

Almost all known sauropod necks are incomplete and distorted

Michael P Taylor^{Corresp. 1}

Sauropods are familiar dinosaurs, immediately recognisable by their great size and long necks. However, their necks are much less well known than is often assumed. Surprisingly few complete necks have been described in the literature, and even important specimens such as the Carnegie *Diplodocus* and *Apatosaurus*, and the giant Berlin brachiosaur, in fact have imperfectly known necks. In older specimens, missing bone is often difficult to spot due to over-enthusiastic restoration. Worse still, even those vertebrae that are complete are often badly distorted — for example, in consecutive cervicals of the Carnegie *Diplodocus* CM 84, the aspect ratio of the posterior articular facet of the centrum varies so dramatically that C14 appears 35% broader proportionally than C13. And even in specimens where the cervicodorsal sequence is preserved, it is often difficult or impossible to confidently identify which vertebra is the first dorsal. Widespread incompleteness and distortion are both inevitable due to sauropod anatomy: large size made it almost impossible for whole individuals to be preserved because sediment cannot be deposited quickly enough to cover a giant carcass on land; and distortion of presacral vertebrae is common due to their lightweight hollow construction. This ubiquitous incompleteness and unpredictable distortion compromise attempts to mechanically analyze necks, for example to determine habitual neck posture and range of motion by modelling articulations between vertebrae.

9 **Abstract**

10 Sauropods are familiar dinosaurs, immediately recognisable by their great size and long
11 necks. However, their necks are much less well known than is often assumed. Surprisingly few
12 complete necks have been described in the literature, and even important specimens such as the
13 Carnegie *Diplodocus* and *Apatosaurus*, and the giant Berlin brachiosaur, in fact have imperfectly
14 known necks. In older specimens, missing bone is often difficult to spot due to over-enthusiastic
15 restoration. Worse still, even those vertebrae that are complete are often badly distorted — for
16 example, in consecutive cervicals of the Carnegie *Diplodocus* CM 84, the aspect ratio of the
17 posterior articular facet of the centrum varies so dramatically that C14 appears 35% broader
18 proportionally than C13. And even in specimens where the cervicodorsal sequence is preserved,
19 it is often difficult or impossible to confidently identify which vertebra is the first dorsal.
20 Widespread incompleteness and distortion are both inevitable due to sauropod anatomy: large
21 size made it almost impossible for whole individuals to be preserved because sediment cannot be
22 deposited quickly enough to cover a giant carcass on land; and distortion of presacral vertebrae is
23 common due to their lightweight hollow construction. This ubiquitous incompleteness and
24 unpredictable distortion compromise attempts to mechanically analyze necks, for example to
25 determine habitual neck posture and range of motion by modelling articulations between
26 vertebrae.

30 Introduction

31 In a paper on how the long necks of sauropods did not evolve primarily due to sexual
 32 selection (Taylor et al. 2011), one of the ideas we discussed is that sexual dimorphism between
 33 the necks of male and female sauropods, expressed as a ratio of neck lengths to shoulder height,
 34 might be an indicator of sexual selection. Rather despairingly, we wrote (Taylor et al. 2011:4):
 35 “Available samples of sauropod taxa are unfortunately not large enough to demonstrate bimodal
 36 distribution of morphological features within any sauropod species.”

37 Sauropod specimens are rarely found in a form complete enough to allow even relatively
 38 rudimentary measurements to be made — for example, neck length or shoulder height. In fact,
 39 the problem is more significant than is generally realised. It is not just that we do not have large
 40 populations of well-preserved sauropod individuals, capable of being subject to statistical
 41 analyses; even individual complete sauropods are extremely rare. This is true especially of the
 42 necks, which are composed of large, fragile vertebrae that are prone to disarticulation and
 43 distortion.

44 The consequent incompleteness of known sauropod necks, and the ubiquitous distortion of the
 45 elements that are available, has negative consequences for taxonomic work (since we are
 46 frequently unable to compare overlapping elements of different specimens), phylogenetic
 47 analysis (due to loss of character data), developmental studies (as we are frequently unable to
 48 determine for example how pneumatic features vary along the neck in patterns mimicking
 49 ontogeny), biomechanical function (since we do not have sufficiently precise joint anatomy to
 50 accurately model neutral posture or range of motion) and ecological impact (using neck length as
 51 a proxy for feeding behaviour). While these problems are appreciated by seasoned campaigners,
 52 they are less well understood by newcomers to the field and to those whose specialisms are in
 53 adjacent fields such as extant animal anatomy, especially as most people’s initial impressions of

54 sauropod are formed by large and apparently complete mounted specimens in public galleries.

55 In this paper I will first show that even the best-preserved and best-known sauropod
56 specimens mostly have necks that are incomplete, then show that distortion of what cervical
57 vertebrae we do have is ubiquitous and unpredictable, and finally explore the implications of this
58 on what we can know of how these necks behaved in life.

95 **Incompleteness**

96 A truly complete neck would consist of all vertebrae, each of them individually complete.
 97 Unfortunately, it is rarely possible to tell from published descriptions whether a given neck is
 98 complete in this sense: necks are sometimes described superficially as “complete” when all that
 99 is meant is that some portion of each vertebra is preserved. In the cases of necks that are
 100 described in detail, it is almost always apparent that a “complete” neck is complete only in this
 101 limited sense: for example, in the *Cathetosaurus lewisi* holotype BYU 9047, McIntosh et al.
 102 (1996:76) note that although all 12 cervicals are present, “10–12, particularly 12, have suffered
 103 such severe damage that it is impossible to restore them”. For the purposes of this paper, then we
 104 use “complete” in the unsatisfactory sense that at least a good part of each vertebra is present.

105 The determination of completeness of necks is also hindered by the problem that for many
 106 species we do not know how many vertebrae would constitute a complete neck. When necks are
 107 not found in articulation but a probably complete set of cervicals is found scattered, the
 108 possibility that additional vertebrae were present in life cannot be discounted. The mode of
 109 preservation can vary wildly with disarticulated necks, giving us a greater or lesser degree of
 110 confidence that all vertebrae are present. At one end of the spectrum, vertebrae may be scattered
 111 around, and intermixed with those of other species or even other individuals of the species, as
 112 with the numerous cervical vertebrae included in the *Camrasaurus specimen* complex AMNH
 113 5761/5761a and assigned somewhat arbitrarily to three sequences (Osborn and Mook 1921:plates
 114 LXVII–LXIX). In happier cases, such as that of the *Qijianglong guokr* holotype QJGPM 1001,
 115 partial sequences are articulated (in this case C2–11) and other cervicals closely associated.
 116 However, even a neck found in articulation may be impossible to evaluate as to its completeness,
 117 as with *Lavocatisaurus agrioensis* (see below).

118 With these caveats in mind, I now survey the known complete and nearly-complete sauropod
 119 necks.

120 **Catalogue of complete necks**

121 Unambiguously complete necks are known from published accounts of only a few sauropod
 122 specimens. In chronological order of description, the following specimens were found with their
 123 necks complete and articulated, and have been adequately described — each of them known to
 124 include the posteriormost cervicals because the vertebral column is articulated through into the
 125 dorsal region:

- 126 • CM 11338, a referred specimen of *Camarasaurus lentus* described by Gilmore (1925).
 127 This is a juvenile specimen, and thus does not fully represent the adult morphology.
 128 (McIntosh et al. 1996:76 claim that this specimen is the holotype, but this is not correct:
 129 YPM 1910 is the holotype — see below.)
- 130 • CM 3018, the holotype of *Apatosaurus louisae*, described by Gilmore (1936). The neck

- 131 was separated from the torso but articulated from C1–C15, though the last three cervicals
 132 were badly crushed: see below for details.
- 133 • CCG V 20401, the *Mamenchisaurus hochuanensis* holotype, described by Young and
 134 Zhao (1972). Each vertebra is broken in half at mid-length, with the posterior part of each
 135 adhering to the anterior part of the its successor; and all the vertebrae are badly crushed in
 136 an oblique plane.
 - 137 • ZDM T5402, a *Shunosaurus lii* referred specimen, described in Chinese by Zhang
 138 (1988), with English figure captions. Their figure 22 depicts the atlas. Unlike the
 139 holotype T5401, this specimen is mature.
 - 140 • BYU 9047, the *Cathetosaurus lewisi* holotype, described by Jensen (1988). (Jensen
 141 incorrectly gives the specimen number as BYU 974.) This specimen was redescribed, and
 142 the species referred to *Camarasaurus*, by McIntosh et al. (1996). Although all 12
 143 cervicals are present, “10–12, particularly 12, have suffered such severe damage that it is
 144 impossible to restore them” (McIntosh et al. 1996:76).
 - 145 • MACN-N 15, the holotype of *Amargasaurus cazau* MACN-N 15, described by Salgado
 146 and Bonaparte (1991) who described “22 presacral vertebrae articulated with each other
 147 and attached to the skull and sacrum, relatively complete” (Salgado and Bonaparte
 148 1991:335, translated).
 - 149 • ZDM 0083, the holotype of *Mamenchisaurus youngi*, described in Chinese by Ouyang
 150 and Ye (2002) with English figure captions. Their figure 14 depicts the atlas and axis.
 - 151 • MUCPv-323, the holotype of *Futalognkosaurus dukei*, initially described by Calvo et al.
 152 2007a and redescribed by Calvo et al. 2007b. The neck was found in two articulated
 153 sections which fit together without needing additional vertebrae in between (Jorge O.
 154 Calvo, pers. comm., 2021).
 - 155 • SSV12001, the holotype of *Xinjiangtitan shanshanensis*, described by Zhang et al. (2018).
 156 The original description of this specimen by Wu et al. 2013 included only the last two
 157 cervicals, which were the only ones that had been excavated at that time.

158 A few additional specimens are known to have complete and articulated necks, but have not
 159 yet been described:

- 160 • USNM 13786, a referred subadult specimen of *Camarasaurus lentus* recently mounted at
 161 the Smithsonian. The specimen “was almost completely buried before the sinews had
 162 allowed the bones to separate” (letter from Earl Douglass to William J. Holland, 22
 163 August 1918), and photographs kindly supplied by Andrew Moore show that the atlas
 164 was preserved.
- 165 • MNBH TIG3, the holotype of *Jobaria tiguidensis*. Sereno et al. (1999:1343) assert that
 166 this species has 12 cervicals in all and say “One articulated neck was preserved in a fully
 167 dorsiflexed, C-shaped posture”. Paul C. Sereno (pers. comm., 2021) confirms that the
 168 articulated neck is MNBH TIG3
- 169 • SMA 002, referred to *Camarasaurus* sp. Tschopp et al. (2016), in a description of its feet,
 170 say that this specimen “lacks only the vomers, the splenial bones, the distal end of the
 171 tail, and one terminal phalanx of the right pes. The bones are preserved in three
 172 dimensions and in almost perfect articulation”.
- 173 • MAU-Pv-LI-595, the “La Invernada” Titanosaur. Filippi et al. (2016) give a very brief
 174 account in an abstract. Filippi (pers. comm, 2021) says that the entire preserved specimen
 175 was articulated.

176 • MAU-Pv-AC-01, an unnamed titanosaur mentioned in abstracts by Calvo et al. (1997)
 177 and Coria and Salgado (1999). The specimen was found in perfect articulation from skull
 178 down to the last caudal vertebrae (Rodolfo A. Coria, pers. comm., 2021).

