decade. To avoid this outcome, an ICZN petition may be warranted.

430 Janensch (1950:33) indicates that the confusion of the cervical vertebrae is not as bad as that  
431 of the dorsals, but the situation is still far from clear, as Janensch’s description explains:

432 The vertebrae from the 3rd to 15th presacrals [of MB.R.2181] lay in articulation in a

433 consolidated lime sandstone lens; of them, the 3rd to 5th vertebrae are tolerably  
434 complete, the remaining 10 vertebrae were articulated with one another, with one  
435 interruption that arose when the 8th presacral vertebra rotated out of the series and  
436 was displaced. [Translation by Gerhard Maier.]

437 Janensch's words are somewhat at odds with the quarry map, which shows cervical material  
438 scattered around the northeastern part of the quarry (Figure 6). Other quarry sketches drawn by  
439 Janensch, including one reproduced by Heinrich (1999: figure 18), certainly show at least some  
440 cervicals having been found in articulation, but it is not clear what the correspondence is between  
441 the field numbers on these sketches and subsequently assigned element identifications.

442 So it is possible, though unlikely, that there might have been other displaced cervicals, before  
443 or after the one designated "8th", that were not recovered. Neither can we be wholly confident  
444 that the anteriormost preserved cervical in the MB.R.2181 series is really C3. Its identification is  
445 based on the overlap with vertebrae of MB.R.2180, but we cannot be certain that MB.R.2180 is a  
446 member of the same species as MB.R.2181. Perhaps the anteriormost preserved cervical is really  
447 C4? Or perhaps some of the "MB.R.2181" cervicals really belong to MB.R.2180. This is not  
448 particularly likely, as Janensch pointed out, due to the difference in size between the two  
449 specimens — the MB.R.2181 cervical centra are about 30–40% longer than those assigned the  
450 same serial position in MB.R.2180. But the size difference cannot be considered a conclusive  
451 argument, especially given the uncertainty in serial-position assignments in both specimens.

452 In conclusion: *Giraffatitan brancai* probably had thirteen cervicals, but may have had more,  
453 or possibly less; and the neural arches are only known for cervicals 3, 4, 5 and 8 in MB.R.2181  
454 (if these are the correct serial positions for those vertebrae). If MB.R.2180 is indeed a member of  
455 the same species then cervicals 2–7 are known from well-preserved elements, but no more. All  
456 of this uncertainty is exacerbated by the problem that no complete or even nearly complete neck  
457 of any other brachiosaur has been described.

458 To summarise this section, not only are complete sauropod necks in very short supply, even  
459 those that are considered complete cannot generally be confidently considered so, and  
460 complexities of interpretation bedevil the best-known specimens.

## 461 **Distortion**

462 Even in necks where most or all of the vertebrae are present and largely complete, extensive  
463 distortion is common. This is difficult to quantify, even in principle, given the very complex  
464 shapes of sauropod cervicals. But we can take tentative steps towards recognising the extent of  
465 the problem by considering one simple aspect: the shapes of the cotyles of consecutive vertebrae.

466 In sauropod cervical vertebrae (and most dorsal vertebrae), the posterior articular face of the  
467 centrum is called the cotyle, due to its distinctive hollow shape. The anterior articular face is  
468 convex, and so is called the condyle. The cotyle of one vertebra and the condyle of the  
469 succeeding one form a ball-and-socket joint (see Taylor and Wedel 2013b: figures 2–3), similar  
470 to the condition in extant horses and camels (see Taylor and Wedel 2013b: figures 20–21) among  
471 other animals.

472 In extant animals, including birds, crocodylians, lizards and mammals, the articular facets of  
473 consecutive vertebrae are of much the same shape, varying only gradually along the neck. In  
474 particular, the aspect ratio of the facet — its width:height ratio — remains constant or nearly so

475 (Figures 7–10). However, in the fossilised necks of sauropods, it's not unusual for even  
476 consecutive vertebrae to be crushed in opposite directions, giving their cotyles (apparently)  
477 wildly different aspect ratios.

478 Consider for example the *Giraffatitan brancai* lectotype MB.R.2180 (formerly HMN SI), one  
479 of the best preserved sauropod neck series. Cervicals 4 and 6 of this specimen are shown in  
480 posterior view in Figure 11. (The intermediate cervical 5 has part of its cotyle rim broken off,  
481 and cannot be reliably measured.) Measuring from the photos, the width:height ratio of C4 (on  
482 the left) is 683/722 pixels = 0.95, and that of C6 (on the right) is 1190/820 pixels = 1.45. So  
483 these two vertebrae — from the same neck, and with only one other vertebrae coming in between  
484 them — differ in preserved cotyle aspect ratio by a factor of 1.53.

485 As a second example, consider the single most studied sauropod neck specimen in the world,  
486 that of the *Diplodocus carnegii* holotype CM 84. Figure 12 shows adjacent cervicals 13 and 14,  
487 in posterior view. Note that the posterior part of the neck was considered well preserved by  
488 Hatcher (1901), with only anterior vertebrae noted as having been damaged. Measuring from  
489 Hatcher's photos, the width:height for C14 (on the left) is 342/245 pixels = 1.40. For C13 (on the  
490 right), it is 264/256 pixels = 1.03. So C14 is apparently 35% broader than its immediate  
491 predecessor.

492 There is no established metric for quantifying change in a measure, such as the aspect ratio of  
493 articular surfaces, along a vertebral column. Table 1 offers two candidate metrics and shows how  
494 they are worked out for six of the seven specimens discussed in this section. (The cat has too few  
495 available vertebrae for the metric to be meaningful.) Using the first metric, average difference  
496 between aspect ratios in consecutive vertebrae, the young juvenile giraffe, the monitor lizard, the  
497 alligator and the ostrich all score in the range 4.2–6.3, while the two sauropods score 9.1 and  
498 16.3. Using the second metric, average ratio between aspect ratios of consecutive vertebrae, the  
499 four extant animals score in the range 6.7–8.9, and the sauropods 12.0 and 22.1. It would be  
500 useful in future to calculate these metrics for larger sets of extant and fossil vertebrates, and to  
501 see whether it is generally the case that the variation metrics are higher for fossils than for extant  
502 vertebrates. For now, though, this tentative initial analysis corroborates the “eye-test” conclusion  
503 that variation is significantly greater along sauropod necks.

504 It might be argued that variation on cotyle shape in sauropod necks arises from mechanical  
505 factors. Since their necks were elongate, segmented cantilevers, they become broader towards  
506 their base, and this could be reflected in cotyle shape. However, we would expect mechanical  
507 influences such as this to produce gradual monotonic variation — cotyles either becoming  
508 consistently broader or consistently taller towards the base of the neck. But this is not what we  
509 observe: instead, the preserved aspect ratios of sauropod condyles vary erratically along the  
510 neck. Such extreme variation in apparent aspect ratio of the cotyles of adjacent and near-adjacent  
511 cervical vertebrae can only be the result of extensive and unpredictable crushing.

512 This variation in preservation of aspect ratios has implications for calculating the elongation  
513 index (EI) of vertebrae, a calculated character widely used in phylogenetic analyses and  
514 elsewhere. For example, Janensch's (1950:39) table of measurements for the *Giraffatitan*  
515 *brancai* lectotype MB.R.2180 (formerly HMN SI) gives the centrum length and cotyle height of  
516 C4 as 45.7 and 13.8 cm, for an EI *sensu* Wedel et al. (2000:346) of 3.31. For C6, he gives  
517 centrum length and cotyle height as 69.1 and 15.0, for a much greater EI of 4.6. But if the true  
518 cotyle proportions of C6 were the same as those of C4, then the cotyle height corresponding to

519 its width of 22.1 would be a much taller 23.1 cm, yielding an EI of only 3.0. Some recent work  
520 uses the aEI of Chure et al. (2010), in which the centrum length is divided not by cotyle height,  
521 but by the average of cotyle height and width. This goes some way towards mitigating the  
522 confounding effects of crushing, but cannot fully allow for its unpredictable effects: for example,  
523 oblique crushing may increase both maximum height and width of the cotyle, yielding a  
524 misleadingly low eEI. At the very least, we need to be circumspect in our use of elongation  
525 indices as phylogenetic characters or ecological correlates.

526 Deformation of the articular cotyle is only one example of the many ways in which sauropod  
527 vertebrae, with their complex and fragile anatomy are subject to crushing. It is certain that other  
528 parts of the vertebrae, especially the delicate lateral processes and zygapophyseal rami, were also  
529 often distorted, and it is generally not possible to reliably restore to their undistorted state.

