Most herbivorous mammals have symbiotic microbes living in their gastrointestinal tracts that help with harvesting energy from recalcitrant plant fibre. The bulk of research into these microorganisms has focused on samples collected from faeces, representing the distal region of the gastrointestinal (GI) tract. However, the GI tract in herbivorous mammals is typically long and complex, containing different regions with distinct physico-chemical properties that can structure resident microbial communities. Little work has been done to document the composition of GI microbial communities of herbivorous animals at these sites. In this study, we use 16S rRNA gene sequencing to characterize the microbial biogeography along the GI tract in two species of wombats. Specifically, we survey the microbes along four major gut regions (stomach, small intestine, proximal colon, distal colon) in a single bare-nosed wombat (*Vombatus ursinus*) and a single southern hairy-nosed wombat (*Lasiorhinus latifrons*). Our preliminary results show that GI microbial communities of wombats are structured by GI region. For both wombat individuals, we observed a trend of increasing microbial diversity from stomach to distal colon. The microbial composition in the first proximal colon region was more similar between wombat species than the corresponding distal colon region in the same species. We found several microbial genera that were differentially abundant between the first proximal colon (putative site for primary plant fermentation) and distal colon regions (which resemble faecal samples). Surprisingly, only 10.6% (99) and 18.7% (204) of amplicon sequence variants (ASVs) were shared between the first proximal colon region and the distal colon region for the bare-nosed and southern hairy-nosed wombat, respectively. These results suggest that microbial communities in the first proximal colon region—the putative site of primary plant fermentation in wombats—are distinct from the

distal colon, and that faecal samples may have limitations in capturing the diversity of these communities. While faeces are still a valuable and effective means of characterising the distal colon microbiota, future work seeking to better understand how GI microbiota impact the energy economy of wombats (and potentially other hindgut-fermenting mammals) may need to take gut biogeography into account.

Microbial biogeography of the wombat gastrointestinal tract

Abstract

Most herbivorous mammals have symbiotic microbes living in their gastrointestinal tracts that help with harvesting energy from recalcitrant plant fibre. The bulk of research into these microorganisms has focused on samples collected from faeces, representing the distal region of the gastrointestinal (GI) tract. However, the GI tract in herbivorous mammals is typically long

and complex, containing different regions with distinct physico-chemical properties that can structure resident microbial communities. Little work has been done to document the composition of GI microbial communities of herbivorous animals at these sites. In this study, we use 16S rRNA gene sequencing to characterize the microbial biogeography along the GI tract in two species of wombats. Specifically, we survey the microbes along four major gut regions (stomach, small intestine, proximal colon, distal colon) in a single bare-nosed wombat (*Vombatus ursinus*) and a single southern hairy-nosed wombat (*Lasiornhinus latifrons*). Our preliminary results show that GI microbial communities of wombats are structured by GI region. For both wombat individuals, we observed a trend of increasing microbial diversity from stomach to distal colon. The microbial composition in the first proximal colon region was more similar between wombat species than the corresponding distal colon region in the same species. We found several microbial genera that were differentially abundant between the first proximal colon (putative site for primary plant fermentation) and distal colon regions (which resemble faecal samples). Surprisingly, only 10.6% (99) and 18.7% (204) of amplicon sequence variants (ASVs) were shared between the first proximal colon region and the distal colon region for the bare-nosed and southern hairy-nosed wombat, respectively.

These results suggest that microbial communities in the first proximal colon region—the putative site of primary plant fermentation in wombats—are distinct from the distal colon, and that faecal samples may have limitations in capturing the diversity of these communities. While faeces are still a valuable and effective means of characterising the distal colon microbiota, future work seeking to better understand how GI microbiota impact the energy economy of wombats (and potentially other hindgut-fermenting mammals) may need to take gut biogeography into account.

Introduction

Gut functionality and health relies on a diverse community of microbes inhabiting the entire gastrointestinal tract. These microbes are instrumental in digesting food, producing nutrients for the host, and as a potential first barrier to invading pathogens (reviewed in (Rowland et al. 2018; Ubeda, Djukovic, and Isaac 2017)). In herbivores specifically, gut microbes break down cellulose and other plant cellular components so they may be used as nutrients by the animal (Flint et al. 2012), and can detoxify plant defense compounds (Dearing and Kohl 2017). Without these microbes there would be little to no nutritional value in much of the plant matter herbivorous mammals are known to consume and thrive on. In ruminants, the bulk of microbial digestion and fermentation occurs in a highly modified foregut (rumen) where nutrients are broken down by rumen microbiota and made ready for absorption through the small intestine (Immig 1996). However, in herbivores without a rumen, the microbial breakdown of plant matter into usable nutrients and energy occurs in the latter parts of the gut—principally the cecum and colon (Stevens and Hume 1998). Prior research has found that microbial communities vary along the mammalian GI tract (Donaldson, Lee, and Mazmanian 2015; Costa et al. 2015; Ericsson et al. 2016; Kelly et al. 2017; Crespo-Piazuelo et al. 2018; Eckburg et al. 2005; Flynn et al. 2018; Vasapolli et al. 2019). In mice, large differences were observed between cecum, distal colon, and faeces microbial communities (Gu et al. 2013; Pang et al. 2012). Marked microbial community differences between caecal, colon, and faecal samples were also identified in a study on koalas, which are in the same family as wombats (Barker et al. 2013). How representative faecal samples are to other parts of the GI tract is likely host species specific, resulting from variations in GI morphology and function. Yet our understanding of these differences outside of domesticated placental mammals remains unstudied. As a major goal of gut microbiome research is to understand how microbes influence host health and ecology, efforts should be made to better characterize the site-specific nature of microbes along the GI tract and determine how representative faecal samples are.

