Social communication difficulties are a diagnostic feature in autism. These difficulties are sometimes attributed, at least in part, to impaired ability in making inferences about what other people mean. In this registered report, we tested a competing hypothesis that the communication profile of adults on the autism spectrum can be more strongly characterised by reduced confidence in making inferences in the face of uncertain information. We tested this hypothesis by comparing the performance of 101 autistic and 108 non-autistic adults on a test of implied meaning, using a test of grammaticality judgements as a control task. We hypothesised that autistic adults would report substantially lower confidence, allowing for differences in accuracy, than non-autistic adults on the test of implied meaning compared to the grammaticality test. However, our results did not suggest this. Instead, we found that accuracy and confidence were both reduced to a similar extent on the test of implied meaning in the autistic group compared to the control group, although these were only subtle differences. This pattern of results was specific to inference-making, as the autistic and non-autistic groups did not differ on the grammar test. This supports the idea that specific differences in pragmatic language processing can exist in autism in the absence of core language problems. Importantly, this pattern of results (differences on the test of implied meaning and no differences on the grammar test) was reversed in a group with self-reported reading difficulties, indicating that the differences in inference-making were specific to the autistic group. Lastly, we found relationships between Intolerance of Uncertainty, performance on the test of implied meaning, and self-reported social communication challenges. This supports the idea that discomfort with uncertainty plays a role in the pragmatic language and communication challenges in autism.

**Abstract**

21      Social communication difficulties are a diagnostic feature in autism. These difficulties are

22    sometimes attributed, at least in part, to impaired ability in making inferences about what other

23    people mean. In this registered report, we tested a competing hypothesis that the communication

24    profile of adults on the autism spectrum can be more strongly characterised by reduced

25    confidence in making inferences in the face of uncertain information. We tested this hypothesis

26    by comparing the performance of 102 autistic and 109 non-autistic adults on a test where

27    individuals needed to make inferences about implied meaning, using a test of grammaticality

28    judgements as a control task. We hypothesised that, regardless of accuracy, autistic adults would

29    report substantially lower confidence than non-autistic adults on the test of implied meaning but

30    not on the grammar test. We confirmed that the autistic and non-autistic groups did not differ in

31    accuracy or confidence on the grammaticality judgement task. However, contrary to prediction,

32    on the test of implied meaning, accuracy and confidence were both reduced to a small but

33    significant extent in the autistic group compared to the control group. This supports the idea that

34    specific differences in processing non-literal language and inferencing can exist in autism in the

35    absence of core language problems. This pattern of results was specific to the autistic group, as a

36    contrasting profile was found in a group with self-reported reading difficulties, who showed no

37    differences on the test of implied meaning but were less accurate on the grammar test. Lastly, we

38    found relationships between Intolerance of Uncertainty, performance on the test of implied

39    meaning, and self-reported social communication challenges. This supports the idea that

40    discomfort with uncertainty plays a role in the pragmatic language and communication

41    challenges in autism.

## Introduction

45      Persistent challenges with social communication are a defining feature for the diagnosis

46  of autism (American Psychiatric Association, 2013). The underlying nature of these challenges

47  remains unclear, although they are sometimes attributed to a core impairment in pragmatics (e.g.

48  Baron-Cohen, 1988; Rapin & Dunn, 2003). Pragmatics refers to the role of context in

49  communication, including the ability to "read between the lines" to infer intended meaning

50  beyond what is explicitly stated (Baird & Norbury, 2016). However, empirical research suggests

51  that pragmatic difficulties may be rather subtle in autistic people, and mostly attributable to

52  language ability (Kalandadze, Norbury, Nærland & Næss, 2018; Loukusa & Moilanen, 2009).

53  An alternative suggestion is that social communication difficulties are less the result of an

54  impairment in pragmatics, but more impacted by cognitive preferences that differ between

55  autistic and non-autistic people. We propose that a preference for certainty and explicit

56  communication commonly occurs in autistic people, and that this trait may be a critical factor in

57  the communication difficulties experienced by autistic people, as communicative situations often

58  involve ambiguity, uncertainty and implied meanings.