179 The first cervical (the atlas) in sauropods is very different in form from the other vertebrae,
 180 and small and fragile. Consequently it is easily lost. Some further specimens have necks that are
 181 complete and articulated from C2 (the axis) backwards:

- 182 • MB.R.4886, the holotype of *Dicraeosaurus hansemanni*, described by Janensch (1929),
 183 has a neck that complete and well preserved from C2 to C12 (the last cervical). Janensch
 184 referred to this as “specimen m” and writes “It was found articulated from the 19th
 185 caudal vertebra to the 9th cervical vertebra inclusive. The proximal part of the neck from
 186 the 8th cervical vertebra up to the axis was bent ventrally and lay at right angles to the
 187 distal part of the neck.” (Janensch 1929:41).
- 188 • PMU 233, the holotype of *Euhelopus zdanskyi*, described by Wiman (1929) as “exemplar
 189 a” and redescribed by Wilson and Upchurch (2009).
- 190 • ZDM T5401, the subadult holotype of *Shunosaurus lii*, described in Chinese by Zhang et
 191 al. 1984. The quarry map (Zhang et al. 1984:figure 1) suggests that the atlas is missing.
- 192 • MCT 1487-R, informally known as “DGM Series A”, described by Powell (2003).
 193 Gomani (2005:9) summarises as “12 cervical vertebrae, except the atlas, preserved in
 194 articulation with three proximal dorsal vertebrae”.
- 195 • GCP-CV-4229, the holotype of *Spinophorosaurus nigerensis*, described by Remes et al.
 196 (2009). This species is known from two specimens, of which the holotype was found in
 197 very good condition and well articulated from C2 to C13, the last cervical (Figure 1). The
 198 atlas seems to be missing (Kristian Remes, pers. comm., 2021; Ralf Kosma, pers. comm.,
 199 2021).

200 One other sauropod is complete from the first cervical, but probably not to the last:

- 201 • MOZ-Pv1232, the holotype of *Lavocatisaurus agrioensis*, described by Canudo et al.
 202 (2018). This is complete from C1–C11. Canudo’s guess is that this is the complete neck
 203 (Jose I. Canudo, pers. comm, 2021), but the specimen doesn’t demand that conclusion
 204 and no known eusauropod is definitively known to have fewer than 12 cervicals.
 205 However, Upchurch (pers. comm., 2021) notes that the dicraeosaurid neosauropod
 206 *Amargasaurus* has 22 presacral vertebrae in total, and difficulties in locating the
 207 cervicodorsal junction (see below) make it impossible to state confidently whether it had
 208 12 or only 11 cervicals, so caution is warranted here.

209 Other sauropod specimens have necks that are complete and articulated from further back in
 210 the cervical sequence:

- 211 • YPM 1910, the holotype of *Camarasaurus lentus*, a mounted specimen described by Lull
 212 (1930). The neck is complete from C2 or C3, Lull was uncertain which. (It should be
 213 possible to clear that up by re-examining the specimen in light of what has subsequently
 214 become known about *Camarasaurus lentus*, but this work has not yet been done.)
- 215 • SMA 0004, *Kaatedocus siberi*, described by Tschopp and Mateus (2012). Cervicals 3–14
 216 are preserved.
- 217 • AODF 888 (informally “Judy”), probably referable to *Diamantinasaurus*, briefly
 218 described by Poropat et al. (2019). Preserved from C3 or maybe C4. “One posterior

219 cervical (XIII or XIV) found several metres from articulated series, but appears to slot
220 nicely into the gap between the articulated cervical series and the unprepared thoracic
221 section, which might include at least one additional cervical (XIV or XV)” (Poropat, pers.
222 comm. 2021).

223 Several necks are probably nearly complete, but it is not possible to know due to their not
224 being found in articulation:

- 225 • CM 84, the holotype of *Diplodocus carnegii*, described by Hatcher (1901). C2–C15 are
226 preserved, though not all in articulation; C11 may be an intrusion: see below for details.
- 227 • ZDM T5701, the holotype of *Omeisaurus tianfuensis*, described by He et al. (1988). The
228 neck was not articulated (He et al. 1988:figure 1), and was missing “two elements or so”
229 (He et al. 1988:120).
- 230 • QJGPM 1001, the holotype of *Qijianglong guokr*, described by Xing et al. (2015). On
231 page 8, the authors say “The axis to the 11th cervical vertebra were fully articulated in
232 the quarry. The atlas intercentrum and the 12th–17th cervical vertebrae were closely
233 associated with the series.”
- 234 • MNBH TIG9, a referred specimen of *Jobaria tiguidentis*. Wilson (2012:103) writes that
235 this specimen “includes a partially articulated series of 19 vertebrae starting from the axis
236 and extending through the mid-dorsal vertebrae.”
- 237 • MNBH TIG6, another referred specimen of *Jobaria tiguidentis*, which has not been
238 mentioned in the literature. Paul C. Sereno (pers. comm., 2021) says that it is “a subadult
239 partial skeleton with excellent neck” and that “the sequence was articulated from C2–11.
240 Most of the ribs were attached as well.”

241 **Note.** The *Jobaria tiguidentis* individuals previously had specimen numbers beginning MNN,
242 but the Musée National du Niger changed its name to Musée National Boubou Hama and the
243 specimen numbers have changed with it.

244 The breakdown of these complete and near-complete necks is interesting (Figure 2). Non-
245 neosauropods are relatively well represented, both inside and outside of Mamenchisauridae —
246 although it is unfortunate many of these specimens are not well well described in English: two of
247 the ten are of *Jobaria*, for which the cursory summary of Sereno et al. (1999) remains the only
248 published description, and some of the Chinese sauropods are described only in Chinese.

249 Diplodocoids are surprisingly poorly represented, with only a single specimen in each of
250 Dicraeosauridae and Diplodocidae that is complete. Brachiosaurids have absolutely no
251 representation — see below on how unconvincing the neck of *Giraffatitan* is. More advanced
252 titanosauriforms are better represented, but there is still only one with a complete neck,
253 *Futalognkosaurus dukei*. By contrast, the single genus *Camarasaurus* is very well represented,
254 with five specimens of which four are fully complete (though only two of those have been
255 described). Probably this does not indicate a taxon-specific taphonomic signal, but follows from
256 the sheer abundance of *Camarasaurus* specimens — an abundance likely influenced by over-
257 lumping of multiple rather different species into a single genus.

258 It is surprising, though, that the second and third best represented sauropods in museums,
259 *Diplodocus* and *Apatosaurus*, are both barely represented in terms of complete necks. And while
260 the number of complete and nearly-complete necks among somphospondyls, including
261 titanosaurs, is encouraging, it is disappointing that so many of them are not yet described.

262 At the time of writing (21 December 2021), the Paleobiology Database
263 (<https://paleobiodb.org/>) lists 342 sauropod species. The nine unambiguously complete and
264 articulated necks therefore represent only one in 38 known sauropod species — and recall that
265 even these are mostly “complete” only in the weak sense of preserving some part of each
266 cervical vertebra.

267 As best we can tell, only one sauropod species, *Camarasaurus lentus*, is known from more
268 than a single complete neck. Of the two individuals, CM 11338 is a juvenile and USNM 13786 is
269 a subadult, so the mature morphology is unknown. If we allow necks missing the atlas, then there
270 are also two individuals of *Shunosaurus lii*: ZDM T5401, the subadult holotype, which is
271 missing its atlas; and ZDM T5402, an adult referred specimen whose neck is complete. (These
272 specimens have not been described in English.) With sample sizes this small, it is not possible
273 even in principle to determine whether there is a bimodal distribution in the length of any
274 sauropod’s neck.

275 Several well-known sauropod specimens are often thought of as having complete, undamaged
276 necks, but in each case the truth is less clear. I now discuss three important specimens.

277 ***Diplodocus carnegii* CM 84**

278 The Carnegie *Diplodocus* is one of the most recognised dinosaurs in the world: not only is the
279 original specimen, CM 84, on display as a mounted skeleton in the Carnegie Museum in
280 Pittsburgh, but casts are displayed in many other major museums (e.g. the Natural History
281 Museum in London, the Museum für Naturkunde Berlin and the Muséum National d’Histoire
282 Naturelle in Paris.) The neck appears complete in these mounted skeletons, with fifteen cervical
283 vertebrae, and is illustrated as such by Hatcher (1901: plate 8); Figure 3. However, the situation
284 is not as clear as it appears in these exhibits.

285 Holland (1900:816), in the first published account of the Carnegie *Diplodocus*, assigned to
286 this specimen only eleven cervicals, noting (on p. 817) that:

287 The cervicals were for the most part interarticulated, all lying in such position as to
288 show the serial order [...] Eleven are found in the specimen at the Carnegie Museum,
289 atlas and axis being as yet undiscovered.

290 Allowing for the missing atlas and axis, Holland concluded only that the cervical count was
291 “at least 13”.

292 However, Hatcher (1900:828–829) corrected this count later the same year:

293 About 45 feet (14 meters) of the vertebral column is preserved in our specimen.
294 When discovered the vertebrae did not lie in a connected and unbroken series, yet
295 there can be little doubt that they all pertain to the same individual [...]
296 Unfortunately no diagram was made, at the time of exhuming the remains, showing
297 the relative position of each of the vertebrae in the quarry [...] Early last spring, at
298 the request of the writer, Mr. W. H. Reed (who assisted in unearthing the skeleton),
299 while again on the ground, made a diagram of the quarry, showing the relative
300 positions, as he remembered them, of the various bones of the skeleton.

301 Despite this uncertainty, Hatcher asserted (p. 828–829):

302 “In all 41 vertebrae are represented, including 14 cervicals (all but the atlas) [...]

303 Assuming that no vertebrae are missing from our series the vertebral formula of
304 *Diplodocus* should now be written as follows: Cervicals, 15 [...] The number of
305 cervical vertebrae in *Diplodocus* is definitely fixed at at least 15.”

306 Hatcher’s 1900 paper is unsatisfactory in that it gives no reason for his revision of the cervical
307 count. Hatcher also hedged by leaving open the possibility of there being more than 15 cervicals.
308 The lack of a reliable quarry map is unfortunate.

309 In his subsequent monograph, Hatcher (1901:4) expanded on the completeness and condition
310 of the material as follows (emphasis added):

311 [*Diplodocus carnegii* holotype CM 84] has been entirely freed from the matrix and is
312 found to consist of [appendicular material and] forty-one vertebrae divided as
313 follows: fourteen cervicals including the axis, eleven dorsals, four sacrals, and twelve
314 caudals. These vertebrae are for the most part fairly complete, though unfortunately
315 the sacrals and **anterior cervicals are more or less injured**. This series of forty-one
316 vertebrae are believed to pertain to one individual and to form an unbroken series
317 from the axis to the twelfth caudal, although as was shown in a previous paper, **there**
318 **is some evidence that there are perhaps one or more interruptions in the series**
319 **and that one or more vertebrae are missing**. On the other hand, as will appear
320 later, **it is not entirely impossible that at least one vertebra of this supposed**
321 **series pertains to a second individual** belonging perhaps to a distinct genus.