Wombats represent a useful herbivorous hindgut fermenting group to contribute to knowledge on microbial community differences along the GI tract. As marsupials, they are a valuable taxonomic group to add to a growing body of GI tract microbiota research. Bare-nosed (*Vombatus ursinus*, hereafter BNW) and Southern hairy-nosed (*Lasiorhinus latifrons*, hereafter SHNW) wombats represent two of the three extant wombat species and are also in the same sub-order as the koala (Diprotodontia). The BNW and SHNWs are large (20-35 kg), fossorial, metabolically depressed, nocturnal, and largely solitary marsupials found allopatrically across large areas of southeastern and southern Australia (Wells 1989). These two wombat species also represent temperate and arid adapted grazing diets, respectively (Wells 1989; Camp et al. 2020), and are thought to have shared a common ancestor ~8 million years ago (Mitchell et al. 2014). The SHNW has a comparatively longer distal colon, with the BNW possessing a wider digestive tract and greater proximal colon surface area (Figure 1) (Barboza and Hume 1992a; Hume 1999). Both species have caeca that are smaller and less functional than other hindgut fermenters, and the digesta passage rates are thought to be the same between wombat species (Hume 1999). Previous research measuring short chain fatty acids indicates that most plant fermentation occurs in the proximal colon of both wombat species rather than in other regions of the GI tract (Barboza and Hume 1992b). It has been estimated that plant fermentation accounts for >60% of a wombat's daily energy intake (Barboza and Hume 1992b). To date, gut microbiota research in wombats has focused on faecal samples obtained from captive (Shiffman et al. 2017) and wild wombats (Eisenhofer, Helgen, and Taggart 2021; Weiss et al. 2021), with nothing known about how microbial communities are structured throughout the GI tract, and how representative faeces are to other GI regions.

Here, we used 16S rRNA gene sequencing to investigate the microbial community changes along the GI tract of two wombat individuals, a wild BNW and SHNW. We predicted that the proximal colon, the putative primary site of plant fermentation in wombats, would harbor a

distinct microbial community to that of the rest of the gastrointestinal tract, including the distal colon in these wombat species.

Materials & Methods

Sample collection

Sample collection occurred during necropsies on two deceased wild wombats (n=2), one BNW and one SHNW. A 17.1 kg female BNW was hit by a vehicle in the New Norfolk area, Tasmania, Australia and taken to Bonorong Wildlife Sanctuary. Injuries to this wombat were too severe for rehabilitation, and it was euthanized on 13th November 2019. Immediately following euthanasia the carcass was placed in a -20°C freezer at the University of Tasmania, Hobart. The SHNW was captured near Swan Reach in the Murraylands of South Australia, approximately 100 km north-east of Adelaide, as part of an ecological study on seasonal reproduction and breeding, but then died later of an upper respiratory tract infection. The carcass was driven to Adelaide and put into a -20°C freezer within 2 hours of death. Given that storage of faecal samples for extended periods at room-temperature can result in microbial ‘blooming’ and distorted taxonomic compositions, the rapid freezing of the samples in this study (both within 8 hours of death) should help mitigate such biases (Song et al. 2016; Lauber et al. 2010). Regardless, any biological differences between wombat species should outweigh any technical biases introduced during sample storage (Song et al. 2016; Lauber et al. 2010).

Prior to necropsy, carcasses were put into a 4°C refrigerator and defrosted for ~48 h. In human faecal samples, freeze-thawing was only found to influence taxon abundance after the fourth cycle of freeze-thaw (Gorzalak et al. 2015). The entire digestive systems were then removed from the abdominal cavity and the functional sections of the GI tract were labeled as per (Barboza and Hume 1992a). For the stomach, small intestine, and proximal colon, samples were collected in the middle of each functional section (Figure 1). For distal colon samples, the BNW sample was

collected halfway through the distal colon. For the SHNW four samples were collected: DC1 was collected 1 meter down from the proximal colon/distal colon boundary, DC2 was collected 2 meters down, etc. Samples of the digesta were collected in duplicate in the SHNW and in triplicate in the BNW. While faecal samples could not be collected from the euthanized animals, the distal colon samples collected resembled faeces, being similar in size, shape, and moisture content. To avoid cross-contamination between sites the digesta was squeezed directly into individual sterile containers. Samples were then stored at -20°C prior to molecular work.