59  **Intolerance of Uncertainty**

60      A "preference for certainty and explicit communication" may link to the widely-

61  researched cognitive trait, Intolerance of Uncertainty (IU). IU has been defined as a tendency to

62  negatively evaluate uncertain situations and information (Shihata, McEvoy, Mullan & Carleton,

63    2016). We use the term "Intolerance of Uncertainty" in line with previous research and intend to

64    convey a value-neutral meaning in using it, as we recognise that high levels of IU may be an

65    understandable, even adaptive, response where individuals have experienced mishaps in

66    confusing situations. IU has mostly been investigated as a transdiagnostic construct that plays a

67    central role in emotional disorders across the general population (see Shihata et al., 2016 for a

68    review), but it also seems especially relevant to autism, with autistic children and adults showing

69    significantly elevated levels of the trait compared to the general population (e.g. Hwang et al.,

70    2020; Vasa et al., 2018). IU has been closely linked to anxiety in autistic people (Jenkinson et al.,

71    2020), and also relates to core features of autism, including social difficulties, sensory

72    sensitivities, insistence on sameness and repetitive behaviours (e.g. Hwang et al., 2020; Vasa et

73    al., 2018; Wigham et al., 2015).

74        A possible link between IU and communication in autistic people remains largely

75    unexplored. However, there are reasons to believe that a link is plausible. First, inferential

76    models of communication, such as Relevance Theory (Sperber & Wilson, 1986), propose that

77    communication inherently involves uncertainty. Under Relevance Theory, language

78    comprehension is not simply a process of "understanding what the words mean", as there are

79    often indeterminacies and ambiguities in uses of language; instead, the words are used as

80    evidence by the listener in supporting a hypothesis about what the speaker *probably* means in the

81    context, i.e. inferring intended meaning under uncertainty. Relevance Theory suggests that there

82    is a gradient of uncertainty in communication. Sometimes, the listener can rely mostly on the

83    explicit content of the utterance to compute the intended meaning, but in other situations there is

84    a greater reliance on inferential processing to understand the speaker's probable meaning by

85    integrating the utterance with contextual cues and world knowledge. Compare for instance the

86    utterances "No, let's stay inside" and "It's quite cold today" as responses to a suggestion to go

87    outside. In the second example, the speaker communicates implicitly, leaving the listener to

88    process the implicature that they would probably prefer to stay inside. In a previous study, we

89    provided evidence for cognitive differences between autistic and non-autistic people in

90    processing implicatures (Wilson & Bishop, 2020c). Crucially, it seemed that a cognitive

91    preference for certainty and explicit communication, and not simply reduced ability, may

92    account for some of the differences. Participants completed the Implicature Comprehension Test,

93    which required individuals to listen to short conversational interchanges that are followed by a

94    comprehension question to assess whether an implied meaning has been processed; test-takers

95    responded with "yes", "no" or "don't know". Controlling for grammar/vocabulary ability, we

96    found that autistic adults ($N = 66$) were 6.19, 95% CI [3.63, 10.39], times more likely to select

97    the "don't know" rather than the correct response compared to non-autistic people ($N = 118$), and

98    also 2.56, 95% CI [1.76, 3.77], times more likely to choose the "incorrect" response (Wilson &

99    Bishop, 2020c). Group differences were large, and performance on the test gave 76% sensitivity

100   and specificity for differentiating between autistic and non-autistic groups. On the face of it,

101   these results suggest that autistic people have difficulties inferring the gist of a speaker's

102   meaning, as predicted by the 'central coherence' theory, which proposes that autistic people may

103   show less tendency than non-autistic people to process information at a global level (Frith,

104   1989).

105       However, in an alternative version of the test without a "don't know" response, autistic

106   individuals showed high accuracy for items for which they had selected "don't know" first time

107   round. This marked tendency to select "don't know" when given a chance, but to process the

108   inference as intended when constrained by the task, suggested reduced confidence in the face of

109    uncertain information and a preference for explicit communication. This could be due to possible

110    difficulties around metacognition in autistic people, who may experience a mismatch between

111    performance and confidence in their performance due to differences in self-monitoring. There is

112    evidence that autistic people may show such a mismatch (Grainger et al., 2016; Nicolson et al.,

113    2019) although there is some concern about the replicability of these results (Maras et al., 2020).

