Estimates of animal abundance provide essential information for population ecological studies. However, the recording of individuals in the field can be challenging, and accurate estimates require analytical techniques which account for imperfect detection. Here, we quantify local abundances and overall population size of Morelet's crocodile (*Crocodylus moreletii*) in the region of Calakmul (Campeche, Mexico), comparing traditional approaches for crocodylians (Minimum Population Size - MPS; King's Visible Fraction Method - VFM) with binomial *N*-mixture models based on Poisson, zero-inflated Poisson (ZIP) and negative binomial (NB) distributions. A total of 256 nocturnal spotlight surveys were conducted across 50 representative locations (hydrologically highly dynamic aquatic sites locally known as aguadas) over a period of five years (2015-2019). Population size estimates through MPS and VFM revealed a median of 0.4 (min - max: 0 - 67; Q1 - Q3: 0 - 3) and 0.95 (0 - 159; 0 - 8) non-hatchling *C. moreletii* for each aguada, respectively. The ZIP based *N*-mixture model structure shown overall superior confidence over Poisson and NB, and revealed a median of  $5 \pm 2$  individuals (min = 0; max =  $116 \pm 15$ ; Q1 =  $0.9 \pm 0.6$ ; Q3 =  $23 \pm 4$ ) jointly with high detectabilities in drying aguadas with low and intermediate vegetation cover. Extrapolating these inferences across all waterbodies in the study area yielded in an estimated  $\sim 12,000$  *C. moreletii* present, demonstrating that Calakmul is an important global stronghold for this species. Because covariates enable insights into population responses to local environmental conditions, we confirm that *N*-mixture models applied to spotlight count data result in particularly insightful estimates of crocodylian detection and abundance.

## 29 Abstract

30 Estimates of animal abundance provide essential information for population ecological studies.  
31 However, the recording of individuals in the field can be challenging, and accurate estimates  
32 require analytical techniques which account for imperfect detection. Here, we quantify local  
33 abundances and overall population size of Morelet's crocodile (*Crocodylus moreletii*) in the  
34 region of Calakmul (Campeche, Mexico), comparing traditional approaches for crocodilians  
35 (Minimum Population Size – MPS; King's Visible Fraction Method – VFM) with binomial  $N$ -  
36 mixture models based on Poisson, zero-inflated Poisson (ZIP) and negative binomial (NB)  
37 distributions. A total of 256 nocturnal spotlight surveys were conducted across 50 representative  
38 locations (hydrologically highly dynamic aquatic sites locally known as aguadas) over a period  
39 of five years (2015-2019). Population size estimates through MPS and VFM revealed a median  
40 of 0.4 (min – max: 0 – 67; Q1 – Q3: 0 – 3) and 0.95 (0 – 159; 0 – 8) non-hatchling *C. moreletii*  
41 for each aguada, respectively. The ZIP based  $N$ -mixture model shown overall superior  
42 confidence over Poisson and NB, and revealed a median of  $5 \pm 2$  individuals (min = 0; max =  
43  $116 \pm 15$ ; Q1 =  $0.9 \pm 0.6$ ; Q3 =  $23 \pm 4$ ) jointly with high detectabilities in drying aguadas with  
44 low and intermediate vegetation cover. Extrapolating these inferences across all waterbodies in  
45 the study area yielded in an estimated  $\sim 12,000$  *C. moreletii* present, demonstrating that Calakmul  
46 is an important global stronghold for this species. Because covariates enable insights into  
47 population responses to local environmental conditions, we confirm that  $N$ -mixture models  
48 applied to spotlight count data result in particularly insightful estimates of crocodilian detection  
49 and abundance.

## 58 **Introduction**

59 Measures of abundance and population size are key to understand the ecology and natural history  
60 of wild animals, and form a main basis for the implementation of conservation management  
61 plans. However, due to elusive behaviours and logistic constraints, researchers are often unable  
62 to record all individual animals in a given location. Because detectability also interacts with for  
63 example local environmental conditions, precise abundance estimates based on census data alone  
64 are generally difficult to obtain (e.g. Mazerolle et al., 2007; Sutherland, 2006).

65 An emerging approach to estimate population sizes from repeated standard count surveys is  
66 represented by  $N$ -mixture models, which jointly quantify a measure of abundance ( $\lambda$ ) with the  
67 probability of detecting an individual ( $p$ ) (Denes, Silveira & Beissinger, 2015; Kéry & Royle,  
68 2016; Royle, 2004; Zipkin et al., 2014). Binomial  $N$ -mixture models, for example, treat  $\lambda$  as a  
69 random independent variable generated from a statistical distribution to estimate  $p$  (Kéry, Royle  
70 & Schmid, 2005; Royle, 2004).  $N$ -mixture models are particularly promising for wildlife studies  
71 because they have the potential to reveal estimates which are comparable to those obtained by  
72 more labour-intensive (and often more invasive) capture-mark-recapture approaches, and because  
73 explanatory variables that may influence  $\lambda$  and  $p$  can be investigated in a straightforward way  
74 using generalized linear models (GLMs; Courtois et al., 2016; Ficetola et al., 2018; Priol et al.,  
75 2014).  $N$ -mixture models have already been applied to a wide range of wildlife species (e.g.  
76 Belant et al., 2016; Hunter, Nibbelink & Cooper, 2017; Kéry, 2018; Kidwai et al., 2019; Manica  
77 et al., 2019; Romano et al., 2017; Ward et al., 2017), but are still considered as an emerging  
78 framework with ongoing extensions to original parameterizations (Barker et al., 2018; Bötsch,  
79 Jenni & Kéry, 2019; Denes, Silveira & Beissinger, 2015; Kéry & Royle, 2016).

80 Despite their large size, crocodylians are an example taxonomic group for which imperfect  
81 detection during surveys is common (e.g. Balaguera-Reina et al., 2018; Da Silveira, Magnusson  
82 & Thorbjarnarson, 2008; Hutton & Woolhouse, 1989). Historically, crocodylian population size  
83 estimations outside the capture-recapture framework have largely been based on spotlight  
84 surveys to reveal minimal counts, or accounting for visible fractions (Balaguera-Reina et al.,  
85 2018; Bayliss, 1987; King, Espinal & Cerrato, 1990). Although not yet widely used,  $N$ -mixture  
86 models have already been explored to investigate the influence of covariates on both local

87 abundance and crocodile detection (Fujisaki et al., 2011; Gardner et al., 2016; Lyet et al., 2016;  
88 Mazzotti et al., 2019; Naveda-Rodriguez, Utreras & Zapata-Ríos, 2020; Waddle et al., 2015), but  
89 detailed comparisons with more traditional methods particularly in hydrologically dynamic  
90 habitats are as yet lacking.