322 Hatcher (1901:11) went on to quote a statement from A. S. Coggeshall, who had assisted in
323 the excavation, explaining in more detail how the elements of the neck were discovered:

324 [The] last (fifteenth) cervical was considerably removed from the succeeding dorsals
325 and less so from the preceding cervicals. Commencing with the next vertebra
326 (cervical fourteen), the direction of the entire cervical series was altered so that it lay
327 with its axis almost at right angles to that of the dorsal series. The cervicals extended
328 in an almost straight line from the fourteenth to the fifth, but there was a considerable
329 gap between cervicals eleven and ten, while the axis and cervicals three, four and
330 five were doubled back under the succeeding vertebrae.

331 This account almost explains why Holland underestimated the number of cervicals: the
332 anteriormost four, lying under more posterior cervicals, had not yet been found. However, if ten
333 cervicals (C6–C15) had been found and the atlas and axis were both missing, Holland
334 (1900:816) would surely have stated “Ten are found in the specimen at the Carnegie Museum,
335 atlas and axis being as yet undiscovered” rather than eleven. Some mystery remains: perhaps
336 Holland was aware of one of the anteriormost four preserved cervicals.

337 Coggeshall’s description is somewhat corroborated by Reed’s quarry map, which is included
338 as Plate 1 of Hatcher’s (1901) monograph (Figure 4). However, the map is in some respects at
339 odds with the description: for example, it shows all 13 vertebrae C2–C14 in a single straight line
340 rather than indicating that C2–C5 were doubled back; and it shows gaps both between C10 and
341 C11 (as stated), and also between C11 and C12 (not mentioned in the text).

342 Regarding the vertebra that might pertain to “a second individual belonging perhaps to a
343 distinct genus”, Hatcher (1901:22) explained: “*Eleventh Cervical*.—This vertebra is so unlike
344 either the immediately preceding or succeeding vertebrae that if it had been found isolated it
345 would have been unhesitatingly referred to a different genus. Mr. Coggeshall, however, assures

346 me that it was interlocked with the succeeding, or twelfth cervical.” Yet, as noted, the quarry
347 map suggests that there was some distance between C11 and C12, perhaps invalidating
348 Coggeshall’s assertion. It is to be lamented that both the map and the description were created
349 some time after the excavation actually took place, by which time memories had evidently
350 become unreliable.

351 In conclusion, *Diplodocus carnegii* most likely had fifteen cervicals, but may have had more
352 (if some vertebrae were not recovered), or maybe fewer (if C11 was misassigned). Furthermore,
353 the anterior cervicals are damaged in a way that is not at all apparent from Hatcher’s drawings
354 (plate III) or photographs (plate IV) because they were restored before these illustrations were
355 prepared. As Hatcher (1901:23) noted, “The work of freeing these vertebrae from the matrix and
356 restoring them was for the most part done during my absence in the field. Unfortunately no
357 drawings or photographs were taken prior to the process of restoring with colored plaster.” (In
358 the early 20th Century, it was routine to restore damaged fossils in ways that completely
359 obscured the degree of damage: see Figure 5.)

360 *Apatosaurus louisae* CM 3018

361 *Apatosaurus louisae* is the best known species of *Apatosaurus*, since its holotype CM 3018 is
362 much more complete and better preserved than that of the type species *A. ajax* (YPM 1680), or
363 that of the closely related *Brontosaurus excelsus* (YPM 1980).

364 The specimen was collected by Earl Douglass in 1909 and 1910, from what was then known
365 as the Carnegie Museum Dinosaur Quarry near Jensen, Utah, and is now Dinosaur National
366 Monument. It was mounted for exhibition in 1913, and somewhat belatedly named the type of a
367 new species in a brief initial description by Holland (1915). He noted that “the specimen consists
368 of a series of vertebrae, complete from the atlas to nearly the end of the tail” and appendicular
369 material; but also that “the cervical vertebrae had been separated from the dorsals and shifted,
370 but the entire series was found articulated in regular order” (p. 143). (Holland’s description also
371 mentioned that “a skull, which judging by its location, belongs to the specimen, was found
372 within eleven feet of the atlas. It does not differ greatly in form from the skull which belongs to
373 *Diplodocus*”. Had Holland stuck to his guns, *Apatosaurus* could have been restored with its
374 correct skull 63 years before Berman and McIntosh (1978) corrected Marsh’s long-standing and
375 influential misapprehension that it had a *Camarasaurus*-like skull.)

376 Holland stated (p. 144) that he had “in preparation a large monographic paper relating to the
377 genus, based in part upon [CM 3018]”. However, completion was long delayed, and Holland
378 died in 1932 before it was ready to be published. It was eventually brought to completion by
379 Gilmore (1936) and it is from this monograph that the species is primarily known.

380 Gilmore’s monograph explains that all is not as it seems in the neck of his specimen. He notes
381 (p. 191) that “there was some distortion due to the compression to which [the cervicals] had been
382 subject, but this has been largely corrected during preparation” — a questionable decision, as it
383 means that the shapes of the vertebrae as originally found are now lost, and cannot be subjected
384 to more modern retrodeformation techniques (e.g. Tschopp et al. 2013). He continues “Cervicals
385 thirteen, fourteen, and fifteen, however, were so badly crushed that it was thought best to replace
386 them in the mounted skeleton by plaster restorations of these vertebrae”, although he does claim
387 that “they are, however, sufficiently well preserved so that most of their important characteristics
388 can be determined”. The caption to Gilmore’s plate XXIV reads “Cervical vertebrae of
389 *Apatosaurus louisae*. Type, No. 3018 [...] Cervicals 13, 14 and 15 have been much restored

390 from badly crushed originals, and should be used with caution.” It is also evident from this plate
391 that most of C5 is also missing, although this is not acknowledged in the text. As noted by
392 Upchurch (2000), the poor condition of the posterior cervical vertebrae, and their replacement by
393 plaster models in the mounted skeleton, compromise the validity of biomechanical modelling
394 based on this specimen, such as that of Stevens and Parrish (1999).

395 In conclusion, while the articulation of the cervical sequence of CM 3018 leaves little doubt
396 that all cervicals are present and in the correct order, the crucial posterior cervicals are largely
397 uninformative.

398 ***Giraffatitan brancai* MB.R.2181**

399 This specimen is the paralectotype of *Giraffatitan brancai* (= “*Brachiosaurus*” *brancai*).
400 Much of the material is incorporated in the mounted skeleton in the atrium of the Museum für
401 Naturkunde Berlin, which remains the largest substantially real mounted skeleton of a terrestrial
402 animal anywhere in the world. (There are larger mounts of sauropods, such as the skeletons of
403 *Patagotitan* at the AMNH and FMNH, but these are casts and sculptures, not real material.)
404 While most of the material of the Berlin brachiosaur mount is real fossil bones, the presacral
405 vertebrae are too heavy and fragile to mount: instead, high quality sculptures are used, and the
406 vertebrae themselves are held in collections.

407 The presacrals in the mount are based on real bones that are from two specimens — the
408 lectotype MB.R.2180 (formerly known as SI) and the paralectotype MB.R.2181 (formerly SII).
409 The former includes cervicals 2–7, an assignment that can be accepted with some confidence if
410 the vertebrae indeed form a sequence because the axis, C2, in sauropods is very distinctive,
411 having a completely different anterior articular surface from all the subsequent cervicals (see e.g.
412 Janensch 1950:figs. 9–16, cf. figs. 17–48.) MB.R.2181 includes cervicals assigned by Janensch
413 to positions 3–13 (although almost all of them are damaged, some very severely).

414 However, the two individuals MB.R.2180 and MB.R.2181 were found together in a single
415 quarry (designated Quarry S). Bones of the two individuals were jumbled up together, with little
416 articulation, as shown in the quarry map, redrawn by Heinrich (1999: figure 16; Figure 6) from
417 an original drawn in the field by Werner Janensch. Any reconstruction — or even assignment of
418 individual vertebrae to one specimen or the other — must be considered provisional.

419 I have previously suggested (Taylor 2009:800–801) that the distinctively high-spined dorsal
420 vertebra usually considered the fourth of MB.R.2181 may not actually belong to that specimen,
421 or even that taxon. Instead, this unusually tall vertebra may belong to an animal more closely
422 resembling the Tendaguru titanosauriform briefly described by Migeod (1931) and which I am in
423 the process of redescribing (Taylor 2005, Taylor in prep at
424 <https://github.com/MikeTaylor/palaeo-archbishop/>). If this vertebra is indeed not part of
425 MB.R.2181 then the most likely inference is that it is part of MB.R.2180. This would be
426 unfortunate if these two specimens were indeed representatives of different taxa. The smaller and
427 less complete MB.R.2180, rather than the larger, more complete and better known MB.R.2181,
428 is the lectotype (Janensch 1935–1936). Therefore, the ICZN rules dictate that the name
429 *Giraffatitan brancai* would adhere to MB.R.2180, and that a new name would be required for the
430 better-known MB.R.2181. Since this species was thought until relatively recently to be a species
431 of the North American genus *Brachiosaurus* (see Taylor 2009), a further reassignment would
432 mean that this charismatic and iconic specimen would become known by a third different name
433 in not much more than a decade. To avoid this outcome, an ICZN petition may be warranted.

434 Janensch (1950:33) indicates that the confusion of the cervical vertebrae is not as bad as that
435 of the dorsals, but the situation is still far from clear, as Janensch's description explains:

436 The vertebrae from the 3rd to 15th presacrals [of MB.R.2181] lay in articulation in a
437 consolidated lime sandstone lens; of them, the 3rd to 5th vertebrae are tolerably
438 complete, the remaining 10 vertebrae were articulated with one another, with one
439 interruption that arose when the 8th presacral vertebra rotated out of the series and
440 was displaced. [Translation by Gerhard Maier.]

441 Janensch's words are somewhat at odds with the quarry map, which shows cervical material
442 scattered around the northeastern part of the quarry (Figure 6). Other quarry sketches drawn by
443 Janensch, including one reproduced by Heinrich (1999: figure 18), certainly show at least some
444 cervicals having been found in articulation, but it is not clear what the correspondence is between
445 the field numbers on these sketches and subsequently assigned element identifications.

446 So it is possible, though unlikely, that there might have been other displaced cervicals, before
447 or after the one designated "8th", that were not recovered. Neither can we be wholly confident
448 that the anteriormost preserved cervical in the MB.R.2181 series is really C3. Its identification is
449 based on the overlap with vertebrae of MB.R.2180, but we cannot be certain that MB.R.2180 is a
450 member of the same species as MB.R.2181. Perhaps the anteriormost preserved cervical is really
451 C4? Or perhaps some of the "MB.R.2181" cervicals really belong to MB.R.2180. This is not
452 particularly likely, as Janensch pointed out, due to the difference in size between the two
453 specimens — the MB.R.2181 cervical centra are about 30–40% longer than those assigned the
454 same serial position in MB.R.2180. But the size difference cannot be considered a conclusive
455 argument, especially given the uncertainty in serial-position assignments in both specimens.

456 In conclusion: *Giraffatitan brancai* probably had thirteen cervicals, but may have had more,
457 or possibly less; and the neural arches are only known for cervicals 3, 4, 5 and 8 in MB.R.2181
458 (if these are the correct serial positions for those vertebrae). If MB.R.2180 is indeed a member of
459 the same species then cervicals 2–7 are known from well-preserved elements, but no more. All
460 of this uncertainty is exacerbated by the problem that no complete or even nearly complete neck
461 of any other brachiosaur has been described.

462 To summarise this section, not only are complete sauropod necks in very short supply, even
463 those that are considered complete cannot generally be confidently considered so, and
464 complexities of interpretation bedevil the best-known specimens.