530 In addition, whole-vertebra distortion is common. For example, in CCG V 20401, the  
531 holotype specimen of *Mamenchisaurus hochuanensis* for which the neck is complete and  
532 articulated, every vertebra of the neck and trunk is sheared and rotated such that the left side is  
533 displaced downwards (Taylor 2004, personal observation of mounted casts in Copenhagen,  
534 Denmark; Trzic, Slovenia; and Chicago, USA). This distortion is illustrated for dorsal vertebra 2  
535 by Young and Zhao (1972:figure 6); although they do not illustrate it for a cervical vertebra, it is  
536 present throughout the column.

537 While the *Mamenchisaurus hochuanensis* distortion is very apparent, subtler distortions are  
538 ubiquitous but easier to overlook. For example, the *Giraffatitan brancai* holotype cervical  
539 vertebrae MB.R.2180 (formerly HMN SI) appear undistorted to the naked eye, but manual  
540 articulation of C2 and C3 demonstrates that sufficient distortion has occurred to prevent the  
541 bones being posed in ways that the live animal surely could have achieved (Figure 13).

## 542 **Location of cervicodorsal junction**

543 One further issue impedes our ability to analyse and compare the necks of different  
544 sauropods, and that is the difficulty of identifying the last cervical vertebra — and therefore of  
545 defining how many vertebrae make up the neck (and how many make up the dorsal series). In  
546 general it is easy to tell cervical and dorsal vertebrae apart: for example, compare C13 and D3 of  
547 the *Diplodocus carnegii* holotype CM 84 (Hatcher 1901:plates III and VII). The cervical vertebra  
548 is relatively low, its centrum is elongated, its neural spine is roughly triangular and its  
549 parapophysis hangs down below the centrum and has a cervical rib fused to it and the  
550 diapophysis (though this latter character is not consistent in sauropods: see below). By contrast,  
551 the dorsal vertebra is tall, its centrum is short, its neural spine is anteroposteriorly compressed its  
552 parapophysis is up on the dorsal half of the centrum, and no rib is fused to it. But the change in  
553 these characters is gradual, and at the transition it is much more difficult to distinguish between  
554 cervical and dorsal vertebrae. Compare C15 and D1 of CM 84 (Hatcher 1901:plates III and VII  
555 once more). Had Hatcher classified his C15 as the first dorsal, or his D1 as the last cervical, it  
556 would not be obvious that this was incorrect. Similarly, Wilson and Upchurch (2009:20) found it  
557 difficult to unambiguously identify the first dorsal vertebra even when dealing with the relatively  
558 complete and well-preserved presacral sequence of *Euhelopus zdanskyi*.

559 The difficulty of locating the cervicodorsal junction is exacerbated by the lack of a single  
560 standard definition. Several exist:

- 561 • **Rib fusion.** Hatcher (1901:25) writes “The dorsals are distinguished from the cervicals  
562 by supporting free instead of fixed ribs ...”
- 563 • **Ventral centrum shape.** Hatcher (1901:25–26) continues “... and in having the inferior  
564 surface of the centra regularly convex transversely instead of concave in either direction”.
- 565 • **Scapular support.** In his description of *Haplocanthosaurus* two years later, Hatcher  
566 (1903:8) uses a completely different definition: “That [D1] was a dorsal is conclusively  
567 shown not by the presence of tubercular and capitular rib facets showing that it supported  
568 on either side a free rib [...] The character in this vertebra distinguishing it as a dorsal is  
569 the broadly expanded external border of the anterior branch of the horizontal lamina [i.e.  
570 what we would now call the prezygadiapophyseal lamina ...] to give greater surface for  
571 the attachment of the powerful muscles necessary for the support of the scapula.” (See  
572 Figure 14.)
- 573 • **Parapophysis location.** Hatcher (1901:16) notes “In the fifth dorsal the capitular facet is  
574 on the middle of the neural arch, while in dorsals four and three it has shifted down to the  
575 centrum and encroached upon the pleurocentral cavities of these vertebrae. In dorsals two  
576 and one it lies wholly inferior to that cavity”, and his illustrations show that it is well  
577 below the centrum in all cervical vertebrae.
- 578 • **Gene expression.** Wilson (2002:226) notes that “the cervicodorsal transition in many  
579 tetrapods, for instance, appears to be defined by the expression boundary of the *Hoxc-6*  
580 gene”.

581 However none of these definitions is wholly satisfactory.

- 582 • Rib fusion is not a reliable criterion, as Hatcher (1903:8) notes: “there are in our  
583 collections of sauropods, skeletons of other dinosaurs fully adult but, with the posterior  
584 cervical, bearing free cervical ribs articulating by both tubercular and capitular facets as  
585 do the ribs of the dorsal region”. As one example, the *Mamenchisaurus hochuanensis*  
586 holotype CCG V 20401 has free ribs on its last three cervicals (Young and Zhao 1972;  
587 personal observation). It may be argued that those last three cervicals are really dorsals,  
588 but while a case could possibly be made for the last one, the rib shafts of the previous two  
589 are much too horizontally oriented to sustain such an interpretation.
- 590 • Ventral centrum shape is highly variable between different sauropod taxa.
- 591 • The presence of a scapular support facet on the lateral face of the CPRL is difficult to  
592 detect, and evidently not trusted by Hatcher himself as he noted of C15 of *Diplodocus*  
593 CM 84 that “the superior of the anterior blades of the horizontal lamina has its external  
594 surface somewhat expanded and rugose. It no doubt served as a support for the muscular  
595 attachment of the heavy scapular arch” (Hatcher 1901:25).
- 596 • While the parapophysis migrates dorsally across the centrum to the arch in successive  
597 vertebrae of all sauropods, this migration typically does not commence until after the first  
598 dorsal, making it useless to determining the location of the junction.
- 599 • The genetic definition is obviously useless for fossil organisms.

600 In practice, most workers seem to use a combination of multiple criteria, often not explicitly  
601 specified. For example, in considering the dorsal count of *Barosaurus*, McIntosh (2005:45)

602 writes “The eighth presacral [counting forward from the sacrum] is unquestionably a dorsal and  
603 the tenth a cervical”, but does not explain why he makes these designations. He continues, “But  
604 what is the ninth? At first glance it certainly appears to be a cervical — the parapophysis projects  
605 from the very bottom of the centrum well below the pleurocoel. However [...] neither rib is co-  
606 ossified to the parapophyses and diapophyses as in the cervical vertebrae anterior to it. Largely  
607 for this reason, I have concluded that it is the first dorsal.” Here, McIntosh is making a  
608 judgement on the contradictory evidence of the rib-fusion and parapophysis-location criteria,  
609 while not using ventral centrum shape (perhaps because the ventral view of the centrum is not  
610 available) or scapular-support facets (perhaps due to preservational problems making it  
611 impossible to assess). This example is instructive, as it illustrates pervasive difficulties when  
612 dealing with bones as large, fragile and difficult to manipulate as sauropod presacrals: very few  
613 such bones can be inspected from all cardinal directions, and as noted above distortion and  
614 damage is ubiquitous.

615 Perhaps, then, the best we can hope for in identifying the cervicodorsal junction is to use a  
616 combination of criteria according to what is available for study in the specimen in question, but  
617 to be explicit about which criteria are used. As McIntosh’s example demonstrates, this  
618 identification is important, as it determines the number of cervical vertebrae deemed to belong to  
619 a neck: even in those very rare cases when a presacral vertebral sequence is complete and  
620 undistorted, it is still to some degree a matter of judgement how many cervical vertebra  
621 constitute the neck.

622 (In some older papers (e.g. Migeod 1931), a “shoulder vertebra” is referenced, an intermediate  
623 between the last cervical and the first dorsal, but this terminology is not used in modern  
624 literature. However, introducing this concept does not aid the quest for consensus over how the  
625 junction is located: the issue simply becomes the problem of locating the shoulder vertebra,  
626 rather than locating the first dorsal.)

## 627 **Discussion**

### 628 **Taphonomic factors**

629 All of the problems with sauropod neck preservation arise from the nature of the animals and  
630 the general procedures of taphonomy.

631 First, sauropods are big. This is a recipe for incompleteness of preservation: small skeletons  
632 are more easily destroyed by taphonomic processes, but if they survive are more easily preserved  
633 whole, while large skeletons less rarely survive intact (Brocklehurst et al. 2012). It is no accident  
634 that the most completely preserved sauropods are small individuals such as CM 11338, the cow-  
635 sized juvenile *Camarasaurus lentus* described by Gilmore (1925). For an organism to be  
636 fossilised, it is necessary for the carcass to be swiftly buried in mud, ash or some other substrate.  
637 This can happen relatively easily to small animals, such as the many finely preserved small  
638 theropods from the Yixian Formation in China, but is much less possible with a large animal  
639 (Mannion 2010:284).