114    An alternative view would be that it is less an issue of metacognitive "ability", and more about

115    differences in personality/cognitive preference, with the well-replicated elevated levels of IU in

116    autistic people (e.g. Hwang et al., 2020; Vasa et al., 2018) accounting for this apparent

117    preference for explicit communication observed in our previous study. In the present study, we

118    aim to replicate this finding with more refined methods. In an adapted version of the Implicature

119    Comprehension Test, individuals will respond using a 4-point scale of "yes", "maybe yes",

120    "maybe no", and "no", allowing us to capture accuracy and confidence in the same measure. We

121    hypothesise that confidence is likely to be affected specifically in a pragmatic language task (i.e.

122    where the individual needs to make flexible context-dependent inference about uncertain implied

123    meanings), and not on tasks focused on more structural, codified aspects of language such as

124    grammatical competence. As such, we present another metalinguistic task, the Grammaticality

125    Decision Test, as a control task with a similar response format to the pragmatic task to test the

126    specificity of any differences.

127        We propose that reduced confidence on the Implicature Comprehension Test will be a

128    marker of IU in autistic people, and may be a more influential factor in the communication

129    difficulties diagnostic of autism, as opposed to a "deficit" in understanding social meanings. If

130    this claim is borne out, it would have a couple of implications for psychological practice. First, it

131    would suggest that interventions targeting IU may be useful for autistic people wanting support

132    with communication challenges. Current interventions for communication focus on explicit

133    instruction in social skills, and reviews suggest modest effectiveness although there are questions

134    about the extent to which skills transfer to daily life (Gates, Kang, & Lerner, 2017; Spain &

135    Blainey, 2015). A focus on IU may be a useful alternative target. Existing cognitive interventions

136    involve integrating psychoeducation and cognitive challenge techniques to target a client's

137    beliefs about (un)certainty, and these have shown some effectiveness for treating mental health

138    difficulties and particularly anxiety in the general population (Shihata et al., 2016). It remains to

139    be seen whether such interventions could be adapted to support autistic individuals with

140    distressing communication experiences, although this is a promising possibility given that early

141    studies suggest that such interventions may be feasible and acceptable for autistic groups

142    (Rodgers et al., 2018; Rodgers et al., 2016). Second, if a cognitive preference for certainty is

143    especially significant as an explanation for social difficulties, then it supports an autism-positive

144    approach to intervention which focuses on awareness of cognitive differences across

145    communities. In addition, if performance on the Implicature Comprehension Test is a sensitive

146    marker of IU, that in itself might have clinical and research utility, since measurement of IU is

147    currently limited to self- and informant-report questionnaires.

148          A remaining question is whether any differences observed on our tasks are specific to

149    autism or might also be relevant to other neurodevelopmental diagnoses. This is certainly

150    plausible in the light of dimensional models of neurodiversity, where features of autism,

151    developmental language disorder, dyslexia, ADHD, etc., might show some overlap and exist as a

152    continuum in the general population (Thapar, Cooper, & Rutter, 2017). To test the specificity of

153    any cognitive differences observed on our tests, we will compare performance by autistic people

154    to both a dyslexic and a general population sample. As neurodevelopmental conditions are often

155   co-occurring, we view these three groups as defined less by a specific diagnostic label but rather

156   as varying along a communication continuum. As such, one group is defined by social

157   communication differences potentially alongside co-occurring language/literacy impairments

158   (the autism group), a second group by language/literacy impairments but no diagnosed social

159   communication difficulties (the dyslexia group), and a final group without any communication,

160   language or literacy related diagnosis. It is possible that dyslexic adults may show some

161   difficulty on our pragmatic task (i.e. the Implicature Comprehension Test), as previous research

162   has documented some limited evidence for pragmatic difficulties in dyslexic individuals (e.g.