465 **Distortion**

466 Even in necks where most or all of the vertebrae are present and largely complete, extensive
467 distortion is common. This is difficult to quantify, even in principle, given the very complex
468 shapes of sauropod cervicals. But we can take tentative steps towards recognising the extent of
469 the problem by considering one simple aspect: the shapes of the cotyles of consecutive vertebrae.

470 In sauropod cervical vertebrae (and most dorsal vertebrae), the posterior articular face of the
471 centrum is called the cotyle, due to its distinctive hollow shape. The anterior articular face is
472 convex, and so is called the condyle. The cotyle of one vertebra and the condyle of the
473 succeeding one form a ball-and-socket joint (see Taylor and Wedel 2013b: figures 2–3), similar
474 to the condition in extant horses and camels (see Taylor and Wedel 2013b: figures 20–21) among
475 other animals.

476 In extant animals, including birds, crocodylians, lizards and mammals, the articular facets of
477 consecutive vertebrae are of much the same shape, varying only gradually along the neck. In
478 particular, the aspect ratio of the facet — its width:height ratio — remains constant or nearly so
479 (Figures 7–10). However, in the fossilised necks of sauropods, it's not unusual for even
480 consecutive vertebrae to be crushed in opposite directions, giving their cotyles (apparently)
481 wildly different aspect ratios.

482 Consider for example the *Giraffatitan brancai* lectotype MB.R.2180 (formerly HMN SI), one
483 of the best preserved sauropod neck series. Cervicals 4 and 6 of this specimen are shown in
484 posterior view in Figure 11. (The intermediate cervical 5 has part of its cotyle rim broken off,
485 and cannot be reliably measured.) Measuring from the photos, the width:height ratio of C4 (on
486 the left) is 683/722 pixels = 0.95, and that of C6 (on the right) is 1190/820 pixels = 1.45. So
487 these two vertebrae — from the same neck, and with only one other vertebrae coming in between
488 them — differ in preserved cotyle aspect ratio by a factor of 1.53.

489 As a second example, consider the single most studied sauropod neck specimen in the world,
490 that of the *Diplodocus carnegii* holotype CM 84. Figure 12 shows adjacent cervicals 13 and 14,
491 in posterior view. Note that the posterior part of the neck was considered well preserved by
492 Hatcher (1901), with only anterior vertebrae noted as having been damaged. Measuring from
493 Hatcher's photos, the width:height for C14 (on the left) is 342/245 pixels = 1.40. For C13 (on the
494 right), it is 264/256 pixels = 1.03. So C14 is apparently 35% broader than its immediate
495 predecessor.

496 There is no established metric for quantifying change in a measure, such as the aspect ratio of
497 articular surfaces, along a vertebral column. Table 1 offers two candidate metrics and shows how
498 they are worked out for six of the seven specimens discussed in this section. (The cat has too few
499 available vertebrae for the metric to be meaningful.) Using the first metric, average difference
500 between aspect ratios in consecutive vertebrae, the young juvenile giraffe, the monitor lizard, the
501 alligator and the ostrich all score in the range 4.2–6.3, while the two sauropods score 9.1 and
502 16.3. Using the second metric, average ratio between aspect ratios of consecutive vertebrae, the
503 four extant animals score in the range 6.7–8.9, and the sauropods 12.0 and 22.1. It would be
504 useful in future to calculate these metrics for larger sets of extant and fossil vertebrates, and to
505 see whether it is generally the case that the variation metrics are higher for fossils than for extant
506 vertebrates. For now, though, this tentative initial analysis corroborates the “eye-test” conclusion
507 that variation is significantly greater along sauropod necks.

508 It might be argued that variation on cotyle shape in sauropod necks arises from mechanical
509 factors. Since their necks were elongate, segmented cantilevers, they become broader towards
510 their base, and this could be reflected in cotyle shape. However, we would expect mechanical
511 influences such as this to produce gradual monotonic variation — cotyles either becoming
512 consistently broader or consistently taller towards the base of the neck. But this is not what we
513 observe: instead, the preserved aspect ratios of sauropod condyles vary erratically along the
514 neck. Such extreme variation in apparent aspect ratio of the cotyles of adjacent and near-adjacent
515 cervical vertebrae can only be the result of extensive and unpredictable crushing.

516 This variation in preservation of aspect ratios has implications for calculating the elongation
517 index (EI) of vertebrae, a calculated character widely used in phylogenetic analyses and
518 elsewhere. For example, Janensch's (1950:39) table of measurements for the *Giraffatitan*
519 *brancai* lectotype MB.R.2180 (formerly HMN SI) gives the centrum length and cotyle height of

520 C4 as 45.7 and 13.8 cm, for an EI *sensu* Wedel et al. (2000:346) of 3.31. For C6, he gives
521 centrum length and cotyle height as 69.1 and 15.0, for a much greater EI of 4.6. But if the true
522 cotyle proportions of C6 were the same as those of C4, then the cotyle height corresponding to
523 its width of 22.1 would be a much taller 23.1 cm, yielding an EI of only 3.0. Some recent work
524 uses the aEI of Chure et al. (2010), in which the centrum length is divided not by cotyle height,
525 but by the average of cotyle height and width. This goes some way towards mitigating the
526 confounding effects of crushing, but cannot fully allow for its unpredictable effects: for example,
527 oblique crushing may increase both maximum height and width of the cotyle, yielding a
528 misleadingly low aEI. At the very least, we need to be circumspect in our use of elongation
529 indices as phylogenetic characters or ecological correlates.

530 Deformation of the articular cotyle is only one example of the many ways in which sauropod
531 vertebrae, with their complex and fragile anatomy are subject to crushing. It is certain that other
532 parts of the vertebrae, especially the delicate lateral processes and zygapophyseal rami, were also
533 often distorted, and it is generally not possible to reliably restore to their undistorted state.

534 In addition to such distortions of individual processes of vertebrae, systematic distortion of
535 entire vertebrae is common. For example, in CCG V 20401, the holotype specimen of
536 *Mamenchisaurus hochuanensis* for which the neck is complete and articulated, every vertebra of
537 the neck and trunk is sheared and rotated such that the left side is displaced downwards (Taylor
538 2004, personal observation of mounted casts in Copenhagen, Denmark; Trzic, Slovenia; and
539 Chicago, USA). This distortion is illustrated for dorsal vertebra 2 by Young and Zhao
540 (1972:figure 6); although they do not illustrate it for a cervical vertebra, it is present throughout
541 the column.

542 While the *Mamenchisaurus hochuanensis* distortion is very apparent, subtler distortions are
543 ubiquitous but easier to overlook. For example, the *Giraffatitan brancai* holotype cervical
544 vertebrae MB.R.2180 (formerly HMN SI) appear undistorted to the naked eye, but manual
545 articulation of C2 and C3 demonstrates that sufficient distortion has occurred to prevent the
546 bones being posed in ways that the live animal surely could have achieved (Figure 13).

547 **Location of cervicodorsal junction**

548 One further issue impedes our ability to analyse and compare the necks of different
549 sauropods, and that is the difficulty of identifying the last cervical vertebra — and therefore of
550 defining how many vertebrae make up the neck (and how many make up the dorsal series). In
551 general it is easy to tell cervical and dorsal vertebrae apart: for example, compare C13 and D3 of
552 the *Diplodocus carnegii* holotype CM 84 (Hatcher 1901:plates III and VII). The cervical vertebra
553 is relatively low, its centrum is elongated, its neural spine is roughly triangular and its
554 parapophysis hangs down below the centrum and has a cervical rib fused to it and the
555 diapophysis (though this latter character is not consistent in sauropods: see below). By contrast,
556 the dorsal vertebra is tall, its centrum is short, its neural spine is anteroposteriorly compressed its
557 parapophysis is up on the dorsal half of the centrum, and no rib is fused to it. But the change in
558 these characters is gradual, and at the transition it is much more difficult to distinguish between
559 cervical and dorsal vertebrae. Compare C15 and D1 of CM 84 (Hatcher 1901:plates III and VII
560 once more). Had Hatcher classified his C15 as the first dorsal, or his D1 as the last cervical, it
561 would not be obvious that this was incorrect. Similarly, Wilson and Upchurch (2009:20) found it
562 difficult to unambiguously identify the first dorsal vertebra even when dealing with the relatively

563 complete and well-preserved presacral sequence of *Euhelpus zdanskyi*.

564 The difficulty of locating the cervicodorsal junction is exacerbated by the lack of a single
565 standard definition. Several exist:

- 566 • **Rib fusion.** Hatcher (1901:25) writes “The dorsals are distinguished from the cervicals
567 by supporting free instead of fixed ribs ...”
- 568 • **Ventral centrum shape.** Hatcher (1901:25–26) continues “... and in having the inferior
569 surface of the centra regularly convex transversely instead of concave in either direction”.
- 570 • **Scapular support.** In his description of *Haplocanthosaurus* two years later, Hatcher
571 (1903:8) uses a completely different definition: “That [D1] was a dorsal is conclusively
572 shown not by the presence of tubercular and capitular rib facets showing that it supported
573 on either side a free rib [...] The character in this vertebra distinguishing it as a dorsal is
574 the broadly expanded external border of the anterior branch of the horizontal lamina [i.e.
575 what we would now call the prezygadiapophyseal lamina ...] to give greater surface for
576 the attachment of the powerful muscles necessary for the support of the scapula.” (See
577 Figure 14.)
- 578 • **Parapophysis location.** Hatcher (1901:16) notes “In the fifth dorsal the capitular facet is
579 on the middle of the neural arch, while in dorsals four and three it has shifted down to the
580 centrum and encroached upon the pleurocentral cavities of these vertebrae. In dorsals two
581 and one it lies wholly inferior to that cavity”, and his illustrations show that it is well
582 below the centrum in all cervical vertebrae.
- 583 • **Gene expression.** Wilson (2002:226) notes that “the cervicodorsal transition in many
584 tetrapods, for instance, appears to be defined by the expression boundary of the *Hoxc-6*
585 gene”.

586 However none of these definitions is wholly satisfactory.

- 587 • Rib fusion is not a reliable criterion, as Hatcher (1903:8) notes: “there are in our
588 collections of sauropods, skeletons of other dinosaurs fully adult but, with the posterior
589 cervical, bearing free cervical ribs articulating by both tubercular and capitular facets as
590 do the ribs of the dorsal region”. As one example, the *Mamenchisaurus hochuanensis*
591 holotype CCG V 20401 has free ribs on its last three cervicals (Young and Zhao 1972;
592 personal observation). It may be argued that those last three cervicals are really dorsals,
593 but while a case could possibly be made for the last one, the rib shafts of the previous two
594 are much too horizontally oriented to sustain such an interpretation.
- 595 • Ventral centrum shape is highly variable between different sauropod taxa — and, as
596 noted above, centra are prone to distortion, though this is probably less prevalent in the
597 relatively robust ventral part of the centrum than in the more fragile cotyle.
- 598 • The presence of a scapular support facet on the lateral face of the CPRL is difficult to
599 detect, and evidently not trusted by Hatcher himself as he noted of C15 of *Diplodocus*
600 CM 84 that “the superior of the anterior blades of the horizontal lamina has its external
601 surface somewhat expanded and rugose. It no doubt served as a support for the muscular
602 attachment of the heavy scapular arch” (Hatcher 1901:25).
- 603 • While the parapophysis migrates dorsally across the centrum to the arch in successive

604 vertebrae of all sauropods, this migration typically does not commence until after the first
605 dorsal, making it useless to determining the location of the junction.