640 Cleary et al. (2015:528 and figure 6) showed that medium-sized ichthyosaurs preserve more  
641 completely than either small or large individuals, but since these are aquatic animals their  
642 preservational context is not applicable to the case of sauropods. Brown et al. (2012) found that  
643 in the Dinosaur Park Formation, “large-bodied” dinosaurs preserved more completely than

644 smaller ones, but their sample contained no sauropods, their threshold for “large” was only 60  
645 kg, and the largest animals included were 4.5-tonne hadrosaurs. It may be that if the methods of  
646 Brown et al. (2012) were used to analyse the sauropod-bearing Morrison or Tendaguru  
647 formations, the result would be similar to those of Cleary et al. (2015), with medium-sized  
648 animals having the most complete preservation. At a larger scale, Cashmore et al. (2020:963)  
649 found only a weak, and weakly significant, correlation between sauropod body mass and  
650 specimen completeness ( $R^2 = 0.03$ ;  $p = 0.04$ ), using the SCM2 skeletal completeness metric of  
651 Mannion & Upchurch (2010). However, analysis of their figure 5A, plotting log body mass  
652 against log completeness shows a rapid falling away in completeness above body masses with  
653 log 10 — presumably natural log, representing about 22 tonnes.

654 It is also possible that the light construction of highly pneumatic cervical vertebrae would  
655 have rendered them particularly prone to water transport, disarticulating and scrambling the  
656 necks of even some otherwise adequately preserved specimens.

657 Except in truly exceptional circumstances, sediments simply are not deposited quickly enough  
658 in terrestrial environments to cover a 25 meter, 30 tonne animal with a light neck skeleton before  
659 it is broken apart by scavenging, decay and water transport. Fossilisation of the very largest  
660 sauropods tends to produce even more fragmentary remains. In light of this, it is not surprising  
661 that the very longest sauropod necks are usually known from particularly inadequate specimens.  
662 The longest neck for which we have direct evidence is that of the diplodocid *Supersaurus*,  
663 possibly 15 m long, but the only cervical material of the largest specimen is a single 1.4 m  
664 cervical (BYU 9024, formerly BYU 5003; Jensen 1985, 1987). Similarly, the giant basal  
665 titanosauriform *Sauroposeidon* probably had a neck about 11 m long, but the only definite  
666 material belonging to it is a sequence of three and a half cervicals from the middle of the neck  
667 (OMNH 53062; Wedel et al. 2000). The longest known titanosaur necks are probably those of  
668 *Patagotitan*, *Puertasaurus* and *Dreadnoughtus*, all at around 9–10 m, but the cervical material  
669 from which they are known is meagre: only three vertebrae in the *Patagotitan* holotype MPEF-  
670 PV 3400, of which the longest is 120 cm long (supplementary information to Carballido et al.  
671 2007); a single 118 cm *Puertasaurus* vertebra, MPM-PV 10002 (Novas et al. 2005); and a single  
672 113 cm vertebra of *Dreadnoughtus* MPM-PV 1156 (Lacovara et al. 2014).

673 Secondly, even when complete sauropod skeletons are preserved, or at least complete necks,  
674 distortion of the preserved cervical vertebrae is almost inevitable because of their uniquely  
675 fragile construction. As in modern birds, the cervical vertebrae were lightened by extensive  
676 pneumatisation, so that they were more air than bone (Taylor and Wedel 2013a: figure 4), with  
677 the air-space proportion typically in the region of 60–70% and sometimes reaching as high as  
678 89% (Taylor and Wedel 2013a: table 2; Wedel 2005: figure 7.4C). While this construction  
679 enabled the vertebrae to withstand great stresses for a given mass of bone, it nevertheless left  
680 them prone to crushing, shearing and torsion when removed from their protective layer of soft  
681 tissue. For highly pneumatized cervicals in particular, the chance of the shape surviving through  
682 taphonomy, fossilisation and subsequent deformation would be tiny.

### 683 Possible mitigations

684 Some information about sauropods necks that is not directly observable can be inferred from  
685 phylogenetic bracketing: the observation that if two close outgroups to an organism of interest  
686 both have a feature, then the null hypothesis is that the organism of interest inherited that feature  
687 from the common ancestor (see Witmer 1995). For example, the neck of *Sauroposeidon proteles*

688 is known only from a sequence of four vertebrae (Wedel et al 2000). But as a brachiosaurid it is  
689 bracketed by *Giraffatitan brancai*, which is thought on reasonable evidence (see above) to have  
690 had 13 cervicals, and *Camarasaurus lentus*, which is known from complete specimens to have  
691 had 12 cervicals (Gilmore 1925:367). It is therefore parsimonious on this basis to conclude that  
692 the most recent common ancestor of *Giraffatitan* and *Camarasaurus* probably had 12–13  
693 cervical vertebrae, and that *Sauroposeidon proteles* likewise also had 12–13 cervicals.

694 While this level of inference is better than no information, the present example illustrates  
695 three problems with the use of phylogenetic bracketing for sauropod morphology. First, due to  
696 incomplete knowledge of most sauropods, it is often necessary to move some way down the tree  
697 from the organism of interest before reaching specimens for which morphology is sufficiently  
698 known. In this example, while *Giraffatitan* is probably close to *Sauroposeidon*, *Camarasaurus* is  
699 some way basal to it — but more closely related brachiosaurids such as *Abydosaurus* and  
700 *Europasaurus*, while possessing good cervical material, do not have anything close to a complete  
701 neck, and so cannot be used in bracketing. As a result, the *Giraffatitan*–*Camarasaurus* bracket  
702 used in this example is broader than we would wish. Second, the phylogenetic context in which  
703 we interpret brackets is not always well established. In the present example, I have been  
704 following Wedel et al.'s (2000) referral of *Sauroposeidon* to the clade Brachiosauridae; but if  
705 D'Emic and Foreman (2012) are correct in their assessment that *Sauroposeidon* in fact a  
706 somphospondylian, then it would be more appropriate to bracket it between *Giraffatitan brancai*  
707 and *Euhelopus zdanskyi* — which has 17 cervical vertebrae (Wiman 1929:7), suggesting a  
708 significantly higher cervical count of 13–17 for *Sauroposeidon*. Third, in the case of sauropods,  
709 the morphology of the bracketing taxa is often not as solidly established as we might wish. In  
710 this case, while the cervical counts of *Camarasaurus lentus* and *Euhelopus zdanskyi* are well  
711 established, that of *Giraffatitan brancai* is less so, as documented above, rendering the cervical-  
712 count ranges for *Sauroposeidon* even more uncertain. In conclusion, while phylogenetic  
713 bracketing remains a useful tool, it must be used with care.

714 The problem of distortion in individual vertebrae can be addressed to some extent through  
715 retrodeformation (e.g. Schlager et al. 2018). This term encompasses a suite of techniques in  
716 which mathematical processes are applied to virtual models of fossils in an attempt to restore  
717 them to the shape they had before their deformation in matrix. Various methods have been  
718 proposed in the literature, largely based on an assumption of symmetry. Most of the early  
719 methods were designed for 2D transformations on morphologically simple invertebrate fossils  
720 (e.g. Cooper 1990), but more recent developments have yielded methods more capable of  
721 handling complex 3D shapes (e.g. the Single Axis Method of Kazhdan et al. 2009). Application  
722 of these techniques to sauropod vertebrae has so far been limited, but Tschopp et al. (2013)  
723 conducted experiments on cervical vertebrae of the diplodocid *Kaatedocus siberi* using an  
724 artificially deformed model of a dodo cervical as a control. They found that while the  
725 retrodeformation techniques they tested were capable of restoring symmetry to a deformed  
726 vertebra, they often did so at the expense of artificially making the vertebra shorter, broader or  
727 thinner than it should be. Surprisingly, they also found that applying the same process twice to a  
728 vertebra first made it more robust than the original, then more slender. At this stage it seems that  
729 more sophisticated techniques, preserving more aspects of the 3D geometry, will be necessary  
730 before retrodeformed sauropod cervicals can be taken at face value.

731 But this does not mean that other strategies cannot help in dealing with distorted material. For  
732 example, Hedrick and Dodson (2013) used 3D geometric morphometric techniques to better

733 understand individual and taphonomic variation in a set of 30 skulls representing three nominal  
734 species of *Psittacosaurus*. They showed that the apparent morphological variation between these  
735 “species” actually represent the results of different taphonomic processes, and that all 30 skulls  
736 in fact represent members of the same species. It may be possible to use similar techniques on  
737 sauropod vertebrae, although modifications would be required to deal with the additional  
738 complexity introduced by serial variation in vertebral morphology.