91 The Morelet's crocodile (*Crocodylus moreletii*) is a medium-to-large crocodile species occurring  
92 in Atlantic lowlands surrounding the Gulf of Mexico (Belize, Guatemala and Mexico; Sigler &  
93 Gallegos, 2017). Our knowledge on the population ecology and status of *C. moreletii* has  
94 markedly increased over the last decades, and a standard international survey program to monitor  
95 its wild populations was developed in 2010 (Sánchez-Herrera et al., 2011). However, only  
96 rudimentary information about this species is available for the southern region of the Yucatan  
97 Peninsula, an area which is characterized by very dynamic hydrological regimes and which  
98 harbours parts of the largest remaining expanse of tropical forest in Mesoamerica (Carr III, 1999;  
99 Vester et al., 2007). In the present study, we estimate both local abundances as well as the total  
100 population size of *C. moreletii* in this region, using a set of binomial *N*-mixture modelling  
101 approaches for comparison with more traditionally used methods. Because *C. moreletii* locally  
102 inhabits particularly unstable and heterogeneous waterbodies, the study area provides an  
103 excellent opportunity to probe the versatility of *N*-mixture models under highly variable levels of  
104 detectabilities.

105

## 106 **Materials & Methods**

### 107 **Study area and data collection**

108 Calakmul Biosphere Reserve (CBR) is located within the southern portion of the Yucatan  
109 Peninsula in Campeche, México (18°21.921' N, 089°53.220' W; Fig. 1), and together with the  
110 adjacent state reserves Balam-Ku and Balam-Kin encompasses more than 1.2 million hectares of  
111 protected forest for which *C. moreletii* represents one of the main flagship species. CBR is part  
112 of the Selva Maya, which was home to the ancient Mayan civilization and covers 10.6 million  
113 hectares of forest across Mexico, Guatemala and Belize (Vester et al., 2007). Precipitation  
114 gradually increases from 900 mm annually in the north to 1,400 mm in the south, with significant  
115 effects on local forest structure and tree species composition (Martínez & Galindo-Leal, 2002;

116 Vester et al., 2007). The majority of the reserve is composed of tropical semi-deciduous forest  
117 with a canopy ranging from 15 to 40 m in height, with the northern parts containing deciduous  
118 forest with canopy heights of 8 to 20 m (Chowdhury, 2006). The geological characteristics of the  
119 CBR result in rapid rainwater belowground runoff, and non-permanent as well as semi-  
120 permanent small to medium-sized waterbodies, locally known as aguadas, represent the only  
121 source of water during the dry season (Barão-Nóbrega, 2019; García-Gil, Palacio-Prieto & Ortiz-  
122 Pérez, 2002; Reyna-Hurtado et al., 2010). The distribution, prevalence and morphology of  
123 aguadas across Calakmul is strongly influenced by annual precipitation cycles, resulting in high  
124 levels of seasonal and yearly variation in their general structure (hydric coverage, vegetation  
125 communities and cover; Barão-Nóbrega, 2019; García-Gil, Palacio-Prieto & Ortiz-Pérez, 2002;  
126 Márdero et al., 2019).

127 Candidate aguadas for *C. moreletii* surveys were identified using existing information (García-  
128 Gil, 2000), *Google Earth Pro* (Gorelick et al., 2017), and local knowledge by environmental  
129 authorities (*Comisión Nacional de Áreas Naturales Protegidas* - CONANP and *Pronatura*  
130 *Península Yucatán*), local guides and community representatives to define a total of 50 survey  
131 locations spread across the CBR and its surroundings. While accessibility by vehicles as well as  
132 landowner permissions were a prerequisite for field surveys, information on the presence or  
133 absence of *C. moreletii* was largely unavailable for survey site selection. Exhaustive nocturnal  
134 spotlight counts were performed in July (wet season) 2017 and in March (dry season) as well as  
135 July 2018-2019 for all 50 waterbodies whenever possible, supplemented with additional surveys  
136 for a subset of 20 waterbodies in July 2015 and 2016. Water levels for each aguada were  
137 classified into Dry, Drying, Stable, or Full, and vegetation cover was defined as Low, Medium or  
138 High (for details see Barão-Nóbrega, 2019; Fig. S1). Avoiding days of full moon, high winds  
139 and heavy rain, surveys were conducted by systematically traveling along the perimeter of the  
140 waterbody on foot or by paddling along the shoreline aboard a 3.5 meters aluminium boat.  
141 Individual *C. moreletii* were located by their eyeshine reflection (Sánchez-Herrera et al., 2011).  
142 If the waterbody was empty, the number of detected crocodiles was assumed zero. Crocodile  
143 hatchlings (TL < 30 cm) have high mortality rates (Grigg & Kirshner, 2015) and were excluded  
144 from the count data (Balaguera-Reina et al., 2018). Research permits for fieldwork activities in  
145 CBR were issued annually by Mexico's Secretariat of Environment and Natural Resources

146 (SEMARNAT; SGPA/DGVS/03030/17; SGPA/DGVS/005403/18) and National Commission of  
147 Natural Protected Areas (CONANP; D-RBC-118/2017; D-RBC-030/2018; D-RBC-087/2019).

#### 148 **Abundance estimation**

149 As abundance estimation methods which are in common use for many crocodilians including *C.*  
150 *moreletii* (Cedeño-Vázquez, Ross & Calme, 2006; Tellez et al., 2017), we used a Minimum  
151 Population Size (MPS) approach as well as the King's Visible Fraction Method (VFM). MPS  
152 quantifies the number of recorded individuals per spatial unit to obtain baseline data (Sánchez-  
153 Herrera et al., 2011). VFM makes use of repeated counts per site, estimating the percentage of  
154 the total population observed during a single count (the visible fraction) as  $vf = \frac{\bar{x}}{1.05(2\sigma + \bar{x})}$ ,  
155 where  $\sigma$  is the standard deviation and  $\bar{x}$  is the mean number of crocodiles counted (Balaguera-  
156 Reina et al., 2018; King, Espinal & Cerrato, 1990). Local absolute abundances ( $n$ ) at given  
157 waterbodies can therefore be expressed as  $n = \frac{RA}{vf}$ , with RA being the observed local relative  
158 abundance.