- 606 • The genetic definition is obviously useless for fossil organisms.

607 In practice, most workers seem to use a combination of multiple criteria, often not explicitly
608 specified. For example, in considering the dorsal count of *Barosaurus*, McIntosh (2005:45)
609 writes “The eighth presacral [counting forward from the sacrum] is unquestionably a dorsal and
610 the tenth a cervical”, but does not explain why he makes these designations. He continues, “But
611 what is the ninth? At first glance it certainly appears to be a cervical — the parapophysis projects
612 from the very bottom of the centrum well below the pleurocoel. However [...] neither rib is co-
613 ossified to the parapophyses and diapophyses as in the cervical vertebrae anterior to it. Largely
614 for this reason, I have concluded that it is the first dorsal.” Here, McIntosh is making a
615 judgement on the contradictory evidence of the rib-fusion and parapophysis-location criteria,
616 while not using ventral centrum shape (perhaps because the ventral view of the centrum is not
617 available) or scapular-support facets (perhaps due to preservational problems making it
618 impossible to assess). This example is instructive, as it illustrates pervasive difficulties when
619 dealing with bones as large, fragile and difficult to manipulate as sauropod presacrals: very few
620 such bones can be inspected from all cardinal directions, and as noted above distortion and
621 damage is ubiquitous.

622 Perhaps, then, the best we can hope for in identifying the cervicodorsal junction is to use a
623 combination of criteria according to what is available for study in the specimen in question, but
624 to be explicit about which criteria are used. As McIntosh’s example demonstrates, this
625 identification is important, as it determines the number of cervical vertebrae deemed to belong to
626 a neck: even in those very rare cases when a presacral vertebral sequence is complete and
627 undistorted, it is still to some degree a matter of judgement how many cervical vertebra
628 constitute the neck.

629 (In some older papers (e.g. Migeod 1931), a “shoulder vertebra” is referenced, an intermediate
630 between the last cervical and the first dorsal, but this terminology is not used in modern
631 literature. However, introducing this concept does not aid the quest for consensus over how the
632 junction is located: the issue simply becomes the problem of locating the shoulder vertebra,
633 rather than locating the first dorsal.)

634 Discussion

635 Taphonomic factors

636 All of the problems with sauropod neck preservation arise from the nature of the animals and
637 the general procedures of taphonomy.

638 First, sauropods are big. This is a recipe for incompleteness of preservation: small skeletons
639 are more easily destroyed by taphonomic processes, but if they survive are more easily preserved
640 whole, while large skeletons less rarely survive intact (Brocklehurst et al. 2012). It is no accident
641 that the most completely preserved sauropods are small individuals such as CM 11338, the cow-
642 sized juvenile *Camarasaurus lentus* described by Gilmore (1925). For an organism to be
643 fossilised, it is necessary for the carcass to be swiftly buried in mud, ash or some other substrate.
644 This can happen relatively easily to small animals, such as the many finely preserved small

645 theropods from the Yixian Formation in China, but is much less possible with a large animal
646 (Mannion 2010:284).

647 Cleary et al. (2015:528 and figure 6) showed that medium-sized ichthyosaurs preserve more
648 completely than either small or large individuals, but since these are aquatic animals their
649 preservational context is not applicable to the case of sauropods. Brown et al. (2012) found that
650 in the Dinosaur Park Formation, “large-bodied” dinosaurs preserved more completely than
651 smaller ones, but their sample contained no sauropods, their threshold for “large” was only 60
652 kg, and the largest animals included were 4.5-tonne hadrosaurs. It may be that if the methods of
653 Brown et al. (2012) were used to analyse the sauropod-bearing Morrison or Tendaguru
654 formations, the result would be similar to those of Cleary et al. (2015), with medium-sized
655 animals having the most complete preservation. At a larger scale, Cashmore et al. (2020:963)
656 found only a weak, and weakly significant, correlation between sauropod body mass and
657 specimen completeness ($R^2 = 0.03$; $p = 0.04$), using the SCM2 skeletal completeness metric of
658 Mannion & Upchurch (2010). However, analysis of their figure 5A, plotting log body mass
659 against log completeness shows a rapid falling away in completeness above body masses with
660 log 10 — presumably natural log, representing about 22 tonnes.

661 It is also possible that the light construction of highly pneumatic cervical vertebrae would
662 have rendered them particularly prone to water transport, disarticulating and scrambling the
663 necks of even some otherwise adequately preserved specimens.

664 Except in truly exceptional circumstances, sediments simply are not deposited quickly enough
665 in terrestrial environments to cover a 25 meter, 30 tonne animal with a light neck skeleton before
666 it is broken apart by scavenging, decay and water transport. Fossilisation of the very largest
667 sauropods tends to produce even more fragmentary remains. In light of this, it is not surprising
668 that the very longest sauropod necks are usually known from particularly inadequate specimens.
669 The longest neck for which we have direct evidence is that of the diplodocid *Supersaurus*,
670 possibly 15 m long, but the only cervical material of the largest specimen is a single 1.4 m
671 cervical (BYU 9024, formerly BYU 5003; Jensen 1985, 1987). Similarly, the giant basal
672 titanosauriform *Sauroposeidon* probably had a neck about 11 m long, but the only definite
673 material belonging to it is a sequence of three and a half cervicals from the middle of the neck
674 (OMNH 53062; Wedel et al. 2000). The longest known titanosaur necks are probably those of
675 *Patagotitan*, *Puertasaurus* and *Dreadnoughtus*, all at around 9–10 m, but the cervical material
676 from which they are known is meagre: only three vertebrae in the *Patagotitan* holotype MPEF-
677 PV 3400, of which the longest is 120 cm long (supplementary information to Carballido et al.
678 2007); a single 118 cm *Puertasaurus* vertebra, MPM-PV 10002 (Novas et al. 2005); and a single
679 113 cm vertebra of *Dreadnoughtus* MPM-PV 1156 (Lacovara et al. 2014).

680 Secondly, even when complete sauropod skeletons are preserved, or at least complete necks,
681 distortion of the preserved cervical vertebrae is almost inevitable because of their uniquely
682 fragile construction. As in modern birds, the cervical vertebrae were lightened by extensive
683 pneumatisation, so that they were more air than bone (Taylor and Wedel 2013a: figure 4), with
684 the air-space proportion typically in the region of 60–70% and sometimes reaching as high as
685 89% (Taylor and Wedel 2013a: table 2; Wedel 2005: figure 7.4C). While this construction
686 enabled the vertebrae to withstand great stresses for a given mass of bone, it nevertheless left
687 them prone to crushing, shearing and torsion when removed from their protective layer of soft
688 tissue. For highly pneumatized cervicals in particular, the chance of the shape surviving through
689 taphonomy, fossilisation and subsequent deformation would be tiny.

690 Possible mitigations

691 Some information about sauropods necks that is not directly observable can be inferred from
692 phylogenetic bracketing: the observation that if two close outgroups to an organism of interest
693 both have a feature, then the null hypothesis is that the organism of interest inherited that feature
694 from the common ancestor (see Witmer 1995). For example, the neck of *Sauroposeidon proteles*
695 is known only from a sequence of four vertebrae (Wedel et al 2000). But as a brachiosaurid it is
696 bracketed by *Giraffatitan brancai*, which is thought on reasonable evidence (see above) to have
697 had 13 cervicals, and *Camarasaurus lentus*, which is known from complete specimens to have
698 had 12 cervicals (Gilmore 1925:367). It is therefore parsimonious on this basis to conclude that
699 the most recent common ancestor of *Giraffatitan* and *Camarasaurus* probably had 12–13
700 cervical vertebrae, and that *Sauroposeidon proteles* likewise also had 12–13 cervicals.

701 While this level of inference is better than no information, the present example illustrates
702 three problems with the use of phylogenetic bracketing for sauropod morphology. First, due to
703 incomplete knowledge of most sauropods, it is often necessary to move some way down the tree
704 from the organism of interest before reaching specimens for which morphology is sufficiently
705 known. In this example, while *Giraffatitan* is probably close to *Sauroposeidon*, *Camarasaurus* is
706 some way basal to it — but more closely related brachiosaurids such as *Abydosaurus* and
707 *Europasaurus*, while possessing good cervical material, do not have anything close to a complete
708 neck, and so cannot be used in bracketing. As a result, the *Giraffatitan*–*Camarasaurus* bracket
709 used in this example is broader than we would wish. Second, the phylogenetic context in which
710 we interpret brackets is not always well established. In the present example, I have been
711 following Wedel et al.'s (2000) referral of *Sauroposeidon* to the clade Brachiosauridae; but if
712 D'Emic and Foreman (2012) are correct in their assessment that *Sauroposeidon* in fact a
713 somphospondyliian, then it would be more appropriate to bracket it between *Giraffatitan brancai*
714 and *Euhelopus zdanskyi* — which has 17 cervical vertebrae (Wiman 1929:7), suggesting a
715 significantly higher cervical count of 13–17 for *Sauroposeidon*. Third, in the case of sauropods,
716 the morphology of the bracketing taxa is often not as solidly established as we might wish. In
717 this case, while the cervical counts of *Camarasaurus lentus* and *Euhelopus zdanskyi* are well
718 established, that of *Giraffatitan brancai* is less so, as documented above, rendering the cervical-
719 count ranges for *Sauroposeidon* even more uncertain. In conclusion, while phylogenetic
720 bracketing remains a useful tool, it must be used with care.

721 The problem of distortion in individual vertebrae can be addressed to some extent through
722 retrodeformation (e.g. Schlager et al. 2018). This term encompasses a suite of techniques in
723 which mathematical processes are applied to virtual models of fossils in an attempt to restore
724 them to the shape they had before their deformation in matrix. Various methods have been
725 proposed in the literature, largely based on an assumption of symmetry. Most of the early
726 methods were designed for 2D transformations on morphologically simple invertebrate fossils
727 (e.g. Cooper 1990), but more recent developments have yielded methods more capable of
728 handling complex 3D shapes (e.g. the Single Axis Method of Kazhdan et al. 2009). Application
729 of these techniques to sauropod vertebrae has so far been limited, but Tschopp et al. (2013)
730 conducted experiments on cervical vertebrae of the diplodocid *Kaatedocus siberi* using an
731 artificially deformed model of a dodo cervical as a control. They found that while the
732 retrodeformation techniques they tested were capable of restoring symmetry to a deformed
733 vertebra, they often did so at the expense of artificially making the vertebra shorter, broader or
734 thinner than it should be. Surprisingly, they also found that applying the same process twice to a

735 vertebra first made it more robust than the original, then more slender. At this stage it seems that
736 more sophisticated techniques, preserving more aspects of the 3D geometry, will be necessary
737 before retrodeformed sauropod cervicals can be taken at face value.

738 But this does not mean that other strategies cannot help in dealing with distorted material. For
739 example, Hedrick and Dodson (2013) used 3D geometric morphometric techniques to better
740 understand individual and taphonomic variation in a set of 30 skulls representing three nominal
741 species of *Psittacosaurus*. They showed that the apparent morphological variation between these
742 “species” actually represent the results of different taphonomic processes, and that all 30 skulls
743 in fact represent members of the same species. It may be possible to use similar techniques on
744 sauropod vertebrae, although modifications would be required to deal with the additional
745 complexity introduced by serial variation in vertebral morphology.