739 One thing that is apparent in all this is the necessity of careful documentation on how  
740 specimens were found, in what states of articulation, in what kinds of matrix, and under what  
741 strains. These descriptions should where possible be accompanied by quarry maps, and ideally  
742 by photos and even 3D models of the excavation — something that is increasingly possible given  
743 the unlimited capacity for online supplementary information in many journals. Such additional  
744 documentation may not materially increase our understanding of the specimens but does at least  
745 make it more explicit what we do and do not know, yielding rigidly defined areas of doubt and  
746 uncertainty. Similarly, when fossils are restored, it should be done in such a way that it is  
747 apparent what parts of the restored specimen are real bone and which are reconstructed. Happily,  
748 modern palaeontologists are much much better in all these respects than our predecessors were.  
749 Some “golden age” palaeontologists were concerned primarily with what would constitute a  
750 spectacular museum mount: it is for this reason that O. C. Marsh had YPM 1980, the holotype of  
751 *Brontosaurus excelsus*, so enthusiastically “restored” that it is now impossible to determine  
752 which parts of the cervical vertebrae are real (pers. obs., Barbour 1890). But these days are  
753 mostly behind us, and nearly all modern specimens are prepared in a form that accurately  
754 conveys what was actually preserved.

## 755 **Implications**

756 Both the incompleteness and distortion of sauropod necks have grave consequences for our  
757 ability to reason about sauropods. As noted above, the very small sample of complete necks  
758 makes it quite impossible to perform meaningful statistical analyses. This incomplete  
759 information also impedes our ability to understand the evolution of sauropod necks, making it  
760 difficult to determine the plesiomorphic cervical morphology and vertebral counts at the bases of  
761 clades. Similarly, the frequent, unpredictable and sometimes dramatic distortion of what  
762 vertebrae we do have renders mechanical analysis of neutral poses and ranges of motion  
763 extremely problematic. For vertebrae small and robust enough to be manipulated by hand, this  
764 can be readily observed in physical space (Figure 13). There is no reason to think that computer  
765 modelling of vertebrae and their articulations (e.g. Stevens and Parrish 1999) should yield  
766 models any more informative than the distorted fossils that they are based on.

767 On a more positive note, the lack of complete necks does not mean that we are without  
768 information. For many sauropods that lack complete necks, enough vertebrae are preserved with  
769 enough fidelity that we can have a good idea how morphology varies between anterior, middle  
770 and posterior cervicals, even if precise identification of the vertebrae is not possible. Crucially,  
771 this degree of completeness suffices for the majority of characters to be scored in phylogenetic  
772 analyses: apart from a few characters specific to the atlas or axis, most such characters pertain  
773 only to anterior, middle or posterior cervicals.

## 774 Conclusion

775 What does it all mean? Only this: we don't know as much as we may assume we do. We don't  
776 even know how many cervical vertebrae well-known sauropods such as *Diplodocus* and  
777 *Giraffatitan* had. We don't have complete necks for either of these sauropods, nor for almost any  
778 others. Even those we do have are in some cases badly crushed (e.g. *Mamenchisaurus*  
779 *hochuanensis*). We are woefully short of sauropod necks.

780 As scientists, we must carefully avoid blithely asserting factoids such as “*Diplodocus* had 15  
781 cervicals and *Giraffatitan* only 13”. We simply don't know whether this is true. Evidence  
782 supports it as a hypothesis — these numbers are certainly the best guesses for the taxa in  
783 question — but a hypothesis is all it is. Hypotheses of neck posture and flexibility should be held  
784 even more lightly, since they are based on inferences drawn from distorted elements whose true  
785 shapes we may never know.

786 None of this is necessarily disastrous, so long as we properly acknowledge the degree of  
787 uncertainty that afflicts our work. Problems arise when studies such as that of Stevens and  
788 Parrish (1999) draw apparently firm conclusions about sauropod neck posture based on  
789 specimens that are deficient in respects not acknowledged in the text, lending the results a veneer  
790 of definitiveness that they do not merit.

## 791 Acknowledgments

792 An earlier version of this manuscript was reviewed in 2015 by Paul Barrett, Paul Upchurch  
793 and Jeffrey Wilson; the present version was reviewed by Oliver Rauhut, Paul Upchurch (again)  
794 and Veronica Diez-Diaz. This final version is much stronger for having been updated in response  
795 to their comments. I also thank Brandon Hedrick for his editorial handling of the manuscript, and  
796 my wife, Fiona, for motivating me to finally get the revisions done on this long overdue paper.

797 After the first version of this manuscript was published as a preprint, numerous people  
798 reminded me of additional complete and near-complete sauropod necks. These include (in  
799 alphabetical order) Lee Braithwaite, John D'Angelo, Vahe Demirjian, Oliver Demuth, Daniel  
800 Gonçalves, Stephen Gunnell, Rutger Jansma, Matt Lamanna, Stefan Reiss, Emmanuel Tschopp,  
801 Justin Tweet and Paul Upchurch.

802 I thank Jorge O. Calvo, Paul C. Sereno, Leonardo S. Filippi, Rodolfo A. Coria, Kristian  
803 Remes, Ralf Kosma, Jose I. Canudo and Stephen F. Poropat for permission to cite personal  
804 communications.

805 I thank Mathew J. Wedel for his observations on the phylogenetic distribution of complete  
806 and near-complete necks, and for providing the juvenile alligator neck illustrated in Figure 8.  
807 Matt Cobley provided the ostrich neck illustrated in Figure 7. Andrew Moore supplied  
808 photographs of the neck of the *Camarasaurus lentus* specimen USNM 13786. Daniela Schwarz  
809 provided high-resolution scans of Werner Janensch's site maps of “Quarry S”, where important  
810 *Giraffatitan* material was found. Gerhardt Maier provided the translation of Janensch (1950).  
811 This translation, and others that I referred to, are freely available from the Polyglot  
812 Paleontologist web-site at <http://paleoglot.org/>

813 This paper is based in part on three blog-posts from *Sauropod Vertebra Picture of the Week*  
814 (Taylor 2011, Taylor 2013, Taylor 2014), and also on part of a talk at the Symposium on  
815 Vertebrate Palaeontology and Comparative Anatomy (Taylor and Wedel 2011).

## 1059 Table Captions

1060 **Table 1.** Serial variation in preserved aspect ratios of consecutive cervical vertebrae in extant  
 1061 animals and sauropods from several major amniote clades. Mammalia: giraffe *Giraffa*  
 1062 *camelopardalis*, young juvenile specimen, C2–C7. Lacertilia: savannah monitor, *Varanus*  
 1063 *exanthematicus*, C3–C7. Crocodylia: alligator *Alligator mississippiensis*, juvenile specimen,  
 1064 C5–D2; Aves: ostrich *Struthio camelus*. C5–C11. Sauropoda: *Diplodocus carnegii* holotype  
 1065 CM84 and *Giraffatitan brancai* lectotype MN.R.2180 (formerly HMN SI). **Vertical** and  
 1066 **horizontal** columns contain measurements of the posterior articular surfaces of the vertebrae,  
 1067 except for the procoelous alligator vertebrae for which anterior articular surface was used. For  
 1068 the saddle-shaped ostrich cervicals, the maximum height and width of the posterior articular  
 1069 surface was used, rather than the shorter midline distances. Measurements are in arbitrary  
 1070 units (e.g. mm or pixels in a photograph) but consistent within any one specimen. **V/H** is the  
 1071 aspect ratio of the measured surface, the ratio of the vertical and horizontal measurements, so  
 1072 that values less than 1.0 indicate a surface wider than tall, and values greater than 1.0 indicate  
 1073 a surface taller than wide. Note that this ratio is independent of the measurement units. **1st**  
 1074 **diff** measures the absolute value of the difference between the V/H ratios of each vertebra and  
 1075 its successor. **Max diff** is the highest value of 1st diff for each specimen, and **Avg diff** is the  
 1076 average value; **×100** is this value times 100, a measure of the serial variation along the  
 1077 column. **1st ratio** is the “absolute ratio” of the V/H values of one vertebra and its successor,  
 1078 normalized so that when the ratio is less than 1.0 its inverse is used. **Max ratio** is the highest  
 1079 value of 1st ratio for each specimen, and **Avg ratio** is the average value; **–1×100** is this value  
 1080 minus one, multiplied by 100, another measure of the serial variation along the column. Note  
 1081 that by both measures, the variation in articular surface aspect ratios is greater in the two  
 1082 sauropods than in any of the extant animals, even though these are among the best preserved  
 1083 sauropod necks.

## 1084 Figure Captions

1085 **Figure 1.** *Spinophorosaurus nigerensis* holotype GCP-CV-4229 in situ during excavation in the  
 1086 region of Aderbissinat, Thirozerine Dept., Agadez Region, Republic of Niger. Reproduced  
 1087 from Remes et al. (2009: figure 1).

1088 **Figure 2.** Simplified phylogeny of Sauropoda, showing counts of complete and near-complete  
 1089 necks. Captions: **C**, complete and described; **U**, complete but undescribed; **–I**, missing the  
 1090 atlas but otherwise complete; **O**, other near-complete necks (see text for details); **T**, total.

1091 **Figure 3.** Neck of *Diplodocus carnegii* holotype CM 84, as reconstructed by Hatcher (1901:  
 1092 plate XIII), with fifteen undamaged cervical vertebrae.