159 Aside of these traditionally applied methods, we also used binomial  $N$ -mixture models and  
160 explored three alternative statistical distributions: Poisson, Negative Binomial (NB), and Zero-  
161 Inflated Poisson (ZIP). Poisson distributions are generally applied to describe relative density,  
162 but have a variance which is equal to its mean and therefore do not conform well to under- or  
163 over-dispersed data (Denes, Silveira & Beissinger, 2015). Both Poisson and NB distributions  
164 tend to perform poorly in the presence of a significant number of true zeros in the dataset (Joseph  
165 et al., 2009; Wenger & Freeman, 2008), whereas the ZIP distribution is generally able to better  
166 accommodate both true and false zeros (Denes, Silveira & Beissinger, 2015). Both ZIP and NB  
167 distributions allow for over-dispersion (Kéry & Royle, 2016; Mazzotti et al., 2019). All  $N$ -  
168 mixture models were fitted to the dataset using the *pcount()* function in the unmarked package in  
169 R (Fiske & Chandler, 2011; R Development Core Team, 2019), using RStudio version 1.1.456  
170 (RStudio Team, 2016). At first, we allowed  $\lambda$  to vary as a linear function of year to investigate  
171 the general assumption of population closure and presence of any temporal trend in the dataset.  
172 As no significant difference in abundance values was observed between years ( $F = 1.7$ ;  $p =$   
173  $0.151$ ; Fig. S2), we then assumed that  $\lambda$  remained overall constant with respect to survey year  
174 within survey locations in the final models. Waterbody perimeter (in metres) was used as a

175 covariate for  $\lambda$ , in addition to a geographic specifier to account for possible spatial differences in  
176 abundance within Calakmul. Waterbody hydric state (Dry, Drying, Stable, Full) and vegetation  
177 cover (Low, Medium, High) were used as covariates of  $p$ . Waterbody perimeter was scaled and  
178 centred by subtracting the mean from each value, divided by the standard deviation (Kéry &  
179 Royle, 2016). We discarded models that failed to converge, and used Akaike's Information  
180 Criterion (AIC, Akaike, 1974) to identify the best models from each  $N$ -mixture approach. The  
181 *predict()* function in *unmarked* was used to generate plots of estimated relationships with  
182 predictors for each covariate. Parametric bootstrapping (1000 simulations) was conducted using  
183 the *parboot()* function (Fiske & Chandler, 2011), to calculate p-values from sums of squares  
184 (SSE), Pearson's Chi-square and Freeman-Tukey fit statistics that quantified the fit of models to  
185 the dataset. A dispersion parameter ( $\hat{c}$ ) was calculated as the ratio of the observed fit statistic to  
186 the mean of the simulated distribution (Kéry & Royle, 2016). As caution is often advised when  
187 using NB, even when it is greatly favoured by AIC, particularly when this distribution produces  
188 substantially higher estimates than Poisson and ZIP distributions (Kéry, 2018; Kéry & Royle,  
189 2016), we've further investigated which model structure would provide most overall confidence  
190 in crocodile abundance estimations by running a residual diagnostic analysis using the  
191 *plot.Nmix.resi()* function available in the *AHMbook* package for R (Kéry & Royle, 2016).

192 To assess the total number of *C. moreletii* present in the study area ( $\hat{N}$ ), we extracted the total  
193 number of semi-temporary and permanent aguadas in the study area (CBR and surroundings)  
194 from an existing GIS-based dataset (García-Gil, 2000), and calculated their perimeters using  
195 QGIS Desktop software version 3.0.2 (QGIS Development Team, 2019).  $\hat{N}$  was assessed  
196 through four local abundance estimators ( $n^{\text{MPS}}$ ,  $n^{\text{VFM}}$ ,  $N$ -mixture NB and  $N$ -mixture ZIP). For  $n^{\text{MPS}}$   
197 and  $n^{\text{VFM}}$ , the relationship between local *C. moreletii* abundance and the perimeter of each  
198 surveyed waterbody was determined through a GLM and extrapolated to all waterbodies. Total  
199 population sizes based on MPS and VFM were also calculated by solely multiplying average  
200 local abundance estimations with the total number of waterbodies.

201

## 202 **Results**

203 A total of 256 surveys were conducted between 2015 and 2019 (20 surveys in July of both 2015  
204 and 2016, 42 surveys in July 2017, 47 and 48 surveys in March and July 2018, as well as 50 and  
205 47 surveys in March and July 2019), yielding a total of 1,105 *C. moreletii* records (Total  
206 waterbody perimeter = 24,980 metres; Total survey distance covered = 127,897 m). *Crocodylus*  
207 *moreletii* was detected at least once in 32 of the 50 surveyed sites (64%). Counts per spotlight  
208 survey ranged between zero and 89 (median = 0; Q1 = 0; Q3 = 2) and relative abundance per  
209 waterbody (mean number of individuals counted) averaged between 0 and 67 (median = 0.4; Q1  
210 = 0; Q3 = 3). Across sites,  $vf$  varied between 0.16 and 0.95 (mean  $\pm$  SD =  $0.48 \pm 0.24$ ), with the  
211 resulting local population size estimates ( $n^{\text{VFM}}$ ) ranging from 0 to 159 individuals (median =  
212 0.95; Q1 = 0; Q3 = 8).