746 One thing that is apparent in all this is the necessity of careful documentation on how
747 specimens were found, in what states of articulation, in what kinds of matrix, and under what
748 strains: for example, Angielczyk and Sheets (2007) use strain measurements to quantify
749 deformation. These descriptions should where possible be accompanied by quarry maps, and
750 ideally by photos and even 3D models of the excavation — something that is increasingly
751 possible given the unlimited capacity for online supplementary information in many journals.
752 Such additional documentation may not materially increase our understanding of the specimens
753 but does at least make it more explicit what we do and do not know, yielding rigidly defined
754 areas of doubt and uncertainty. Similarly, when fossils are restored, it should be done in such a
755 way that it is apparent what parts of the restored specimen are real bone and which are
756 reconstructed. Happily, modern palaeontologists are much better in all these respects than our
757 predecessors were. Some “golden age” palaeontologists were concerned primarily with what
758 would constitute a spectacular museum mount: it is for this reason that O. C. Marsh had YPM
759 1980, the holotype of *Brontosaurus excelsus*, so enthusiastically “restored” that it is now
760 impossible to determine which parts of the cervical vertebrae are real (pers. obs., Barbour 1890).
761 But these days are mostly behind us, and nearly all modern specimens are prepared in a form that
762 accurately conveys what was actually preserved.

763 **Implications**

764 Both the incompleteness and distortion of sauropod necks have grave consequences for our
765 ability to reason about sauropods. As noted above, the very small sample of complete necks
766 makes it quite impossible to perform meaningful statistical analyses. This incomplete
767 information also impedes our ability to understand the evolution of sauropod necks, making it
768 difficult to determine the plesiomorphic cervical morphology and vertebral counts at the bases of
769 clades. Similarly, the frequent, unpredictable and sometimes dramatic distortion of what
770 vertebrae we do have renders mechanical analysis of neutral poses and ranges of motion
771 extremely problematic. For vertebrae small and robust enough to be manipulated by hand, this
772 can be readily observed in physical space (Figure 13). There is no reason to think that computer
773 modelling of vertebrae and their articulations (e.g. Stevens and Parrish 1999) should yield
774 models any more informative than the distorted fossils that they are based on.

775 On a more positive note, the lack of complete necks does not mean that we are without
776 information. For many sauropods that lack complete necks, enough vertebrae are preserved with
777 enough fidelity that we can have a good idea how morphology varies between anterior, middle
778 and posterior cervicals, even if precise identification of the vertebrae is not possible. Crucially,

779 this degree of completeness suffices for the majority of characters to be scored in phylogenetic
780 analyses: apart from a few characters specific to the atlas or axis, most such characters pertain
781 only to anterior, middle or posterior cervicals.

782 **Conclusion**

783 What does it all mean? Only this: we don't know as much as we may assume we do. We don't
784 even know how many cervical vertebrae well-known sauropods such as *Diplodocus* and
785 *Giraffatitan* had. We don't have complete necks for either of these sauropods, nor for almost any
786 others. Even those we do have are in some cases badly crushed (e.g. *Mamenchisaurus*
787 *hochuanensis*). We are woefully short of sauropod necks.

788 As scientists, we must carefully avoid blithely asserting factoids such as “*Diplodocus* had 15
789 cervicals and *Giraffatitan* only 13”. We simply don't know whether this is true. Evidence
790 supports it as a hypothesis — these numbers are certainly the best guesses for the taxa in
791 question — but a hypothesis is all it is. Hypotheses of neck posture and flexibility should be held
792 even more lightly, since they are based on inferences drawn from distorted elements whose true
793 shapes we may never know.

794 None of this is necessarily disastrous, so long as we properly acknowledge the degree of
795 uncertainty that afflicts our work. Problems arise when studies such as that of Stevens and
796 Parrish (1999) draw apparently firm conclusions about sauropod neck posture based on
797 specimens that are deficient in respects not acknowledged in the text, lending the results a veneer
798 of definitiveness that they do not merit.

799 **Acknowledgments**

800 An earlier version of this manuscript was reviewed in 2015 by Paul Barrett, Paul Upchurch
801 and Jeffrey Wilson; the present version was reviewed by Oliver Rauhut, Paul Upchurch (again)
802 and Veronica Diez-Diaz. This final version is much stronger for having been updated in response
803 to their comments. I also thank Brandon Hedrick for his editorial handling of the manuscript, and
804 my wife, Fiona, for motivating me to finally get the revisions done on this long overdue paper.

805 After the first version of this manuscript was published as a preprint, numerous people
806 reminded me of additional complete and near-complete sauropod necks. These include (in
807 alphabetical order) Lee Braithwaite, John D'Angelo, Vahe Demirjian, Oliver Demuth, Daniel
808 Gonçalves, Stephen Gunnell, Rutger Jansma, Matt Lamanna, Stefan Reiss, Emmanuel Tschopp,
809 Justin Tweet and Paul Upchurch.

810 I thank Jorge O. Calvo, Paul C. Sereno, Leonardo S. Filippi, Rodolfo A. Coria, Kristian
811 Remes, Ralf Kosma, Jose I. Canudo and Stephen F. Poropat for permission to cite personal
812 communications.

813 I thank Mathew J. Wedel for his observations on the phylogenetic distribution of complete
814 and near-complete necks, and for providing the juvenile alligator neck illustrated in Figure 8.
815 Matt Cobley provided the ostrich neck illustrated in Figure 7. Andrew Moore supplied
816 photographs of the neck of the *Camarasaurus lentus* specimen USNM 13786. Daniela Schwarz
817 provided high-resolution scans of Werner Janensch's site maps of “Quarry S”, where important
818 *Giraffatitan* material was found. Gerhardt Maier provided the translation of Janensch (1950).
819 This translation, and others that I referred to, are freely available from the Polyglot

820 Paleontologist web-site at <http://paleoglot.org/>

821 This paper is based in part on three blog-posts from *Sauropod Vertebra Picture of the Week*
822 (Taylor 2011, Taylor 2013, Taylor 2014), and also on part of a talk at the Symposium on
823 Vertebrate Palaeontology and Comparative Anatomy (Taylor and Wedel 2011).

1070 Table Captions

1071 **Table 1.** Serial variation in preserved aspect ratios of consecutive cervical vertebrae in extant
1072 animals and sauropods from several major amniote clades. Mammalia: giraffe *Giraffa*
1073 *camelopardalis*, young juvenile specimen, C2–C7. Lacertilia: savannah monitor, *Varanus*
1074 *exanthematicus*, C3–C7. Crocodylia: alligator *Alligator mississippiensis*, juvenile specimen,
1075 C5–D2; Aves: ostrich *Struthio camelus*. C5–C11. Sauropoda: *Diplodocus carnegii* holotype
1076 CM84 and *Giraffatitan brancai* lectotype MN.R.2180 (formerly HMN SI). **Vertical** and
1077 **horizontal** columns contain measurements of the posterior articular surfaces of the vertebrae,
1078 except for the procoelous alligator vertebrae for which anterior articular surface was used. For
1079 the saddle-shaped ostrich cervicals, the maximum height and width of the posterior articular
1080 surface was used, rather than the shorter midline distances. Measurements are in arbitrary
1081 units (e.g. mm or pixels in a photograph) but consistent within any one specimen. **V/H** is the
1082 aspect ratio of the measured surface, the ratio of the vertical and horizontal measurements, so
1083 that values less than 1.0 indicate a surface wider than tall, and values greater than 1.0 indicate
1084 a surface taller than wide. Note that this ratio is independent of the measurement units. **1st**
1085 **diff** measures the absolute value of the difference between the V/H ratios of each vertebra and
1086 its successor. **Max diff** is the highest value of 1st diff for each specimen, and **Avg diff** is the
1087 average value; **×100** is this value times 100, a measure of the serial variation along the
1088 column. **1st ratio** is the “absolute ratio” of the V/H values of one vertebra and its successor,
1089 normalized so that when the ratio is less than 1.0 its inverse is used. **Max ratio** is the highest
1090 value of 1st ratio for each specimen, and **Avg ratio** is the average value; **–1×100** is this value
1091 minus one, multiplied by 100, another measure of the serial variation along the column. Note
1092 that by both measures, the variation in articular surface aspect ratios is greater in the two
1093 sauropods than in any of the extant animals, even though these are among the best preserved
1094 sauropod necks.

1095 Figure Captions

- 1096 **Figure 1.** *Spinophorosaurus nigerensis* holotype GCP-CV-4229 in situ during excavation in the
1097 region of Aderbissinat, Thirozerine Dept., Agadez Region, Republic of Niger. Reproduced
1098 from Remes et al. (2009: figure 1).
- 1099 **Figure 2.** Simplified phylogeny of Sauropoda, showing counts of complete and near-complete
1100 necks. Captions: **C**, complete and described; **U**, complete but undescribed; **–1**, missing the
1101 atlas but otherwise complete; **O**, other near-complete necks (see text for details); **T**, total.
- 1102 **Figure 3.** Neck of *Diplodocus carnegii* holotype CM 84, as reconstructed by Hatcher (1901:

1103 plate XIII), with fifteen undamaged cervical vertebrae.

1104 **Figure 4.** W. H. Reed's diagram of Quarry C near Camp Carnegie on Sheep Creek, in Albany
1105 County, Wyoming. The coloured bones belong to CM 84, the holotype of *Diplodocus*
1106 *carnegii*; other bones belong to other individuals, chiefly of *Brontosaurus*, *Camarasaurus* and
1107 *Stegosaurus*. Modified (cropped and coloured) from Hatcher (1901: plate I). Cervical
1108 vertebrae are purple (and greatly simplified in outline by Reed), dorsals are red, the sacrum is
1109 orange, caudals are yellow, limb girdle elements are blue, and limb bones are green.

1110 **Figure 5.** Three images of presacral vertebra 6 (probably dorsal 7) of *Brachiosaurus altithorax*
1111 holotype FMNH P25107, in right lateral view, showing misleading restoration. **Left:** Field
1112 Museum photograph CSGEO16166, photographer Charles Carpenter, taken in 1905, the year
1113 after Riggs's (1904) descriptive monograph. Note the "crazy-paving" effect of the many
1114 cracks and missing areas of bone surface. **Middle:** Illustration of the same vertebra in Riggs
1115 (1904: plate LXXII). Note that the damage to the vertebral surface is not depicted. **Right:**
1116 photograph of the same vertebra, taken by the author in 2005. Note that the damage apparent
1117 in the 1905 photograph is no longer visible: the vertebra seems to have been painted to
1118 conceal its incompleteness.

1119 **Figure 6.** Quarry map of Tendaguru Site S, Tanzania, showing incomplete and jumbled
1120 skeletons of *Giraffatitan brancai* specimens MB.R.2180 (the lectotype, formerly HMN SI)
1121 and MB.R.2181 (the paralectotype, formerly HMN SII). Cervical material is highlighted in
1122 strong yellow, while the remaining elements are desaturated. Anatomical identifications of
1123 MB.R.2181 are underlined. Elements of MB.R.2180 could not be identified on the map with
1124 certainty. Modified from Heinrich (1999: figure 16), which was itself redrawn by Heinrich
1125 from an original field sketch by Werner Janensch. Heinrich's version Copyright Wiley-VCH
1126 Verlag GmbH & Co. KGaA. Reproduced with permission.