DNA extraction and 16S rRNA gene library preparation

DNA extraction was performed using the QIAamp® Fast DNA stool mini kit from QIAGEN according to the manufacturer's protocol (Qiagen Pty. limited Victoria, Australia). Duplicate samples from each GI region for both wombat species were processed. BNW samples were extracted at the University of Tasmania, and SHNW samples were extracted at the University of Adelaide. BNW DNA extracts were then shipped frozen to the University of Adelaide for library preparation. Barcoded V4 region 16S rRNA gene amplicons were generated using primers from (Caporaso et al. 2011) (forward primer 515F: GTGCCAGCMGCCGCGGTAA and barcoded reverse primer 806R: GGACTACHVGGGTWTCTAAT). The PCR reactions were prepared in a pre-PCR laboratory in a 5% sodium hypochlorite-cleaned and UV irradiated hood. Single reactions (Marotz et al. 2019) of 2.5 µL X10 HiFi buffer, 0.1 µL Platinum™ Taq DNA Polymerase (ThermoFisher), 19.2 µL dH2O, 0.2 µL 100 mM dNTP mix, 0.5 µL each of 10 µM forward and reverse primer and 1 µL input DNA. The DNA was amplified using an initial denaturation at 94 °C for 3 min, followed by 35 cycles of denaturation at 94 °C for 45 s, annealing at 50 °C for 1 min, elongation at 68 °C for 90 s, with final adenylation for 10 min at 68 °C (Thompson et al. 2017). Gel electrophoresis was performed on PCR reactions on a 3.5% agarose gel to ensure samples contained amplicons of the desired length (~ 390 bp). For each sample, 1 µL PCR amplified DNA was mixed into 199 µL

Qubit® working solution (diluted Qubit® dsDNA HS Reagent 1:200 in Qubit® dsDNA HS Buffer) and quantified using a Qubit® 2.0 Fluorometer. Samples were then pooled equimolar and cleaned using AxyPrep™ (Axygen) following the manufacturer's instructions. The final pool was quantified and quality checked using an Agilent TapeStation. DNA sequencing was performed on an Illumina MiSeq (v2, 2 × 150 bp) at SAHMRI (South Australian Health and Medical Research Institute).

Bioinformatic analyses

QIIME2 (Bolyen et al. 2019) and R v4.0.2 (R Core Team 2020) were used to perform the bioinformatic analyses and create figures. Reproducible code is publicly available at the following GitHub repository (https://github.com/EisenRa/2021_Wombat_GI_tract_16S). Forward reads were denoised using deblur (Amir et al. 2017) in QIIME2. Representative sequences were assigned taxonomy using the QIIME2 feature-classifier plugin (Bokulich et al. 2018) on the pre-trained SILVA (Quast et al. 2013) 138 V4 region classifier. A phylogenetic tree was created using the SATé-enabled phylogenetic placement (SEPP) technique (Janssen et al. 2018) using the fragment-insertion QIIME2 plugin. Data was then imported into rStudio into a phyloseq (McMurdie and Holmes 2013) object using qiime2R (<https://github.com/jbisanz/qiime2R>), and manipulated with dplyr (<https://github.com/tidyverse/dplyr>), tidyr (<https://github.com/tidyverse/tidyr/>), and the microbiome package (<https://github.com/microbiome/microbiome/>). For all sample type comparisons, the table was rarefied at a depth of 21,710, for colon-only comparisons the table was rarefied to 47,301. ASVs that were found in only 1 single replicate of a gut region were removed. These ASVs represented only 4.3% of identified ASVs and 0.16% of the mean relative abundance of the dataset. Alpha and beta diversity measures (including UniFrac (Lozupone and Knight 2005)) were calculated in R using phyloseq, and figures were plotted using ggplot2 (Wickham 2016) and ggVennDiagram (Gao, Yu, and Cai 2021). Compositional analysis of the community was done using ANCOM-II in R (ANCOM v2.1 (Kaul et al. 2017) in R v.4.0.3). Analysis was undertaken using an ANCOM - adjusted for covariates model which accounts for the

covariation expected at the species/animal level. The analysis was performed at the rarefied genus level for the proximal colon and distal colon samples only. For the venn and euler diagrams, ASVs needed more than 2 reads assigned at a given site (between two replicates) to be considered detected, and were then plotted using ggVennDiagram (<https://github.com/gaospecial/ggVennDiagram>).

Results

DNA sequencing of the 30 gastrointestinal digesta samples (Figure 1) and 1 extraction blank control (EBC) resulted in 4,923,858 (mean of $158,834 \pm 76,389$) forward reads (R1), which were denoised using deblur into 2,524 amplicon sequence variants (ASVs).