213 Considering all possible combinations of covariates, twelve  $N$ -mixture models were generated  
214 for each distribution (Poisson, ZIP and NB). Overall, NB distributions yielded the lowest AIC  
215 values across all parameter combinations, although Poisson and ZIP models achieved a better  
216 agreement between both observed and expected data as well as between residuals and fitted  
217 values (Table 1, Fig. 2). The models which accounted for waterbody location and perimeter on  $\lambda$   
218 as well as the cumulative effects between co-variates on  $p$  exhibited the lowest AIC values  
219 amongst all possible  $N$ -mixture combinations (Table 1). Median abundance estimates for NB,  
220 ZIP and Poisson were  $10 \pm 9$  (min–max = 0 –  $308 \pm 264$ ; Q1 =  $1 \pm 1$ ; Q3 =  $31 \pm 16$ ),  $5 \pm 2$  (min–  
221 max = 0 –  $116 \pm 15$ ; Q1 =  $0.9 \pm 0.6$ ; Q3 =  $23 \pm 4$ ) and  $6 \pm 3$  (min–max = 0 –  $123 \pm 13$ ; Q1 =  $0.9$   
222  $\pm 0.6$ ; Q3 =  $26 \pm 4$ ) individuals per waterbody, respectively. Taken together, we considered that  
223  $N$ -mixture ZIP provided superior model confidence over the Poisson and NB models, as  
224 particularly the latter showed poor residual diagnostic performance and yielded unrealistically  
225 high abundance estimates with wide-ranging confidence intervals, in comparison to the other two  
226 (Fig. 3, Fig. S3). Based on the  $N$ -mixture ZIP model, the highest probabilities of detection ( $p =$   
227 0.70) were observed in Drying waterbodies with Low to Moderate vegetation cover, whereas low  
228 detectability was associated with High vegetation cover ( $p < 0.25$ , Fig. 4, Fig. S4). Bootstrap  $p$ -  
229 values for the best-fit  $N$ -mixture ZIP model based on SSE, Freeman-Tukey, and Chi-square  
230 statistics were 0.14, 0.01 and 0.20 (Fig. S4), respectively, at evidence for over-dispersion ( $\hat{c} =$   
231 2.70).

232 The relationships between waterbody perimeter and local abundance estimates ( $n^{\text{MPS}}$ ,  $n^{\text{VFM}}$ ,  $N$ -  
233 mixture NB and  $N$ -mixture ZIP) were used to provide an estimate for the total number of non-  
234 hatchling *C. moreletii* in the study area (Table 2). Analyses of the GIS-based dataset revealed a  
235 total of 1,663 aguadas, which had a median perimeter of 139 (min = 40 m; max = 3639 m; Q1 =  
236 98 m; Q3 = 207 m; Fig. 5). Based on these numbers, MPS<sup>GLM</sup> defined a minimum *C. moreletii*  
237 population size of 4,273 non-hatchling individuals, which is considerably lower than the values  
238 obtained by approaches which take detectability into account (Table 2). The  $N$ -mixture ZIP  
239 model revealed a total population size of 11,681 crocodiles, which was slightly below the value  
240 obtained by VFM<sup>GLM</sup> (12,177 crocodiles). The highest population size estimate of 15,184  
241 individuals was produced by VFM without taking waterbody perimeter into account.

## 242 Discussion

243 Allowing for the separate estimation of abundance and detection probabilities from replicated  
244 counts of unmarked individuals (e.g. Kéry & Royle, 2016; Zipkin et al., 2014),  $N$ -mixture  
245 models have in recent years become applied to taxa ranging from mosquitoes to megafaunal  
246 mammals (Kidwai et al., 2019; Manica et al., 2019). In the present study, we applied a set of  
247 such models to multi-year and multi-site data for the Morelet's crocodile *C. moreletii* in southern  
248 Yucatan, where it inhabits particularly dynamic waterbodies and serves as an important flagship  
249 species for a large expanse of protected forest. We reveal that Calakmul represents a global *C.*  
250 *moreletii* stronghold and show that  $N$ -mixture models offer a flexible approach for abundance  
251 estimates when ecological conditions cause wide variations in detectability.

252 Count data are often used as a proxy for true abundance, but require the implicit assumption that  
253 the relationship between observed counts and actual population sizes remains constant (e.g.  
254 Kéry, Royle & Schmid, 2005). For crocodylians, count data may indeed serve as abundance  
255 surrogates to capture population temporal and spatial trends related with for example habitat  
256 structure or human induced changes to the environment, but only when conditions during  
257 multiple surveys allow for the recording of similar proportions of individuals (Bayliss, 1987;  
258 Platt & Thorbjarnarson, 2000). As this was likely not the case in our study, we assumed that  
259 local crocodile abundances remained overall constant and did not allow  $\lambda$  to vary with respect to  
260 survey year, water level and vegetation cover, due to the more evident effect on these variables

261 on the observational process rather than on local abundance (Fig. 4). In Calakmul, decreasing  
262 water availability caused by disruptions in the timing and intensity of precipitation resulted in  
263 marked shifts in water level and vegetation cover of aguadas across the study period (Barão-  
264 Nóbrega, 2019; Márdero et al., 2019; Reyna-Hurtado et al., 2019). Under such conditions, the  
265 observer's ability to detect individuals will widely vary both temporally as well as spatially,  
266 requiring the effects of environmental conditions to be taken into account for obtaining accurate  
267 estimates (see also Fujisaki et al., 2011).

268 Given that the majority of *C. moreletii* habitat across its range is represented by rivers and lakes  
269 where spotlight searches are conducted over larger areas than in the case of our more confined  
270 aguadas (Cedeño-Vázquez, Ross & Calme, 2006; Sánchez-Herrera et al., 2011; Tellez et al.,  
271 2017), we argue that our surveys provide particularly accurate information. The non-linear rise in  
272 abundances with increasing size of aguadas for the MPS, VFM and *N*-mixture ZIP curves is  
273 likely linked to larger waterbodies representing more hydrologically stable environments,  
274 therefore supporting higher relative numbers of reproductive individuals. Small to medium sized  
275 aguadas are generally more prone to desiccation (Barão-Nóbrega, 2019), and are often inhabited  
276 by only 1-2 adult *C. moreletii* which might not locally reproduce. It also needs to be born in  
277 mind that the relationship between waterbody surface and volume with perimeter, while  
278 depending on the overall shape, is non-linear in general. Given that detection rates are not  
279 accounted for, the low abundance values for the MPS approach are not surprising. The VFM and  
280 the *N*-mixture ZIP model, on the other hand, consider detectability and reveal remarkably  
281 converging abundances for waterbodies below 1200 metres in perimeter, a size class which  
282 accounts for 98% of aguadas in the study area (Barão-Nóbrega, 2019; García-Gil, Palacio-Prieto  
283 & Ortiz-Pérez, 2002). The lower abundance estimates as predicted by the *N*-mixture ZIP model  
284 for larger sites, where relative variation around mean counts for repeated surveys are low,  
285 suggests that this model generally assumes higher detectabilities under such scenarios; that  
286 surface area is related to encounter rates for crocodylians has been previously documented (e.g.  
287 Da Silveira, Magnusson & Thorbjarnarson, 2008; Fujisaki et al., 2011).