1093 **Figure 4.** W. H. Reed’s diagram of Quarry C near Camp Carnegie on Sheep Creek, in Albany  
 1094 County, Wyoming. The coloured bones belong to CM 84, the holotype of *Diplodocus*  
 1095 *carnegii*; other bones belong to other individuals, chiefly of *Brontosaurus*, *Camarasaurus* and  
 1096 *Stegosaurus*. Modified (cropped and coloured) from Hatcher (1901: plate I). Cervical  
 1097 vertebrae are purple (and greatly simplified in outline by Reed), dorsals are red, the sacrum is  
 1098 orange, caudals are yellow, limb girdle elements are blue, and limb bones are green.

1099 **Figure 5.** Three images of presacral vertebra 6 (probably dorsal 7) of *Brachiosaurus altithorax*  
 1100 holotype FMNH P25107, in right lateral view, showing misleading restoration. **Left:** Field

1101 Museum photograph CSGEO16166, photographer Charles Carpenter, taken in 1905, the year  
1102 after Riggs's (1904) descriptive monograph. Note the "crazy-paving" effect of the many  
1103 cracks and missing areas of bone surface. **Middle:** Illustration of the same vertebra in Riggs  
1104 (1904: plate LXXII). Note that the damage to the vertebral surface is not depicted. **Right:**  
1105 photograph of the same vertebra, taken by the author in 2005. Note that the damage apparent  
1106 in the 1905 photograph is no longer visible: the vertebra seems to have been painted to  
1107 conceal its incompleteness.

1108 **Figure 6.** Quarry map of Tendaguru Site S, Tanzania, showing incomplete and jumbled  
1109 skeletons of *Giraffatitan brancai* specimens MB.R.2180 (the lectotype, formerly HMN SI)  
1110 and MB.R.2181 (the paralectotype, formerly HMN SII). Cervical material is highlighted in  
1111 strong yellow, while the remaining elements are desaturated. Anatomical identifications of  
1112 MB.R.2181 are underlined. Elements of MB.R.2180 could not be identified on the map with  
1113 certainty. Modified from Heinrich (1999: figure 16), which was itself redrawn by Heinrich  
1114 from an original field sketch by Werner Janensch. Heinrich's version Copyright Wiley-VCH  
1115 Verlag GmbH & Co. KGaA. Reproduced with permission.

1116 **Figure 7.** Cervical vertebrae 5–11 of an ostrich, *Struthio camelus*, in posterior view, showing  
1117 that articular facet shape remains similar along the column. Specimen kindly provided by  
1118 Matt Cogley.

1119 **Figure 8.** Cervical and dorsal vertebrae (C5–9 and D1–2) of a juvenile alligator, *Alligator*  
1120 *mississippiensis*, in anterior view, showing that articular facet shape remains similar along the  
1121 column. Specimen kindly provided by Matthew J. Wedel.

1122 **Figure 9.** Sequences of cervical vertebrae of extant animals, showing that articular facet shape  
1123 remains similar along the column. **Top.** Cervical vertebrae 3–7 of a mature savannah monitor  
1124 lizard, *Varanus exanthematicus*, in anterior view. (The cervicals of monitor lizards, unlike  
1125 those of sauropods and most mammals, are procoelous, with the anterior facet being concave  
1126 and the posterior convex.) **Bottom.** cervical vertebrae 2–5 of a mature house-cat, *Felis catus*,  
1127 in posterior view.

1128 **Figure 10.** Cervical vertebrae of a baby giraffe, *Giraffa camelopardalis*, in posterior view,  
1129 showing that articular facet shape remains similar along the column. Top row, left to right:  
1130 cervicals 7, 6 and 5; bottom row, left to right: cervicals 4, 3 and 2. Despite changes in the  
1131 vertebrae along the column, the flattened inverted pentagon shape of the articular facets  
1132 remains similar along the sequence. (Note that extensive cartilage caps existed on the articular  
1133 facets of this very young specimen, but were lost in preparation.)

1134 **Figure 11.** Cervical vertebrae 4 (left) and 6 (right) of *Giraffatitan brancai* lectotype MB.R.2180  
1135 (formerly HMN SI), in posterior view. Note the dramatically different aspect ratios of their  
1136 cotyles, indicating that extensive and unpredictable crushing has taken place. Photographs by  
1137 the author.

1138 **Figure 12.** Cervical vertebrae 14 (left) and 13 (right) of *Diplodocus carnegii* holotype CM 84, in  
1139 posterior view. Note the dramatically different aspect ratios of their cotyles, indicating that  
1140 extensive and unpredictable crushing has taken place.

1141 **Figure 13.** Manipulation of consecutive sauropod vertebrae by hand. Cervicals 2 and 3 of  
1142 *Giraffatitan brancai* lectotype MB.R.2181 (formerly HMN SI). I attempted to articulate these  
1143 two vertebrae, and empirically determine the feasible range of motion. Due to subtle

1144 distortion of the zygapophyses of these vertebrae, it was not possible to articulate C2 in a  
1145 more extended position relative to C3 than shown here. Photograph by Mathew J. Wedel.

1146 **Figure 14.** Cervicodorsal transition of *Haplocanthosaurus priscus* holotype CM 572. Top row,  
1147 right lateral view; bottom row, anterior view. From left to right, D1, C15 and C14. Pink  
1148 highlights indicate the expanded lateral surface of the prezygadiapophyseal lamina, anchoring  
1149 the supporting muscles of the scapula, which Hatcher considered diagnostic of the 1st dorsal  
1150 vertebra. Modified from Hatcher (1903: plate I).

1151

**Table 1** (on next page)

Serial variation in preserved aspect ratios of consecutive cervical vertebrae in extant animals and sauropods from several major amniote clades.

Mammalia: giraffe *Giraffa camelopardalis*, young juvenile specimen, C2–C7. Lacertilia: savannah monitor, *Varanus exanthematicus*, C3–C7. Crocodylia: alligator *Alligator mississippiensis*, juvenile specimen, C5–D2; Aves: ostrich *Struthio camelus*. C5–C11. Sauropoda: *Diplodocus carnegii* holotype CM84 and *Giraffatitan brancai* lectotype MN.R.2180 (formerly HMN SI). **Vertical** and **horizontal** columns contain measurements of the posterior articular surfaces of the vertebrae, except for the procoelous alligator vertebrae for which anterior articular surface was used. For the saddle-shaped ostrich cervicals, the maximum height and width of the posterior articular surface was used, rather than the shorter midline distances. Measurements are in arbitrary units (e.g. mm or pixels in a photograph) but consistent within any one specimen. **V/H** is the aspect ratio of the measured surface, the ratio of the vertical and horizontal measurements, so that values less than 1.0 indicate a surface wider than tall, and values greater than 1.0 indicate a surface taller than wide. Note that this ratio is independent of the measurement units. **1st diff** measures the absolute value of the difference between the V/H ratios of each vertebra and its successor. **Max diff** is the highest value of 1st diff for each specimen, and **Avg diff** is the average value; **x100** is this value times 100, a measure of the serial variation along the column. **1st ratio** is the “absolute ratio” of the V/H values of one vertebra and its successor, normalized so that when the ratio is less than 1.0 its inverse is used. **Max ratio** is the highest value of 1st ratio for each specimen, and **Avg ratio** is the average value; **-1x100** is this value minus one, multiplied by 100, another measure of the serial variation along the column. Note that by both measures, the variation in articular surface aspect ratios is greater in the two sauropods than in any of the extant animals, even though these are among the best preserved

sauropod necks.

	Vertebra	Vertical	Horizontal	V/H	1st diff	Max diff	Avg diff	×100	1st ratio	Max ratio	Avg ratio	-1×100

# Figure 1

*Spinophorosaurus nigerensis* holotype GCP-CV-4229 in situ during excavation in the region of Aderbissinat, Thirozerine Dept., Agadez Region, Republic of Niger.