Microbial biogeography through the digestive tract of two wombat species

To test if these different gut regions influenced the microbial communities, we analyzed the microbial composition, richness (the number of ASVs), and diversity of duplicate luminal samples taken throughout the GI tract of each wombat species. We first investigated what types of microbes (the taxonomic composition) were present in the different GI samples for both wombat species. At the phylum level, stomach and small intestine samples tended to be dominated by Proteobacteria, Firmicutes, and Fusobacteriota (SI Figure 1). We observed a large difference in phyla composition between the proximal (PSI) and distal small intestine (DSI) samples from the SHNW, with the PSI dominated by Proteobacteria, and DSI dominated by Fusobacteria (SI Figure 1). The dominant families in the stomach and small intestine samples were Pasteurellaceae (59% in BNW-ST (ST = Stomach), 56% in SHNW-ST, 43% in SHNW-PSI), Peptostreptococcaceae (67% in BNW-SI), and Fusobacteriaceae (81% in SHNW-DSI) (Figure 2). In contrast, the colon samples for both wombat species were dominated by the Bacteroidota, Firmicutes, and Spirochaetota phyla (SI Figure 1). We also observed taxonomic differences between proximal

(especially proximal colon 1&2) and distal colon samples for both the wombat species (Figure 2). The first proximal colon samples were dominated by Prevotellaceae (~40% relative abundance), and Fibrobacteraceae (~10% for the BNW), whereas the latter proximal colon and distal colon samples contained higher proportions of Spirochaetaceae, Rikenellaceae, and WCHB1-41. A heatmap of all microbial families is available in SI Figure 4.

Microbial richness tended to increase through the length of the digestive tract for both wombat species (Figure 3). Stomach and small intestine samples had the lowest ASV richness (~100-200), followed by the first two proximal colon samples (PC1/PC2: ~400-500), with the latter proximal colon and distal colon samples exhibiting the highest ASV richness (~500-800). Due to our limited sampling, we were unable to run linear models to confirm this pattern statistically, and future studies employing larger sample sizes should test the observed pattern.

Like richness, the types of microorganisms living in a site and how they are structured (composition) can also be influenced by the environmental factors of that site. To test this, we compared the microbial community structure of these distinct sites using both the abundance weighted and unweighted UniFrac distance metrics. As predicted, major differences were observed in microbial composition along the GI tract in both wombat individuals, with stomach, small intestine colon, and colon samples clustering across the axis of most variation (Axis 1: Figure 4A/B). Note that the colon samples are likely driving the placement of samples on the first two axes. Colon samples from the different wombats were separated across axis 2 for the unweighted UniFrac analysis (Figure 4A), and separation between proximal and distal colon samples was observed for both unweighted and weighted UniFrac distances (Figure 4). Interestingly, the microbial composition of the first proximal colon samples of different wombat species is more similar to each other than they are to the distal colon samples of the same species (Figure 4B, SI Figure 2B). Considering colon samples only, potentially species-specific

differences in abundance-weighted microbial composition between distal colon samples were observed across axis 2 (SI Figure 2B). Note however, that we only have 1 sample per species, and can therefore not account for intra-species diversity. These results indicate that microbial diversity and composition vary throughout the GI tract of two hindgut fermenting species, and that the start of the proximal colon--the putative primary site of fermentation in these wombat species -- is distinct from the distal colon.

Microbial differences between proximal and distal colon sites

Because the proximal colon is the putative primary site of plant fermentation in wombats, we next focused on further characterising microbial community compositional differences between the proximal and distal colons for both species. As there were many ASVs that were classified to the same taxa we collapsed the ASV table to the genus-level, and ran ANCOM-II to identify genera that were differentially abundant between different regions of the colon (i.e. PC1, PC2, DC, etc.). Of the 253 genera classified in the dataset, ANCOM-II identified 60 that were significantly differentially abundant throughout the colon when the W-statistic threshold for rejecting the null was at 70% (Figure 5) (SI Table 1). Taxa that had significantly higher abundance in PC1/2 vs. DC include: *Prevotella* (W=245), *Prevotellaceae_UCG-001* (W=241), *Bacteroides* (W=239), and *Bacteroidales_RF16_group* (W=231). Taxa with a higher relative abundance in DC vs. PC1/2 include: *Bacteroidales_BS11_gut_group* (W=250), *Bacteroidales_UCG-001* (W=243), *WCHB1-41* (W=242), and *Izemoplasmatales* (W=226).

To test how representative the microbial community of faeces are to the first proximal colon site, we measured how many ASVs were shared between PC1 and the last DC sample for each wombat species. Surprisingly, only 99 (10.6%) and 204 (18.8%) ASVs were shared between PC1 and DC samples for the BNW and SHNW, respectively (Figure 6). See (SI Figure 3) for a cross-species comparison. The ASVs that were unique to the BNW PC1 and DC sites accounted for

254 25% and 64% of the relative abundance in those sites, respectively. Likewise, the ASVs that were
 255 unique to the SHNW PC1 and DC sites accounted for 32% and 67%, respectively. These
 256 differences remained after collapsing ASVs to the genus-level (SI Figure 5), albeit with a smaller
 257 magnitude (relative abundance of site-specific genera: BNW DC = 5% BNW PC = 20% SHNW
 258 DC = 3% SHNW PC = 12%). These results indicate that the first proximal colon and distal colon
 259 sites harbour distinct communities of microbes.