163   Cappelli et al., 2018; Cardillo et al., 2018; Griffiths, 2007). An alternative possibility is that

164   adults with dyslexia will show greater difficulty with tasks focused more on structural language

165   skills compared to pragmatics. For instance, a meta-analysis has found that dyslexic adults

166   perform less well on language measures, such as vocabulary, speeded naming, verbal memory

167   and phonological processing, than people without a diagnosis of dyslexia, with moderate to large

168   effect sizes (Swanson & Hsieh, 2009). Given that there is no clear reason to support one of these

169   possibilities over the other, we will take a more exploratory approach with the dyslexic group to

170   examine how they compare with autistic adults.

171      In summary, we propose the following hypotheses:

172         (1)    Autistic adults will score lower on a pragmatic language task when

173            responses are coded purely in terms of confidence (number of yes and no responses,

174            regardless of polarity) than when responses are coded in terms of accuracy (with yes and

175            maybe yes, and maybe no and no responses, combined according to polarity), compared

176            to adults without any neurodevelopmental diagnosis, but will not show this same

177            disparity between accuracy and confidence on a core language task.

178    (2)    The number of less confident responses (maybe responses) on the

179    pragmatic language task, the score on the Intolerance of Uncertainty Scale, and self-

180    reported social communication difficulties will significantly intercorrelate across the full

181    sample.

## Methods

183    Methods and out analysis plan for this project were published as a registered report

184    (Wilson & Bishop, 2020b): https://peerj.com/articles/10398/. Ethical approval for this project

185    was granted on 30/03/2020 by the Medical Science Interdivisional Research Ethics Committee at

186    Oxford University (Ref: R68518/RE001). Scripts, data and example materials for this project are

187    available on the Open Science Framework here: https://osf.io/wk97s/. We are very happy to

188    share full materials for this study, but to protect the validity of the items for future uses, we ask

189    that researchers contact us to request a link to the full assessments. See further information on

190    requesting access by following the link above.

**Power calculation**

192    We determined power to detect the three-way interaction described in Hypothesis 1 using

193    simulations. We used data reported in Wilson and Bishop (2020c) to estimate the likely size of

194    fixed and random effects in the mixed model described in Data Analysis below. Using R package

195    simr (Green & MacLeod, 2016) we ran 1000 simulations with a sample size of 200 people (100

196    autistic, 100 non-autistic) and a significant three-way interaction was found in 9830 simulations,

197    indicating that power was over 98% to detect our effect of interest at an alpha level of .05.

198    Effectively, this allowed us to detect a significant difference where approximate Cohen's $d$

199    values in favour of the non-autistic group were 0.70 and 1.10 for the implicature accuracy and

200    confidence variables and 0.20 for the grammar variables, as suggested by our previous data.

201    Allowing for exclusion of up to 10% of participants during the outlier exclusion phase described

202    in Data Analysis, power remained very high (98% in a sample of 180). For hypothesis 2, a

203    sample of 200 was powered at over 99% to detect a correlation of .3.

204    **Participants**

205        We recruited individuals with autism, self-reported reading difficulties, and no

206    neurodevelopmental diagnosis. Based on the power calculation, we aimed to recruit 100 autistic

207    adults and 100 adults without a neurodevelopmental diagnosis in order to run the confirmatory

208    analysis. In addition, we set out to recruit 50 dyslexic adults as a clinical control group for

209    exploratory analysis. All participants met the following eligibility criteria: (i) age of 18 years or

210    over, (ii) native-level fluency in English, (iii) no history of acquired brain injury, (iv) no

211    significant uncorrected sensory impairment, and (v) access to a computer with internet and

212    audio.

213        Individuals were recruited into three groups defined by communication and

214    language/literacy problems. One group was recruited on the basis of a clinical diagnosis of

215    autism; participants needed to declare where, by whom and what label was used for their

216    diagnosis on the Study Questionnaire. For inclusion, the diagnosis must have been made in a

217    clinical service by appropriately trained individuals, such as clinical psychologists, psychiatrists

218    or developmental paediatricians. We recruited autistic individuals through Autistica, the research

219    network for families and individuals with autism, as well as support groups arranged privately

220 and by the National Autistic Society, and through social media. A second group included

221 individuals reporting dyslexia or specific reading difficulties. For inclusion in this group,

222 individuals needed to score below the clinical threshold of 6 on the Autism Spectrum Quotient

223 (AQ) and at 6 or above on the Reading Scale of the Adult Reading Questionnaire (ARQ); this

224 latter score translates to over 1.5 SDs above the mean in individuals not self-reporting dyslexia in

225 the original validation study (Snowling, Dawes, Nash, & Hulme, 2012). Individuals were

226 recruited through charitable organisations such as the British Dyslexia Association and social

227 media. Other neurodevelopmental diagnoses were not grounds for exclusion from these groups.