288 *N*-mixture models yield unbiased estimates of abundance and detectability in simulated datasets  
289 of closed populations (Kéry & Royle, 2016; Royle, 2004), but benchmarks to assess the  
290 performance of *N*-mixture models from field data are difficult to obtain (Kéry, Royle & Schmid,

291 2005). A particular feature of our dataset is a wide range of count values across sites, with zero  
292 detections being a common occurrence (no *C. moreletii* were recorded for about 40% of aguadas,  
293 and approximately 60% of all surveys yielded in no counts). This likely led to the limited fit of  
294 our data to assumptions of specific distributions, which is a common problem in count data  
295 (Kéry & Royle, 2016; Lee & Nelder, 2000; Ver Hoef & Boveng, 2007). Estimates of local  
296 abundances in Drying aguadas were also possibly slightly biased downward, as such situations  
297 can lead to temporary emigration or hiding behaviour in dens and burrows within or in the  
298 vicinity of waterbodies (Barão-Nóbrega et al., 2016; Platt, 2000). That the geographic specifier  
299 significantly improved the performance of our models however also suggests a high degree of  
300 philopatry, supporting the assumption of closed populations; low levels of dispersal are also  
301 evidenced by genetic data on the relatedness structure within and between aguadas (Barão-  
302 Nóbrega et al., unpublished). A particular strength of the *N*-mixture models was their ability to  
303 directly relate detectability with ecological parameters. While our findings confirm existing  
304 studies on the general nature of such relationships (Bayliss et al., 1986; Cherkiss, Mazzotti &  
305 Rice, 2006; Da Silveira, Magnusson & Thorbjarnarson, 2008; Fujisaki et al., 2011; Montague,  
306 1983; Wood et al., 1985), they enabled an accurate quantification for the estimation and  
307 interpretation of *C. moreletii* abundances specifically for our study setting.

308 The comparison between the three binomial *N*-mixture models suggested that the ZIP  
309 distribution provided best confidence overall. The NB model overall exhibited lower AIC values,  
310 but performed poorly during the residual diagnostic analysis and revealed excessively large  
311 confidence intervals which are likely linked to model unidentifiability (the “good fit/bad  
312 prediction dilemma”; see Dennis, Morgan & Ridout, 2015; Joseph et al., 2009; Kéry, 2018; Kéry  
313 & Royle, 2016 for detailed discussion on this topic). It also resulted in abundance estimates  
314 which appeared unrealistically high, linked to low projected detection probabilities related to  
315 water level and vegetation cover (see also Mazzotti et al., 2019 for a similar finding on the  
316 closely related *Crocodylus acutus*). Hierarchical modelling of abundance from unmarked  
317 individuals using *N*-mixture models will remain a rich ground for both theoretical and applied  
318 investigations also in the future (Bötsch, Jenni & Kéry, 2019; Kéry, 2018; Kéry & Royle, 2016).

319 Extrapolating our abundance data across Calakmul requires that the surveyed aguadas are  
320 unbiased representatives for the entire area. While a randomization process for site selection was

321 not possible due to logistic constraints (landowner permission and site accessibility), we did not  
322 take previous information on the presence or absence of *C. moreletii* into account, and based our  
323 inferences on a large sample size of sites. Comparing our overall population sizes derived for  
324 Calakmul with country-wide estimates for *C. moreletii* numbers (largely based on the MPS  
325 approach, the total population size in Mexico has been estimated at 78,157 – 104,815  
326 individuals; Álvarez, 2005; Rivera-Téllez et al., 2017), reveals that our study area represents a  
327 significant stronghold for the study species. The importance of Calakmul for *C. moreletii* is  
328 further reinforced by the finding that it still harbours genetically pure individuals, whereas  
329 genetic pollution through increased hybridization with the American crocodile *C. acutus* is  
330 common across other parts of its range (Barão-Nóbrega et al., unpublished; Pacheco-Sierra et al.,  
331 2018).

## 332 **Conclusions**

333 Long-term monitoring data using landscape-level systematic surveys provide useful information  
334 to describe spatial and temporal patterns of relative density in crocodylians (Fujisaki et al., 2011;  
335 Waddle et al., 2015). This study constitutes the first population size estimates for the south-  
336 central region of the Yucatan Peninsula, and reveals a healthy population of *C. moreletii*, likely  
337 involving multiple active reproduction areas across the region. Because covariates enable  
338 insights into population responses to local environmental conditions, we confirm that *N*-mixture  
339 models applied to spotlight count data result in particularly insightful estimates of crocodylian  
340 detection and abundance. Future studies could expand the existing field surveys and *N*-mixture  
341 models to investigate whether further factors such as annual precipitation, water quality,  
342 surrounding forest structure, human activity and reproductive activities account for local  
343 presence and abundance. On a larger scale, we also recommend the use of *N*-mixture approaches  
344 to analyse existing and future *C. moreletii* spotlight count data collected across its range  
345 (Álvarez, 2005; Rivera-Téllez et al., 2017; Sánchez-Herrera et al., 2011), to provide more  
346 accurate baseline information for future conservation management plans at species level.

## 347 **Acknowledgements**

348 This study was possible thanks to the financial and logistical support of Operation Wallacea and  
349 the University of Salford. We would like to thank the communities of 16 de Septiembre, Álvaro  
350 Obrégon, Bel-Ha, Conhuas, Cristobal Colón, Dos Lagunas Norte, Dos Naciones, Flores Magón,  
351 Hormiguero, Keiche Las Pailas, Ley Fomento, Mancolona, Nuevo Becal and Valentín Gómez  
352 (Campeche, Mexico) for granting us the opportunity to work in their ejidal land and for  
353 providing guide services and logistical support. We thank O Platas-Vargas, L Hernandez, V  
354 Isoart, V Corradi, K Slater and C Acton for their assistance in the field. We also thank the IUCN-  
355 SSC Crocodile Specialist Group for granting the Student Research Assistance Scheme (SRAS) to  
356 JALBN; JR Cedeño-Vázquez for providing insight in the early planning stages of this project  
357 and S Mandujano-Rodríguez for provided useful suggestions on a previous version of the  
358 manuscript; A Lopez-Cen and D Sima-Pantí for their assistance with obtaining yearly research  
359 permits; SEMARNATCAM, J López-Sosa, A Balam-Koyoc, EL Hernández-Pérez, JG  
360 Hinterholzer Pino, SE Padilla and the team from Centro Operativo de las Direcciones de las  
361 Reservas Balam-Ku Balam-Kin for all their logistical support and assistance in fieldwork  
362 activities in Balam-Ku State Reserve; S Henderson, J Daw, JC Gutierrez, PE Nahuat-Cervera  
363 and the rest of the Operation Wallacea staff and student volunteers for their logistical support  
364 and assistance in the field.