261 Discussion

262 Mammalian gut microbial communities play vital roles in the harvesting of energy and nutrients
 263 (Rowland et al. 2018). Due to ease of sampling, most previous mammalian gut microbiota
 264 research has focused on faecal samples as proxies for the gut microbiota. However, the
 265 mammalian GI tract contains a series of distinct microbial growth conditions that can structure the
 266 diversity and composition of resident microbial communities (Donaldson, Lee, and Mazmanian
 267 2015). Outside of model or domesticated placental mammal species there has been little work in
 268 characterising how GI microbial communities are structured along GI tracts, and how
 269 representative faeces are of other GI regions. Our work here fills this gap for two species of free-
 270 living, large, hindgut-fermenting marsupials—the bare-nosed wombat (BNW) and the southern
 271 hairy-nosed wombat (SHNW). Although we had data for only two individual wombats, our results
 272 showed that microbial community composition, structure and diversity varied along the wombat
 273 GI tract, and that the first proximal colon region—the putative primary site of fermentation—was
 274 highly dissimilar to the distal colon. Our findings also indicate that faecal samples collected for
 275 wombats may not be representative of the primary site of fermentation. Future studies seeking to
 276 understand the roles that GI microbial communities play in host energy acquisition and health
 277 should consider the microbial biogeography of the mammalian GI tract.

A major finding was that the microbial communities present in the first proximal colon region (PC1) were more similar between both individuals, than to subsequent colon region samples from the same individual. This is particularly interesting given that both individuals are from different species – though still preliminary given the small sample size in our study (n=1 for both species). PC1 in both wombat individuals were dominated by the family Prevotellaceae (~40% relative abundance), a family that contains members with extensive carbohydrate/fiber fermentation capabilities (Filippo et al. 2010; Kovatcheva-Datchary et al. 2015). All other GI sites contained lower levels of Prevotellaceae (<5% relative abundance). In addition, PC1 for both wombat individuals contained significantly higher levels of bacteria classified to the genus *Bacteroides*, which are known to possess a diverse suite of carbohydrate-active enzymes (Kaoutari et al. 2013). PC1 of the BNW had relatively high levels (~10% relative abundance) of the genus *Fibrobacter* (~0.3% in the SHNW PC1), which have known fiber-degrading capacity and have been found in various placental foregut- and hindgut-fermenting herbivores (Neumann, McCormick, and Suen 2017). These distinct microbial compositions in PC1 of both wombat individuals compared to subsequent colon regions warrant further investigation with shotgun metagenomics to verify whether these taxonomic differences represent differences in the capacity to ferment fibre. This would further test Barboza and Hume's finding that PC1 represents the primary site of microbial fermentation in the wombat GI tract, and offer us a greater understanding of microbial fermentation in wombats. Finally, such a study could also verify whether the high proportion of Firmicutes found in colon samples are involved fibre degradation as expected (Biddle et al. 2013).

Given the major microbial compositional differences observed between proximal and distal colon samples, we sought to determine how many proximal colon-associated microbes would be detected by sampling faeces, the most commonly used sample type in mammalian gut microbiota research. Surprisingly, only a very small proportion of PC1 ASVs could be detected in distal colon

samples (10.6% and 18.7% in the BNW and SHNW, respectively). This suggests that seeking to understand microbial functions at the putative primary site of fermentation through faecal samples may not be feasible. This is not to say that faecal samples are not useful, as previous gut microbiome research on captive (Shiffman et al. 2017) and wild wombats (Eisenhofer, Helgen, and Taggart 2021; Weiss et al. 2021) have yielded insights into wombat digestion and ecology. Eisenhofer et al. used faecal samples from both captive and wild SHNWs to show that captivity has a large influence on the faecal microbiota of SHNWs. They were also able to identify population-specific microbial signatures and found a correlation between habitat type (degraded vs. intact) and faecal microbiota composition in SHNWs (Eisenhofer, Helgen, and Taggart 2021). Shiffman et al. used shotgun metagenomic sequencing on faecal samples collected from a captive SHNW, and found numerous microbial genes involved in plant degradation and urea recycling (Shiffman et al. 2017). Interestingly, they made note that they could not detect bacteria from the phylum *Fibrobacterota*, which are commonly found in herbivorous mammals (Neumann, McCormick, and Suen 2017). We identified *Fibrobacterota* in both wombat species, with a higher relative abundance in the BNW, particularly in the proximal colon. Overall, our results suggest that faeces may not be a representative sample type for the putative primary site of microbial fermentation in wombats. We propose that future research seeking to understand the roles that GI microbes play in wombat (or other mammal) digestion consider this, and aim to study other regions of the GI tract where possible.

Our study is not without limitations. The opportunistic nature of sample collection from fresh necropsied animals limited this study to only one animal for each wombat species. This hampered our ability to compare microbial differences between wombat species, as the differences observed may be related to individual-level variation—making us unable to run statistical tests on GI tract alpha or beta diversity. However, the consistency observed between the biological replicates and in overall trends for both species of wombat support our findings relating to PC1/distal microbial

differences and the level of representability of the faeces to PC1—despite the ecological differences between wombat species and the estimated ~8 million years since they last shared a common ancestor (Mitchell et al. 2014). Another limitation is that we could not distinguish DNA from living or dead cells, and it is possible that the differences between GI sites is greater than measured in our study due to dead cells/relic DNA moving from site to site and inflating similarity (Lennon et al. 2018). Future studies with larger sample sizes will enable more detailed microbial comparisons between wombat species, and improve estimates of within-animal microbial differences along the GI tract.