228 A third group had no neurodevelopmental diagnosis, and was recruited via the online participant

229 platform, Prolific (https://prolific.co). Individuals were excluded from this third group if they

230 scored above threshold on either the AQ or ARQ (i.e. 6 or above on either) or if they have ever

231 been diagnosed with: a global or specific learning disability, attention deficit hyperactivity

232 disorder, dyspraxia/developmental coordination disorder, a genetic variation (such as Down's

233 syndrome or Fragile-X) or a neurological condition (such as epilepsy).

234 **Procedure**

235 The study was presented online using Gorilla, the online platform for behavioural

236 experiments and surveys (https://gorilla.sc/). Individuals completed an online set of tasks and

237 questionnaires in one sitting at a time and place of their choosing. After providing informed

238 written consent to participate, individuals completed a Study Questionnaire (please see the OSF

239 link) on which they reported on demographics and any neurodevelopmental diagnoses. Then

240 they completed questionnaires/tasks in two sections. The first section included the experimental

241 tasks required for the hypothesis-testing, and the second included several brief measures for

242    characterising the sample. The two experimental tasks were randomized between participants,

243    and all other measures were administered in the order set out below.

244    **Measures**

245    *Section 1: Experimental tasks assessing ability and confidence with pragmatics and core*

246    *language*

247            **Implicature Comprehension Test-2 (ICT-2).** In this test of pragmatic language

248    comprehension, participants completed an adapted version of the Implicature Comprehension

249    Test (Wilson & Bishop, 2019). There was a sequence of 56 videos, each approximately 8 s long,

250    consisting of a conversational adjacency pair between two characters: the first character asked a

251    closed question (eliciting a "yes" or "no" answer) and the second character produced a short

252    answer but did not say yes or no.  Each utterance was between 5 and 10 words in length and

253    grammatically simple, and age of acquisition of the words did not exceed middle primary school

254    level. Following the dialogue, the participant heard a comprehension question directly based on

255    the structure of the first character's question. The participant answered the question on a 4-point

256    scale (yes, maybe yes, maybe no, no) by clicking buttons arranged horizontally on the screen.

257    This was a timed task, with a time limit of 10 s for a response from the offset of the question.

258    There were two item types: implicature and explicit-response. Utterance length and

259    psycholinguistic variables (word frequency, word age-of-acquisition and word concreteness)

260    were controlled across the two item types.

261            For 40 videos, the second character's answer was indirect, and the participant needed to

262    process implicature to answer the comprehension question appropriately. Example:

263    Character 1: Did you hear what the police said?

264    Character 2: There were lots of trains going past.

265    Comprehension Question: Did he hear what the police said?

266    Answer: No

267    Half of the comprehension questions were correctly answered by "yes" and half by "no".

268    There were two measured variables: total accuracy (collapsing yes and maybe yes, and maybe no

269    and no responses, according to polarity) out of 40 and total confidence (number of yes and no

270    responses, regardless of polarity) out of 40.

271    Alongside the implicature items, there were 16 explicit-response items where the second

272    character's answer is more explicit. In these items, the speaker intended to convey uncertainty

273    explicitly, whereas in the implicature items, the uncertainty was in the mind of the listener.

274    Example:

275    Character 1: Will we get there by seven?

276    Character 2: Mmm, yes maybe, I think we're near.

277    Comprehension Question: Will they get there by seven?

278    Answer: Maybe yes

279    For these items, the comprehension questions encouraged the participant to use the full

280    scale, with four questions each correctly answered by "yes", "maybe yes", "maybe no" and "no".

281    There was one measured variable: total accuracy out of 16.

282    **Grammaticality Decision Test (GDT; based on Wilson & Bishop, 2019).** In this test of

283    core language ability, participants listened to a sequence of 50 sentences and decided if the

284    sentence was grammatical and well-formed or not. Half the sentences were grammatical.