**Table 1** (on next page)

Abundance estimation models of *Crocodylus moreletii* in Calakmul using three different  $N$ -mixture model approaches (Poisson, Negative Binomial - NB and Zero Inflated Poisson - ZIP).

Models were fitted with different combinations of waterbody perimeter as covariate of abundance ( $\lambda$ ) and vegetation cover (Low, Moderate, High) and water level (Dry, Drying, Stable, Full) as categorical co-variables of detection ( $p$ ). The models highlighted in bold exhibited the lowest AIC values amongst all possible  $N$ -mixture combinations.

1 **Table 1.** Abundance estimation models of *Crocodylus moreletii* abundance in Calakmul using  
 2 three different  $N$ -mixture model approaches (Poisson, Negative Binomial - NB and Zero Inflated  
 3 Poisson - ZIP), with different combinations of waterbody perimeter as covariate of abundance ( $\lambda$ )  
 4 and vegetation cover (Low, Moderate, High) and water level (Dry, Drying, Stable, Full) as  
 5 categorical co-variables of detection ( $p$ ). The models highlighted in bold exhibited the lowest AIC  
 6 values amongst all possible  $N$ -mixture combinations.

**Table 2** (on next page)

Estimates of total population size of *Crocodylus moreletii* occurring in the region of Calakmul based on five different estimation approaches.

MPS – crocodile count data alone (without considering detection probability); VFM – King’s visible fraction method; MPS<sup>GLM</sup> – Generalized linear model considering the relation between MPS and waterbody perimeter; VFM<sup>GLM</sup> – Generalized linear model considering the relation between VFM and waterbody perimeter; ZIP – Zero Inflated Poisson *N*-mixture approach.

1 **Table 2.** Estimates of total population size of *Crocodylus moreletii* occurring in the region of  
2 Calakmul based on five different estimation approaches. MPS – crocodile count data alone  
3 (without considering detection probability); VFM – King’s visible fraction method; MPS<sup>GLM</sup> –  
4 Generalized linear model considering the relation between MPS and waterbody perimeter;  
5 VFM<sup>GLM</sup> – Generalized linear model considering the relation between VFM and waterbody  
6 perimeter; ZIP – Zero Inflated Poisson *N*-mixture approach.

Approach	Total population size
MPS	9,941 (6,651 – 13,230)
VFM	15,184 (14,014 – 16,355)
MPS <sup>GLM</sup>	4,273 (4,112 – 4,440)
VFM <sup>GLM</sup>	12,177 (11,543 – 12,846)
<i>N</i> -Mixture ZIP	11,681 (2,010 – 19,653)

## Figure 1

Location of the Calakmul Biosphere Reserve (CBR) in southern-central region of the Yucatan Peninsula (Mexico).