The findings of our study have spawned several promising avenues of future research. Using shotgun metagenomics to compare and contrast the microbial functions present between proximal and distal colons could allow for a greater understanding of the roles GI microbes play in wombat digestion and health. The strain-level information obtained from shotgun metagenomics would also allow for greater tracking of microbes along the GI tract, and help disentangle issues relating to the over splitting of microbes due to intragenomic heterogeneity in 16S rRNA genes (Sun et al. 2013). Future, larger sample size comparisons between wombat species could also seek to identify microbes that are shared between wombat species, and consistently found within species. Any such ‘core’ microbes that are still shared between wombat species despite ~8 million years of separation could indicate that they are important for host health. In our study the distal colon exhibited the greatest microbial differentiation between wombat species. Such interspecies microbial differences in the latter parts of the colon could be due to GI morphological/physiological differences between wombat species (Barboza and Hume 1992a) and relate to differences in the ecology of the two wombat species. Further larger-scale comparisons between BNW (mesic living) and SHNWs (arid/semi-arid living), and other phylogenetically distinct mammals could offer insights into the potential roles that GI microbes play in the arid and temperate adaptability of mammals in Australia.

357

358 **Conclusions**

359 Our study suggests that microbial communities in the first proximal colon region—the putative site
 360 of primary plant fermentation in wombats—are distinct from the distal colon, and that faecal
 361 samples may have limitations in capturing the diversity of these communities. While faeces are
 362 still a valuable and effective means of characterising the distal colon microbiota, future work
 363 seeking to better understand how GI microbes impact the energy economy of wombats (and
 364 potentially other hindgut-fermenting mammals) may need to take gut biogeography into account.

Acknowledgements

The authors would like to thank Alejandro Correa Lozano for his help collecting and analysing the BNW samples.

Figure 1

Illustration of wombat gut tracts and samples collected

Drawn illustrations of *Vombatus ursinus* (top) and *Lasiorhinus latifrons* (bottom) gastrointestinal tracts based on Barboza and Hume 1992a. Stars represent locations where duplicate samples were collected for the study. BNW = Bare-nosed wombat, SHNW = Southern hairy-nosed wombat.

Figure 2

Taxonomic composition of the different sample types at the family level

Only the top 20 most abundant families are displayed for clarity (these families account for 81.17% of reads) The 'Other' bin (grey) contains the other families. Replicate samples were merged per sample site. A) bare-nosed wombat. B) southern hairy-nosed wombat. The widths of the bars are scaled to the length of the GI region.