1127 **Figure 7.** Cervical vertebrae 5–11 of an ostrich, *Struthio camelus*, in posterior view, showing
1128 that articular facet shape remains similar along the column. Specimen kindly provided by
1129 Matt Cobley.

1130 **Figure 8.** Cervical and dorsal vertebrae (C5–9 and D1–2) of a juvenile alligator, *Alligator*
1131 *mississippiensis*, in anterior view, showing that articular facet shape remains similar along the
1132 column. Specimen kindly provided by Matthew J. Wedel.

1133 **Figure 9.** Sequences of cervical vertebrae of extant animals, showing that articular facet shape
1134 remains similar along the column. **Top.** Cervical vertebrae 3–7 of a mature savannah monitor
1135 lizard, *Varanus exanthematicus*, in anterior view. (The cervicals of monitor lizards, unlike
1136 those of sauropods and most mammals, are procoelous, with the anterior facet being concave
1137 and the posterior convex.) **Bottom.** cervical vertebrae 2–5 of a mature house-cat, *Felis catus*,
1138 in posterior view.

1139 **Figure 10.** Cervical vertebrae of a baby giraffe, *Giraffa camelopardalis*, in posterior view,
1140 showing that articular facet shape remains similar along the column. Top row, left to right:
1141 cervicals 7, 6 and 5; bottom row, left to right: cervicals 4, 3 and 2. Despite changes in the
1142 vertebrae along the column, the flattened inverted pentagon shape of the articular facets
1143 remains similar along the sequence. (Note that extensive cartilage caps existed on the articular
1144 facets of this very young specimen, but were lost in preparation.)

1145 **Figure 11.** Cervical vertebrae 4 (left) and 6 (right) of *Giraffatitan brancai* lectotype MB.R.2180

1146 (formerly HMN SI), in posterior view. Note the dramatically different aspect ratios of their
1147 cotyles, indicating that extensive and unpredictable crushing has taken place. Photographs by
1148 the author.

1149 **Figure 12.** Cervical vertebrae 14 (left) and 13 (right) of *Diplodocus carnegii* holotype CM 84, in
1150 posterior view. Note the dramatically different aspect ratios of their cotyles, indicating that
1151 extensive and unpredictable crushing has taken place.

1152 **Figure 13.** Manipulation of consecutive sauropod vertebrae by hand. Cervicals 2 and 3 of
1153 *Giraffatitan brancai* lectotype MB.R.2181 (formerly HMN SI). I attempted to articulate these
1154 two vertebrae, and empirically determine the feasible range of motion. Due to subtle
1155 distortion of the zygapophyses of these vertebrae, it was not possible to articulate C2 in a

1160 the supporting muscles of the scapula, which Hatcher considered diagnostic of the 1st dorsal
1161 vertebra. Modified from Hatcher (1903: plate I).

1162

Table 1 (on next page)

Serial variation in preserved aspect ratios of consecutive cervical vertebrae in extant animals and sauropods from several major amniote clades.

Mammalia: giraffe *Giraffa camelopardalis*, young juvenile specimen, C2–C7. Lacertilia: savannah monitor, *Varanus exanthematicus*, C3–C7. Crocodylia: alligator *Alligator mississippiensis*, juvenile specimen, C5–D2; Aves: ostrich *Struthio camelus*. C5–C11. Sauropoda: *Diplodocus carnegii* holotype CM84 and *Giraffatitan brancai* lectotype MN.R.2180 (formerly HMN SI). **Vertical** and **horizontal** columns contain measurements of the posterior articular surfaces of the vertebrae, except for the procoelous alligator vertebrae for which anterior articular surface was used. For the saddle-shaped ostrich cervicals, the maximum height and width of the posterior articular surface was used, rather than the shorter midline distances. Measurements are in arbitrary units (e.g. mm or pixels in a photograph) but consistent within any one specimen. **V/H** is the aspect ratio of the measured surface, the ratio of the vertical and horizontal measurements, so that values less than 1.0 indicate a surface wider than tall, and values greater than 1.0 indicate a surface taller than wide. Note that this ratio is independent of the measurement units. **1st diff** measures the absolute value of the difference between the V/H ratios of each vertebra and its successor. **Max diff** is the highest value of 1st diff for each specimen, and **Avg diff** is the average value; **x100** is this value times 100, a measure of the serial variation along the column. **1st ratio** is the “absolute ratio” of the V/H values of one vertebra and its successor, normalized so that when the ratio is less than 1.0 its inverse is used. **Max ratio** is the highest value of 1st ratio for each specimen, and **Avg ratio** is the average value; **-1x100** is this value minus one, multiplied by 100, another measure of the serial variation along the column. Note that by both measures, the variation in articular surface aspect ratios is greater in the two sauropods than in any of the extant animals, even though these are among the best preserved

sauropod necks.

Figure 1

Spinophorosaurus nigerensis holotype GCP-CV-4229 in situ during excavation in the region of Aderbissinat, Thirozerine Dept., Agadez Region, Republic of Niger.

Reproduced from Remes et al. (2009: figure 1).

Figure 2

Simplified phylogeny of Sauropoda, showing counts of complete and near-complete necks.

Captions: **C**, complete and described; **U**, complete but undescribed; **-1**, missing the atlas but otherwise complete; **O**, other near-complete necks (see text for details); **T**, total.

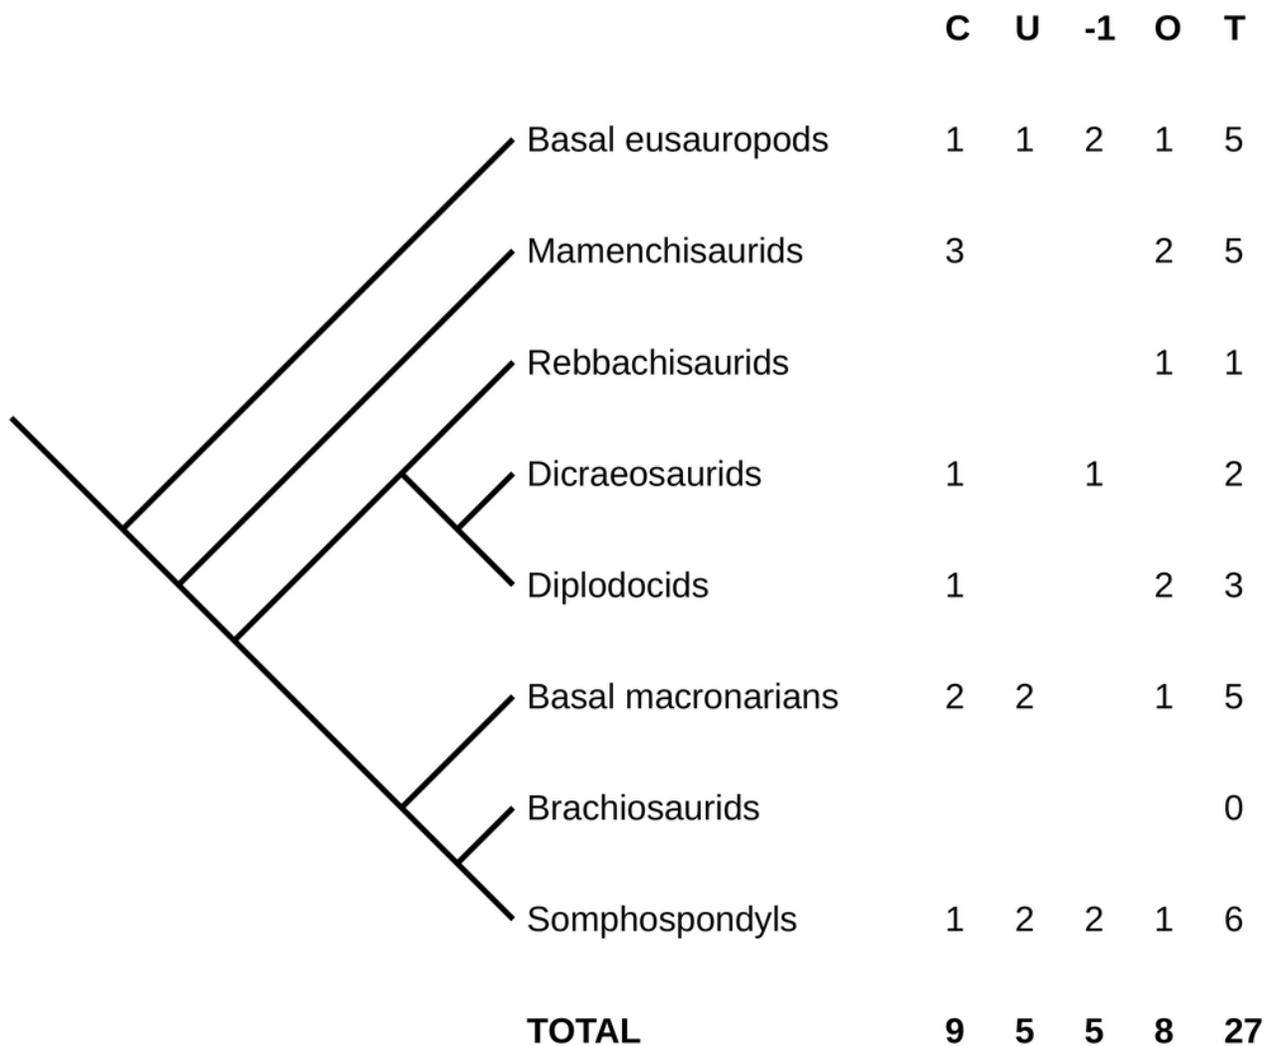

Figure 3

Neck of *Diplodocus carnegii* holotype CM 84, as reconstructed by Hatcher (1901: plate XIII), with fifteen undamaged cervical vertebrae.

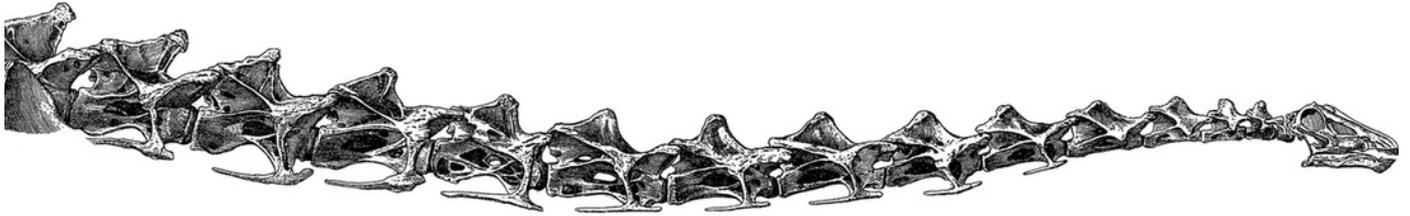

Figure 4

W. H. Reed's diagram of Quarry C near Camp Carnegie on Sheep Creek, in Albany County, Wyoming.

The coloured bones belong to CM 84, the holotype of *Diplodocus carnegii*; other bones belong to other individuals, chiefly of *Brontosaurus*, *Camarasaurus* and *Stegosaurus*. Modified (cropped and coloured) from Hatcher (1901: plate I). Cervical vertebrae are purple (and greatly simplified in outline by Reed), dorsals are red, the sacrum is orange, caudals are yellow, limb girdle elements are blue, and limb bones are green.