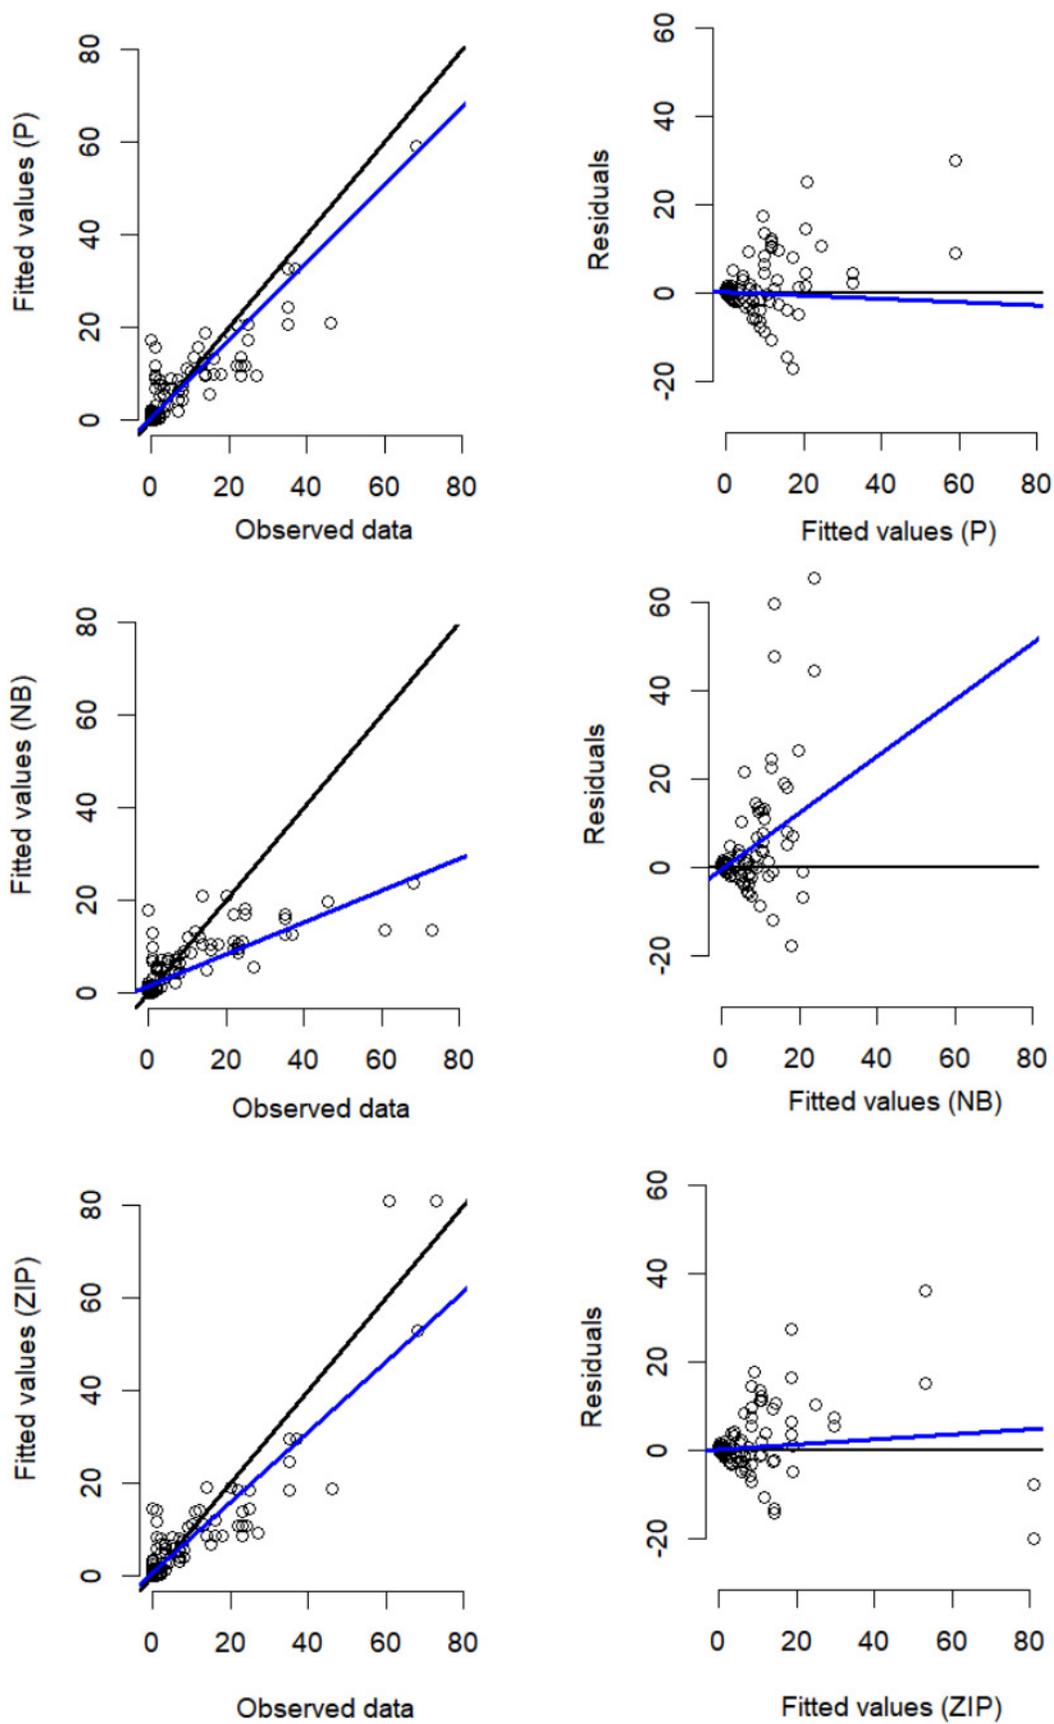

The area delimited inside the inner lines within the grey and dark grey areas (CBR) represent, respectively, the politically established buffer and core zones of the biosphere reserve. White squares represent *C. moreletii* survey locations.

## Figure 2

Residual diagnostics for the three  $N$ -mixture models fitted to the *C. moreletii* spotlight count dataset.

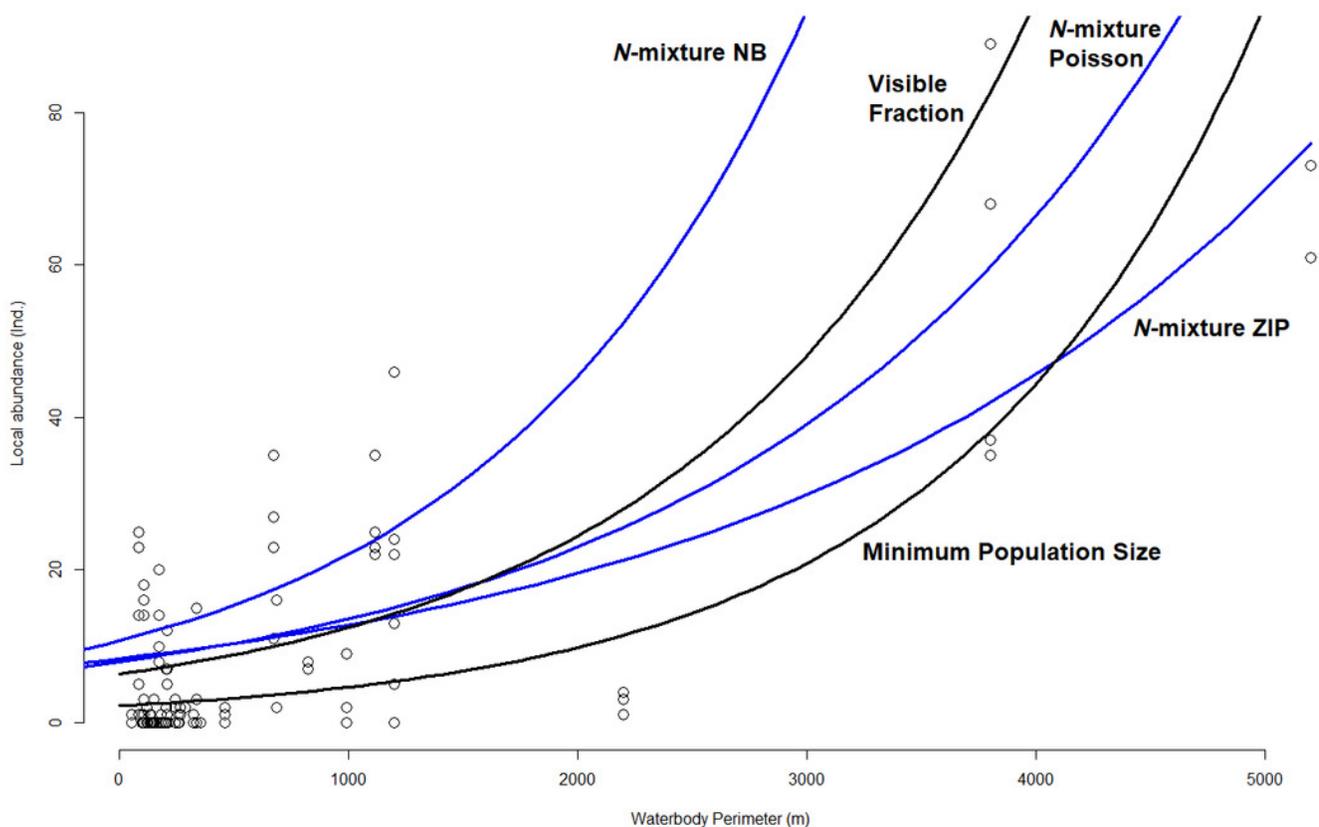

Left hand side figures represent Poisson, NB and ZIP  $N$ -mixture fitted values vs observed crocodile counts, where the black line shows a 1:1 relationship and the blue line is the linear regression line of best fit. Right hand side figures represent residuals vs fitted values (black line denotes a zero residual and the blue line is the linear regression line).