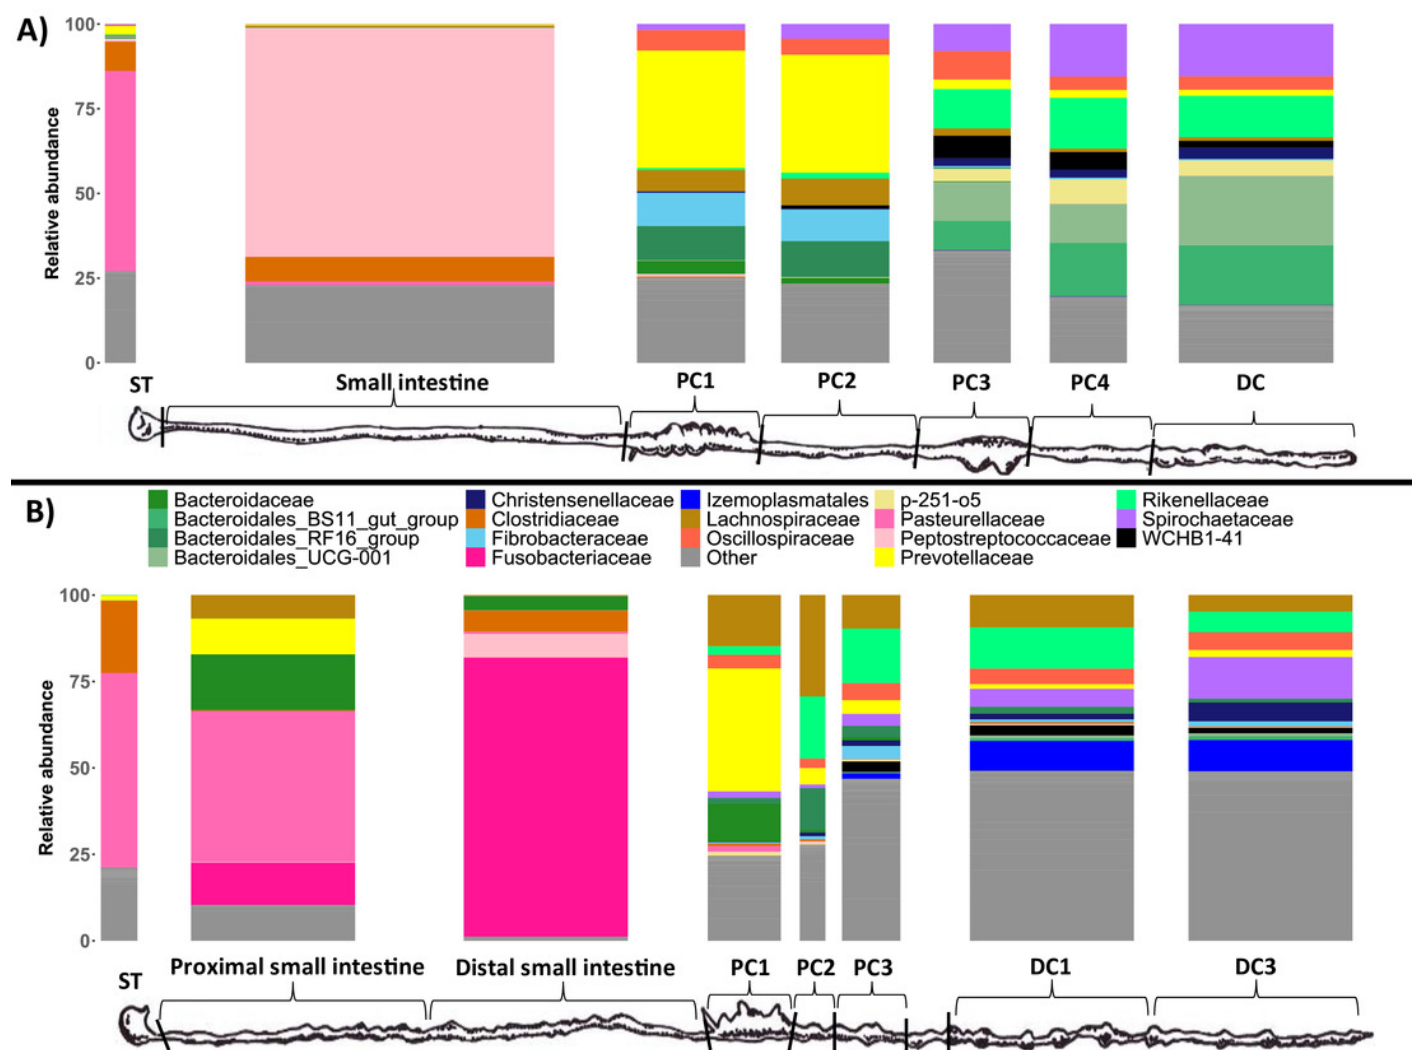

Figure 3

Microbial diversity (ASV richness) of samples collected throughout the wombat digestive tract, ordered from start to end.

ST = stomach, SI = small intestine, PSI = proximal small intestine, DSI = distal small intestine, PC = proximal colon, DC = distal colon. Two technical replicates were collected and processed for each site (joined by lines). A) bare-nosed wombat. B) southern hairy-nosed wombat. Digestive tract drawings were adapted from Barboza and Hume 1992a.

Figure 4

Microbial community structure among sites along the wombat GI tract.

A) PCoA of unweighted UniFrac distances and B) PCoA of weighted UniFrac distances.

Samples are coloured by sample type, and shaped by host species. Numbers indicate order in which samples occur in the digestive tract. Lines connect samples from the same sample type.