285 Grammatical violations represented mistakes that native speakers would not tend to make, such

286 as using an incorrect verb form (e.g. I went out after I have eaten dinner) or atypical placing of

287 adverbs (e.g. If you can't find it, I can send again the letter). Participants were asked whether the

288 sentences were grammatical, indicating "yes", "maybe yes", "maybe no" and "no" as their

289 answer by clicking buttons arranged horizontally on the screen, as in the ICT-2. After offset of

290 the sentence, participants had 10 seconds to give their response.

291 ***Section 2: Questionnaires and tasks for characterising the sample***

292 **Autism Spectrum Quotient-10 (AQ-10; Allison, Auyeung, & Baron-Cohen, 2012).**

293 Autistic traits were measured using this 10-item version of the Autism Spectrum Quotient (AQ).

294 In the original validation study, the measure had 85% correct discrimination between almost 450

295 autistic adults and over 800 control adults. The National Institute for Health and Care Excellence

296 (NICE, 2012) recommend use of the questionnaire for identifying individuals for comprehensive

297 autism assessment. A clinical cut-off of 6 or more is taken as indicating possible autism.

298 **Communication Checklist Self-Report (CC-SR; Bishop, Whitehouse & Sharp, 2009).**

299 This is a norm-referenced questionnaire measuring self-reported communication challenges.

300 Participants were presented with the pragmatic language scale (22 items). For each item,

301 participants identified how frequently certain communication behaviours apply to them on a 4-

302 point scale from "less than once a week (or never)" to "several times a day (or all the time)". An

303 example item is "People tell me that I ask the same question over and over". The authors had

304 permission to use this instrument from the copyright holders.

305 **Adult Reading Questionnaire (ARQ) Reading Scale (Snowling, Dawes, Nashe, &**

306 **Hulme, 2012).** Self-reported reading difficulties were measured using this 5-item questionnaire.

307    In the original validation study, it showed good construct validity (correlating with observed

308    literacy ability at -.67) and, along with self-reported dyslexia status, discriminated with 88%

309    accuracy in identifying those with weaker literacy skills.

310          **International Cognitive Ability Resource (ICAR) Sample Test (Condon & Revelle,**

311    **2014).** This is an open-access test of general cognitive ability, which requires participants to

312    complete 16 items across four item types: matrix reasoning, verbal reasoning, three-dimensional

313    rotation, and letter-number sequences. In the original validation study, the ICAR sample test had

314    good internal consistency (alpha = .81), and good convergent validity (correlating at

315    approximately .8 with commercial IQ measures when correcting for reliability and restriction of

316    range; Condon & Revelle, 2014; Young & Keith, 2020).

317          **Synonyms Test (Wilson, & Bishop, 2019).** General verbal ability was measured using

318    this 25-item test of vocabulary knowledge. Participants selected which of five written words is

319    synonymous with a target word, under a 12-second time limit. The original version of the GDT

320    and this task showed a moderate correlation in both autistic and non-autistic samples, suggesting

321    they are overlapping measures of core language ability (Wilson & Bishop, 2019, 2020a).

322          **Intolerance of Uncertainty Scale (IUS-12; Carleton, Norton, & Asmundson, 2007).** In

323    this self-report measure of intolerance of uncertainty, participants were presented with 12

324    statements about uncertainty, ambiguous situations, and the future. They rated how closely each

325    statement relates to them on a 5-point scale from "not at all characteristic of me" to "entirely

326    characteristic of me". An example item is "When I am uncertain, I can't function very well."

327    **A Priori Data Analysis Plan**

328    Individuals were excluded from the dataset if they had an outlying score for either (a)

329    accuracy on the GDT or the positive control items of the ICT-2, or (b) total number of timeouts

330    across the ICT-2 and GDT. Outliers were defined according to the method of Hoaglin and

331    Iglewicz (1987): more than 2.2 times the interquartile range below the first quartile. In previous

332    work, these criteria led to exclusion of approximately 5% of participants, and captured

333    individuals scoring below approximately 50% on the GDT and 70% on the positive control items

334    of the original version of the ICT (Wilson & Bishop, 2020a).