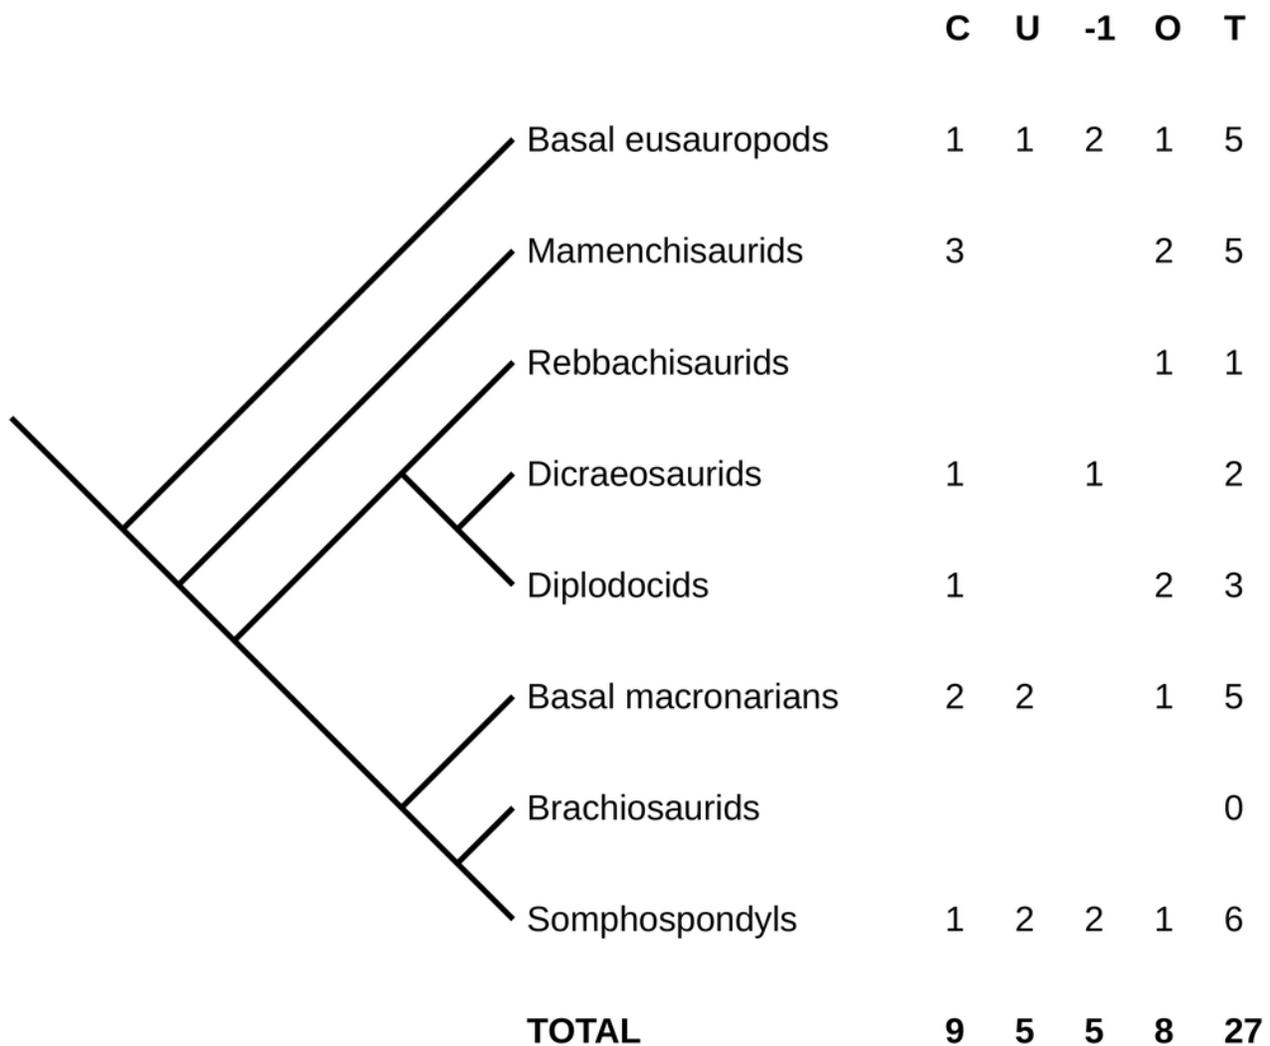

Reproduced from Remes et al. (2009: figure 1).

## Figure 2

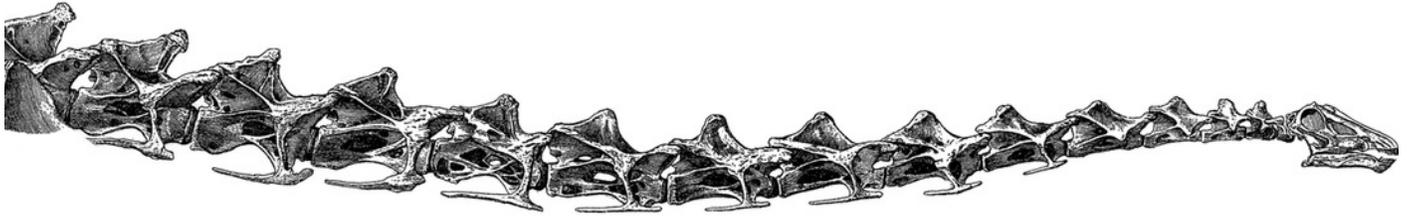

Simplified phylogeny of Sauropoda, showing counts of complete and near-complete necks.

Captions: **C**, complete and described; **U**, complete but undescribed; **-1**, missing the atlas but otherwise complete; **O**, other near-complete necks (see text for details); **T**, total.

## Figure 3

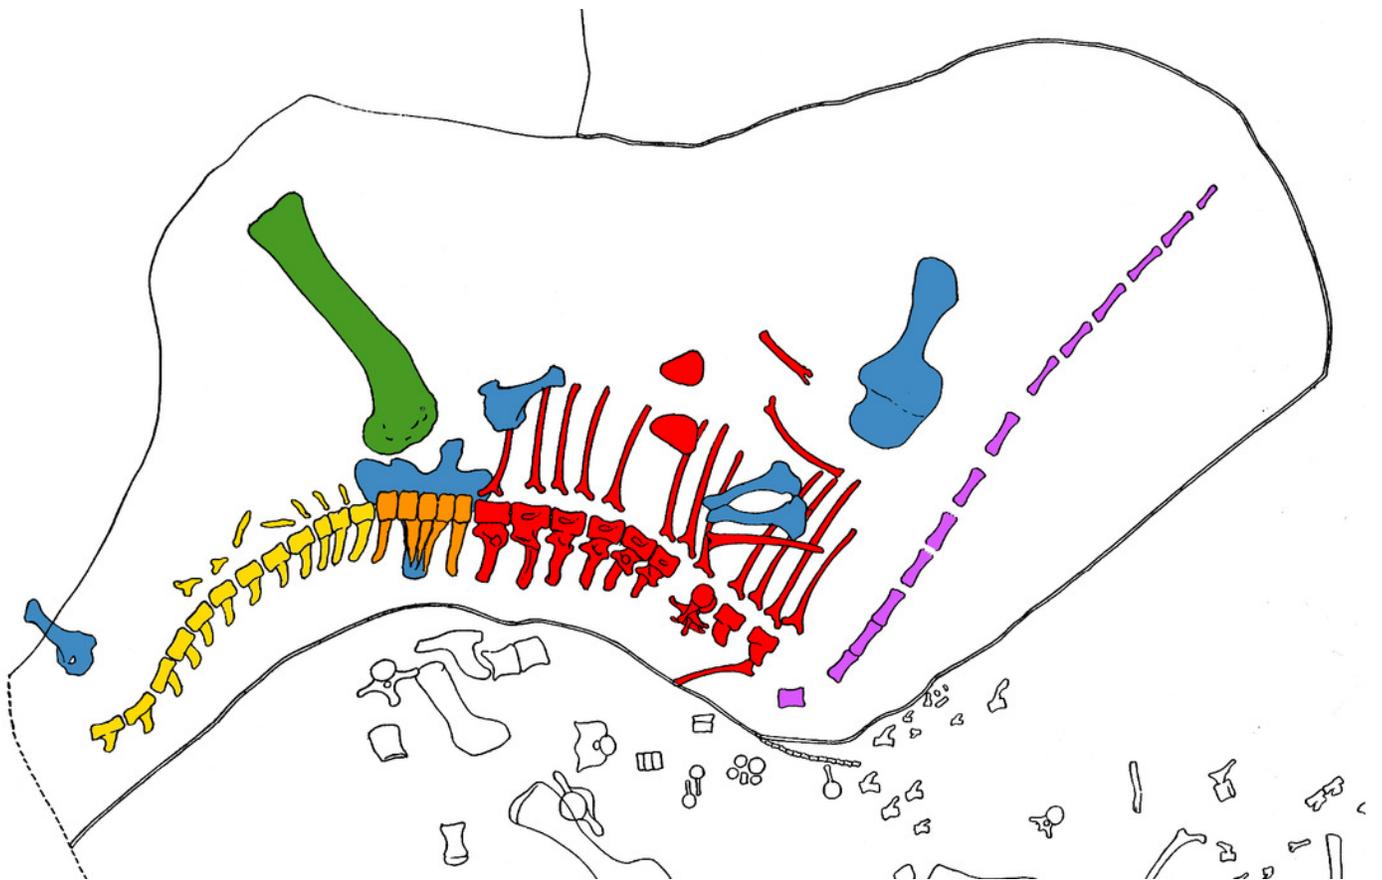

Neck of *Diplodocus carnegii* holotype CM 84, as reconstructed by Hatcher (1901: plate XIII), with fifteen undamaged cervical vertebrae.