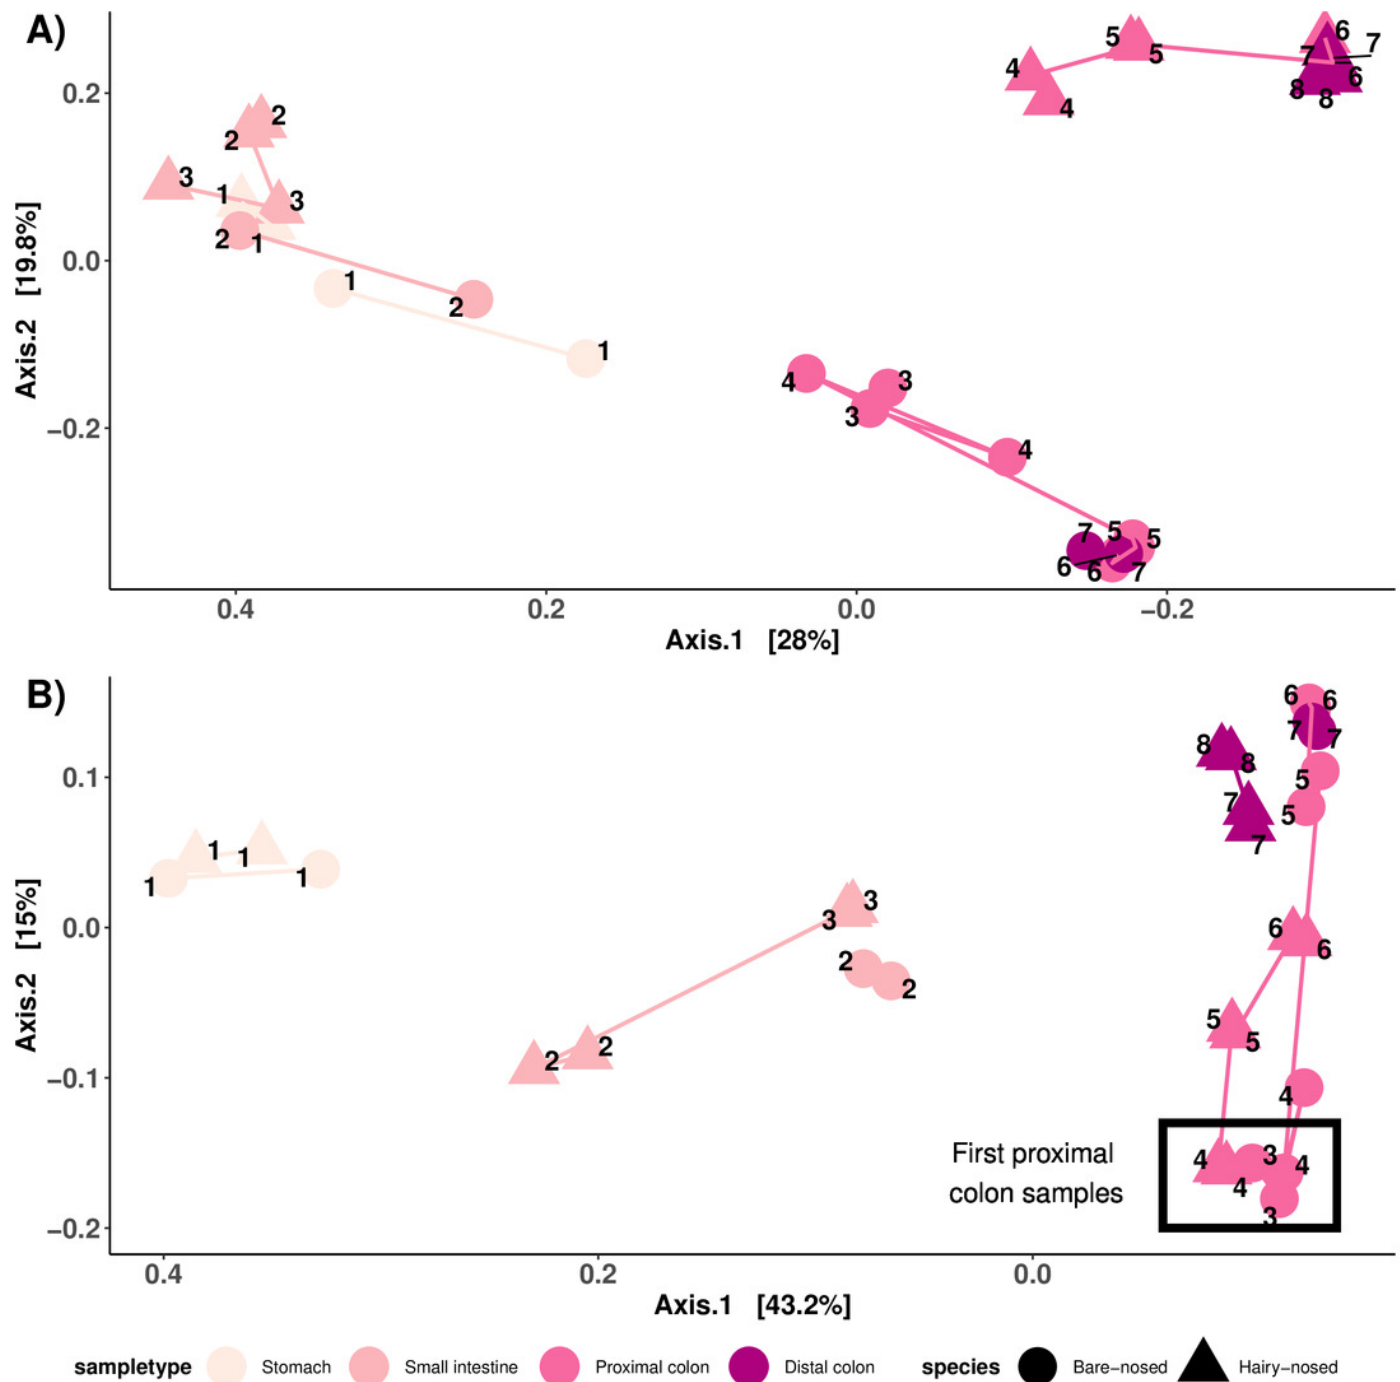

Figure 5

Heat map of the microbial genera that were found to be differentially abundant between proximal and distal colon sites.

The abundance of genera that were found to be differentially abundant (0.7 threshold) in the ANCOM-II analysis are displayed. Black indicates 0 assigned reads. Non-genus assignments are prefixed with the lowest level of taxonomy that could be assigned (e.g. f__ = family).

Taxonomy string are prefixed with 'Phylum -- '.

Figure 6

Euler diagram of amplicon sequence variants (ASVs) shared between proximal and distal colon sites for both wombat species.

Euler diagram of amplicon sequence variants (ASVs) shared between proximal colon 1 (PC1) and last distal colon site (DC) for A) bare-nosed wombat (BNW) and B) southern hairy-nosed wombat (SHNW). Percentages represent the proportion of ASVs specific to a given area.

A) Bare-nosed wombat

B) Southern hairy-nosed wombat