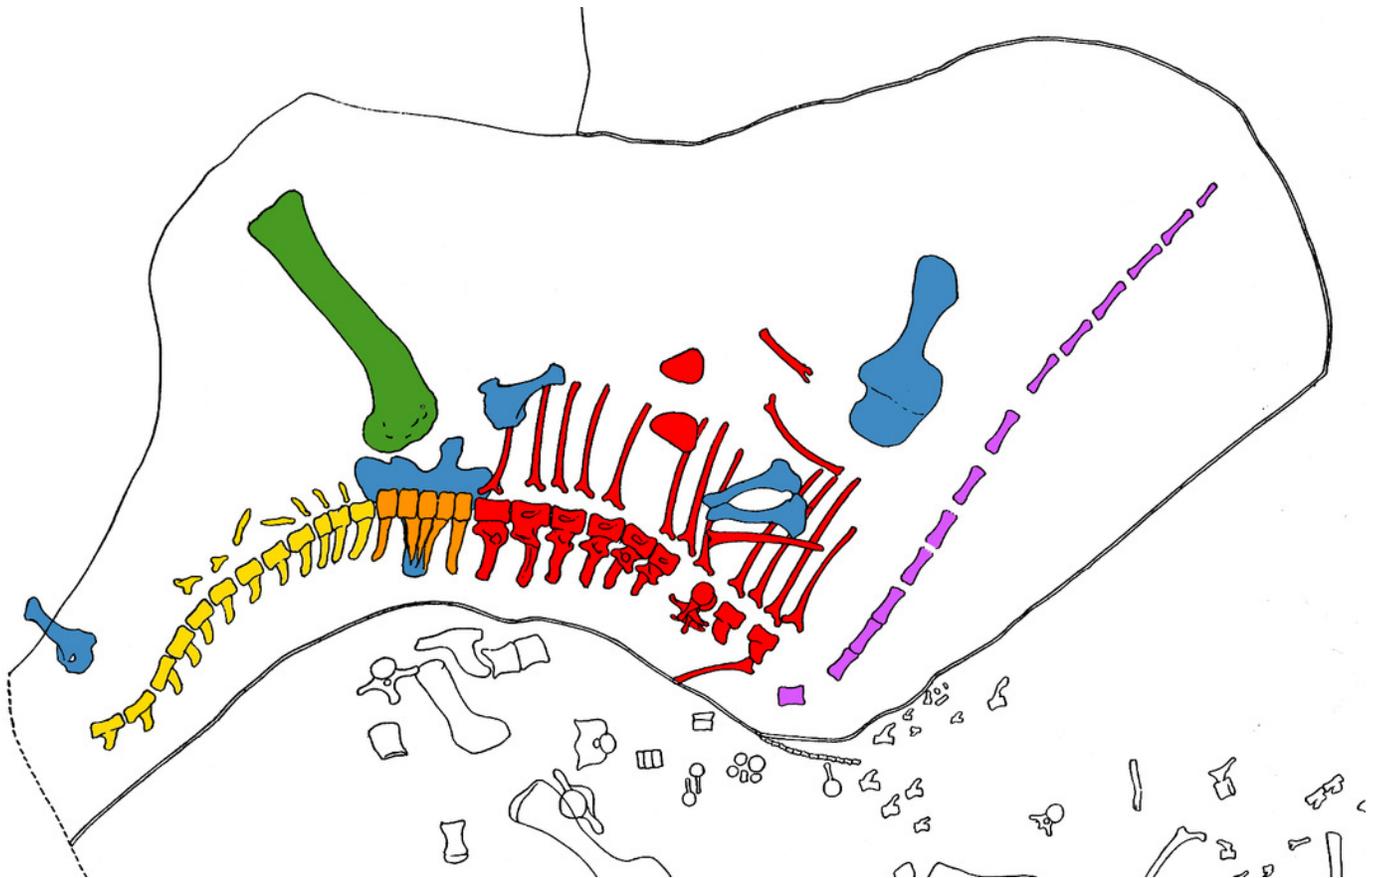

Figure 5

Three images of presacral vertebra 6 (probably dorsal 7) of *Brachiosaurus altithorax* holotype FMNH P25107, in right lateral view, showing misleading restoration.

Left: Field Museum photograph CSGEO16166, photographer Charles Carpenter, taken in 1905, the year after Riggs's (1904) descriptive monograph. Note the "crazy-paving" effect of the many cracks and missing areas of bone surface. **Middle:** Illustration of the same vertebra in Riggs (1904: plate LXXII). Note that the damage to the vertebral surface is not depicted. **Right:** photograph of the same vertebra, taken by the author in 2005. Note that the damage apparent in the 1905 photograph is no longer visible: the vertebra seems to have been painted to conceal its incompleteness.

Figure 7

Cervical vertebrae 5-11 of an ostrich, *Struthio camelus*, in posterior view, showing that articular facet shape remains similar along the column.

Specimen kindly provided by Matt Cobley.

Figure 8

Cervical and dorsal vertebrae (C5-9 and D1-2) of a juvenile alligator, *Alligator mississippiensis*, in anterior view, showing that articular facet shape remains similar along the column.

Specimen kindly provided by Matthew J. Wedel.

Figure 9

Sequences of cervical vertebrae of extant animals, showing that articular facet shape remains similar along the column.

Top. Cervical vertebrae 3-7 of a mature savannah monitor lizard, *Varanus exanthematicus*, in anterior view. (The cervicals of monitor lizards, unlike those of sauropods and most mammals, are procoelous, with the anterior facet being concave and the posterior convex.)

Bottom. cervical vertebrae 2-5 of a mature house-cat, *Felis catus*, in posterior view.

Figure 10

Cervical vertebrae of a baby giraffe, *Giraffa camelopardalis*, in posterior view, showing that articular facet shape remains similar along the column.

Top row, left to right: cervicals 7, 6 and 5; bottom row, left to right: cervicals 4, 3 and 2.

Despite changes in the vertebrae along the column, the flattened inverted pentagon shape of the articular facets remains similar along the sequence. (Note that extensive cartilage caps existed on the articular facets of this very young specimen, but were lost in preparation.)

Figure 11

Cervical vertebrae 4 (left) and 6 (right) of *Giraffatitan brancai* lectotype MB.R.2180 (formerly HMN SI), in posterior view.

Note the dramatically different aspect ratios of their cotyles, indicating that extensive and unpredictable crushing has taken place. Photographs by the author.

Figure 12

Cervical vertebrae 14 (left) and 13 (right) of *Diplodocus carnegii* holotype CM 84, in posterior view.

Note the dramatically different aspect ratios of their cotyles, indicating that extensive and unpredictable crushing has taken place.

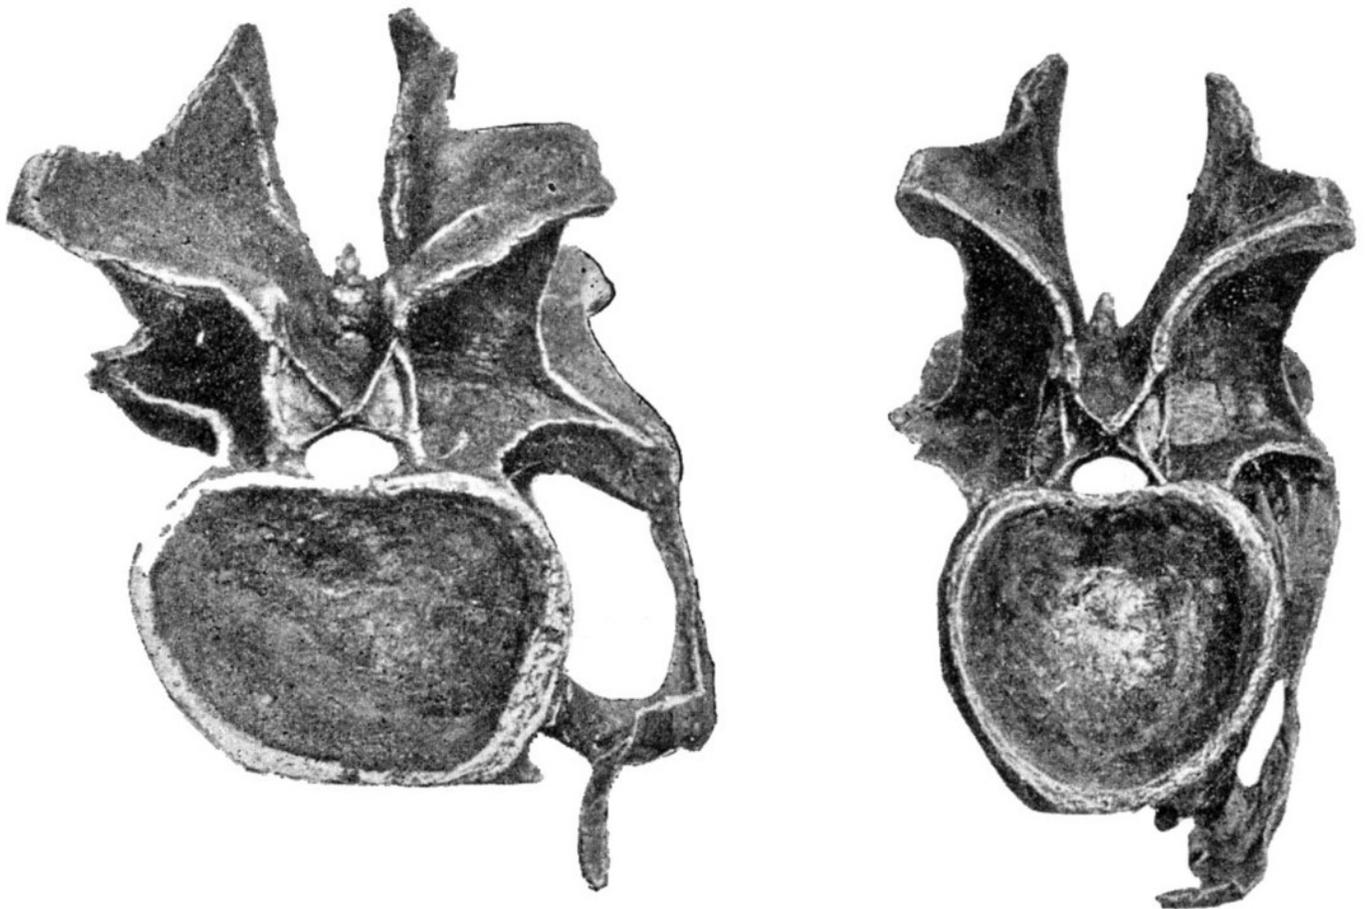

Figure 13

Manipulation of consecutive sauropod vertebrae by hand. Cervicals 2 and 3 of *Giraffatitan brancai* lectotype MB.R.2181 (formerly HMN SI).

I attempted to articulate these two vertebrae, and empirically determine the feasible range of motion. Due to subtle distortion of the zygapophyses of these vertebrae, it was not possible to articulate C2 in a more extended position relative to C3 than shown here.

Photograph by Mathew J. Wedel.

Figure 14

Cervicodorsal transition of *Haplocanthosaurus priscus* holotype CM 572.

Top row, right lateral view; bottom row, anterior view. From left to right, D1, C15 and C14. Pink highlights indicate the expanded lateral surface of the prezygadiapophyseal lamina, anchoring the supporting muscles of the scapula, which Hatcher considered diagnostic of the 1st dorsal vertebra. Modified from Hatcher (1903: plate I).