## Figure 4

W. H. Reed's diagram of Quarry C near Camp Carnegie on Sheep Creek, in Albany County, Wyoming.

The coloured bones belong to CM 84, the holotype of *Diplodocus carnegii*; other bones belong to other individuals, chiefly of *Brontosaurus*, *Camarasaurus* and *Stegosaurus*. Modified (cropped and coloured) from Hatcher (1901: plate I). Cervical vertebrae are purple (and greatly simplified in outline by Reed), dorsals are red, the sacrum is orange, caudals are yellow, limb girdle elements are blue, and limb bones are green.

## Figure 5

Three images of presacral vertebra 6 (probably dorsal 7) of *Brachiosaurus altithorax* holotype FMNH P25107, in right lateral view, showing misleading restoration.

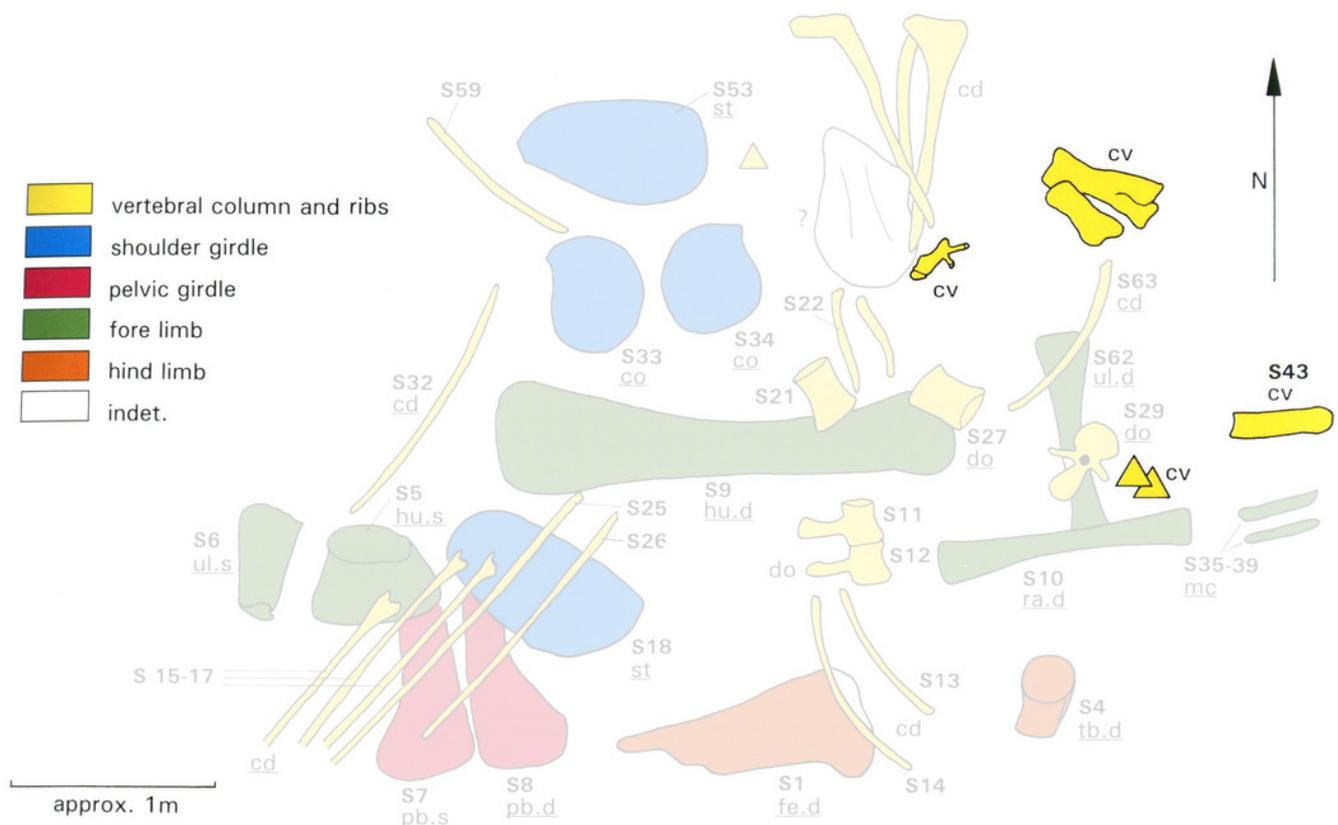

**Left:** Field Museum photograph CSGEO16166, photographer Charles Carpenter, taken in 1905, the year after Riggs's (1904) descriptive monograph. Note the "crazy-paving" effect of the many cracks and missing areas of bone surface. **Middle:** Illustration of the same vertebra in Riggs (1904: plate LXXII). Note that the damage to the vertebral surface is not depicted. **Right:** photograph of the same vertebra, taken by the author in 2005. Note that the damage apparent in the 1905 photograph is no longer visible: the vertebra seems to have been painted to conceal its incompleteness.

## Figure 6

Quarry map of Tendaguru Site S, Tanzania, showing incomplete and jumbled skeletons of *Giraffatitan brancai* specimens MB.R.2180 (the lectotype, formerly HMN SI) and MB.R.2181 (the paralectotype, formerly HMN SII).

Cervical material is highlighted in strong yellow, while the remaining elements are desaturated. Anatomical identifications of MB.R.2181 are underlined>. Elements of MB.R.2180 could not be identified on the map with certainty. Modified from Heinrich (1999: figure 16), which was itself redrawn by Heinrich from an original field sketch by Werner Janensch.

## Figure 7

Cervical vertebrae 5-11 of an ostrich, *Struthio camelus*, in posterior view, showing that articular facet shape remains similar along the column.

Specimen kindly provided by Matt Cobley.

## Figure 8

Cervical and dorsal vertebrae (C5-9 and D1-2) of a juvenile alligator, *Alligator mississippiensis*, in anterior view, showing that articular facet shape remains similar along the column.

Specimen kindly provided by Matthew J. Wedel.