## Figure 3

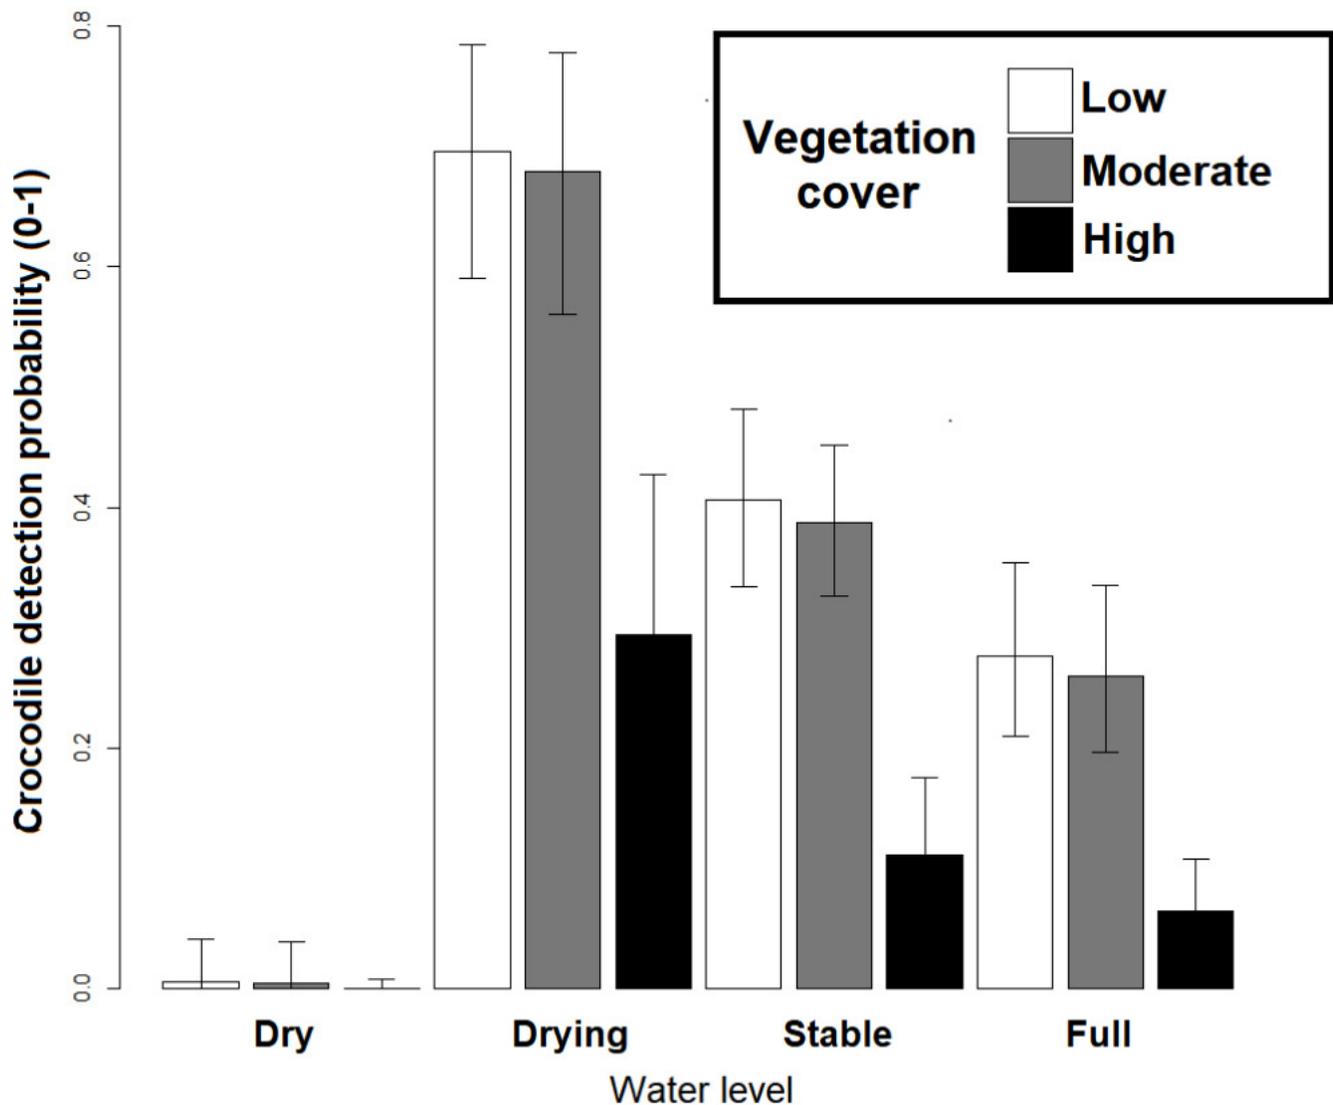

Generalized linear models between local *Crocodylus moreletii* abundance and waterbody perimeter in the region of Calakmul.

Black lines represent fitted values from estimations through King's visible fraction method and Minimum population size using only baseline count data. Dark blue lines represent fitted values from binomial *N*-mixture modelling using a Poisson, Negative Binomial and a Zero Inflated Poisson approach. Open circles represent all our baseline crocodile count values (i.e. number crocodiles observed during the survey).

## Figure 4

*Crocodylus moreletii* detection probability estimations in function of water level and vegetation cover inside the waterbody calculated through Zero Inflated Poisson  $N$ -mixture modelling.

## Figure 5

Perimeter distribution of the 1663 semi-temporary and permanent waterbodies across the region of Calakmul (Campeche, Mexico).

Data extracted from a GIS hydrological dataset published for this region (García-Gil, 2000).

Dashed lines represent the median (red) and mean (blue) waterbody perimeter values.