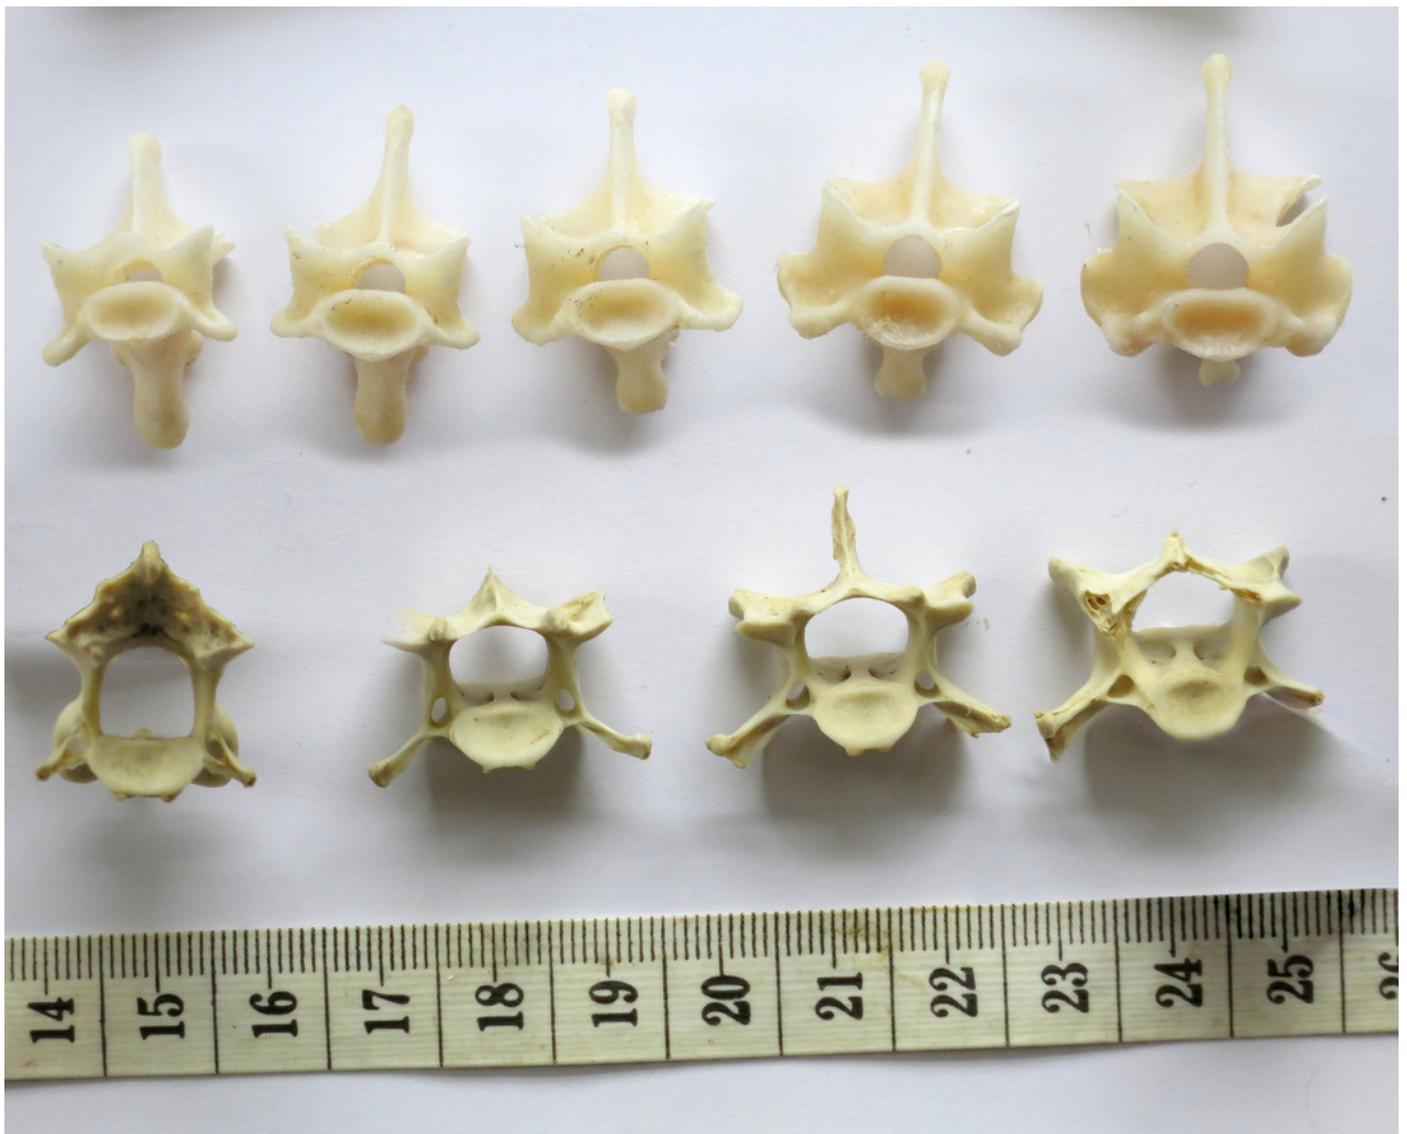

## Figure 9

Sequences of cervical vertebrae of extant animals, showing that articular facet shape remains similar along the column.

**Top.** Cervical vertebrae 3-7 of a mature savannah monitor lizard, *Varanus exanthematicus*, in anterior view. (The cervicals of monitor lizards, unlike those of sauropods and most mammals, are procoelous, with the anterior facet being concave and the posterior convex.)

**Bottom.** cervical vertebrae 2-5 of a mature house-cat, *Felis catus*, in posterior view.

## Figure 10

Cervical vertebrae of a baby giraffe, *Giraffa camelopardalis*, in posterior view, showing that articular facet shape remains similar along the column.

Top row, left to right: cervicals 7, 6 and 5; bottom row, left to right: cervicals 4, 3 and 2.

Despite changes in the vertebrae along the column, the flattened inverted pentagon shape of the articular facets remains similar along the sequence. (Note that extensive cartilage caps existed on the articular facets of this very young specimen, but were lost in preparation.)

## Figure 11

Cervical vertebrae 4 (left) and 6 (right) of *Giraffatitan brancai* lectotype MB.R.2180 (formerly HMN SI), in posterior view.

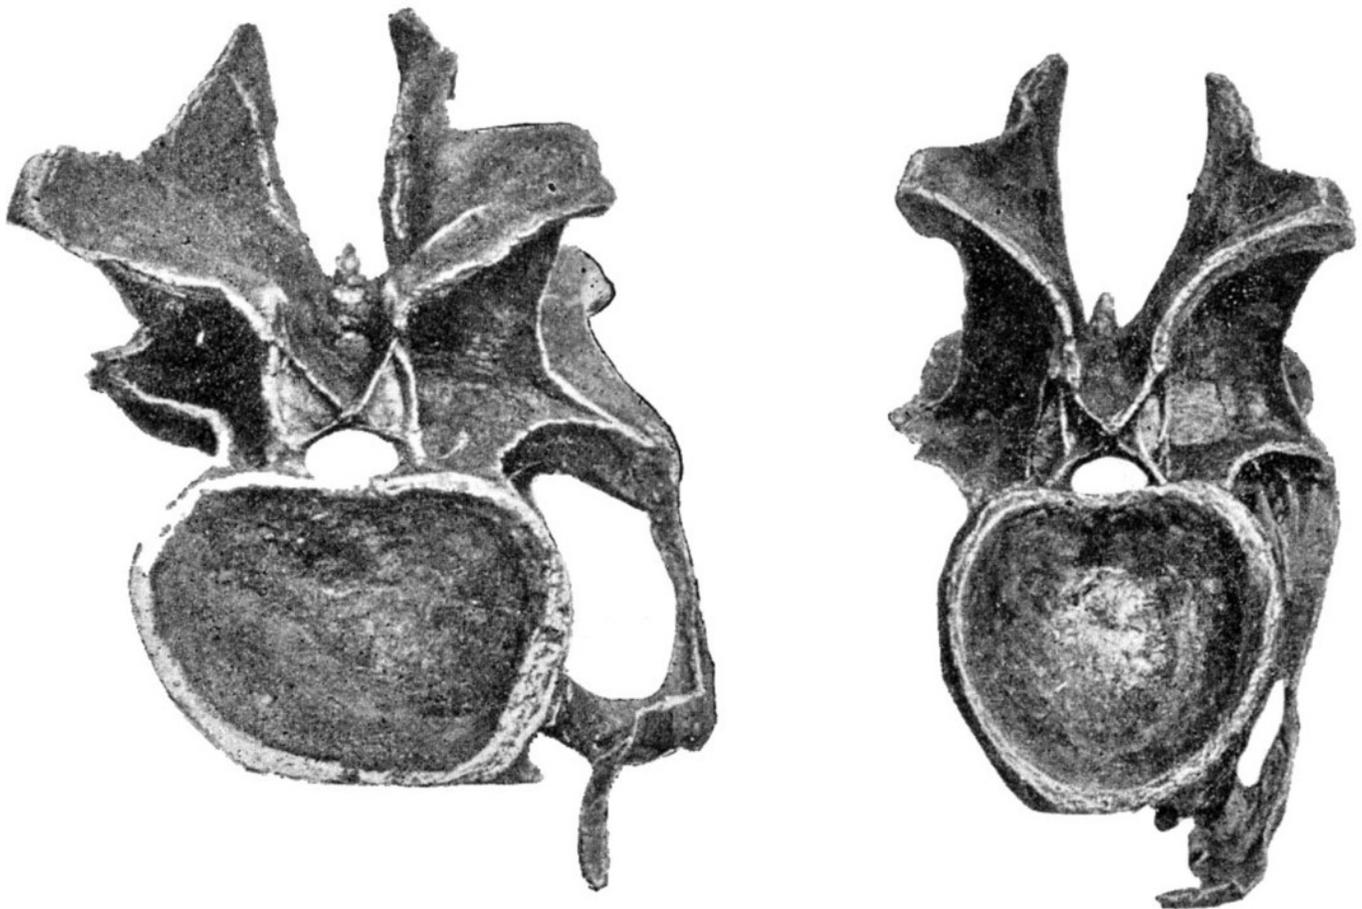

Note the dramatically different aspect ratios of their cotyles, indicating that extensive and unpredictable crushing has taken place. Photographs by the author.

## Figure 12

Cervical vertebrae 14 (left) and 13 (right) of *Diplodocus carnegii* holotype CM 84, in posterior view.

Note the dramatically different aspect ratios of their cotyles, indicating that extensive and unpredictable crushing has taken place.

## Figure 13

Manipulation of consecutive sauropod vertebrae by hand. Cervicals 2 and 3 of *Giraffatitan brancai* lectotype MB.R.2181 (formerly HMN SI).

I attempted to articulate these two vertebrae, and empirically determine the feasible range of motion. Due to subtle distortion of the zygapophyses of these vertebrae, it was not possible to articulate C2 in a more extended position relative to C3 than shown here.

Photograph by Mathew J. Wedel.

## Figure 14

Cervicodorsal transition of *Haplocanthosaurus priscus* holotype CM 572.

Top row, right lateral view; bottom row, anterior view. From left to right, D1, C15 and C14. Pink highlights indicate the expanded lateral surface of the prezygadiapophyseal lamina, anchoring the supporting muscles of the scapula, which Hatcher considered diagnostic of the 1st dorsal vertebra. Modified from Hatcher (1903: plate I).