335    Data were analysed in R (R Core Team, 2019). After exclusions, total scores on the two

336    experimental tasks for the groups with autism and no neurodevelopmental diagnosis were turned

337    into long format, and each participant's total was dummy-coded for task (ICT-2 or GDT), group

338    (autistic or no neurodevelopmental diagnosis), response (accuracy or confidence) and participant.

339    We ran a mixed effects linear regression using the lme4 R package (Bates, Maechler, Bolker, &

340    Walker, 2015). The model included three fixed effects (task, group and response) and the

341    interactions between these, as well as a random effect (participant). The significance level of the

342    three-way interaction offered a test of Hypothesis 1. We also computed correlations between

343    confidence on the ICT-2, self-reported communication challenges on the CC-SR and total score

344    on IUS-12 across the full sample; this tested Hypothesis 2 and represented a dimensional

345    analysis of the relationship between communication difficulties and sensitivity to uncertainty.

346    Table 1 shows a summary of our planned analyses, linking research questions, hypotheses, tests

347    and power calculations.

348    In exploratory analysis, we examined how the group with self-reported reading

349    difficulties compared to the autistic group and the group without a neurodevelopmental diagnosis

350    on the ICT-2 and GDT in terms of accuracy and confidence.

351                                               **Results**

352         Data existed for 320 participants. 18 of these individuals did not report an autism

353     diagnosis/identify as autistic but had an elevated score on the AQ-10 (6 or above); they were

354     excluded from the analysis as planned. In addition, 34 individuals identified as autistic but were

355     not formally diagnosed. Our a priori analysis plan focused only on those with a formal diagnosis,

356     so these individuals were also excluded from the hypothesis-testing set out below. Next, we

357     excluded individuals with outlying scores on the control items of the ICT-2 or accuracy on the

358     GDT. This included 10 people in total (3.73% of the remaining sample): 2 people with an autism

359     diagnosis, 3 people self-reporting reading difficulties and 5 control participants. This left us with

360     a final dataset of 260 people: 102 in Group 1 (individuals with a clinical diagnosis of autism), 49

361     in Group 2 (individuals with self-reported reading difficulties/dyslexia) and 109 in Group 3

362     (control group of individuals drawn from the general population). Please see Table 2 for

363     demographic information and Table 3 for descriptive statistics for these groups.

364     **Testing Hypothesis 1**

365         For this hypothesis, we focused on performance on our two key language tests (the ICT-2

366     and GDT) when comparing Groups 1 and 3 (our autistic and control groups). Please see Table 4

367     which shows effect sizes (Cohen's *d*) for group differences on the four variables drawn from

368     these tests. We can see that there were significant differences on the pragmatic language test

369     (ICT-2) but not the core language test (GDT), with the autistic group showing somewhat lower

370     scores on the ICT-2 but not the GDT. We checked whether these differences on the ICT-2

371     remained when controlling for gender. We included Group (autistic vs control) and Gender

372     (female vs not female) as factors in a two-way ANOVA for each variable extracted from the

373  ICT-2. There remained a significant effect of Group for both accuracy, $F$ (1, 208) = 8.05, $p$ =

374  .005, partial $\eta^2$ = 0.04, and confidence, $F$ (1, 208) = 9.37, $p$ = .003, partial $\eta^2$ = 0.05, whereas

375  Gender did not have a significant effect for either variable.

376      We hypothesised that the autistic group would show lower confidence on the pragmatic

377  language test, controlling for their accuracy on the test and their performance on the core

378  language test. We ran a mixed model with three fixed effects for Group (autistic vs control),

379  Task (ICT-2 vs GDT), and Response (Accuracy vs Confidence) to test this hypothesis. The

380  three-way interaction was not significant, $p$ =.235, indicating that the hypothesis was not

381  supported. As we can see from the effect sizes in Table 4, there is no evidence that the autistic

382  group showed substantially lower confidence on the ICT-2 in relation to accuracy on the test. In

383  fact, the autistic group gave responses on the ICT-2 that were both somewhat less accurate and

384  less confident. They were in line with the control sample in their performance on the core

385  language test (the GDT). See plots in Figure 1 which show all data for each variable extracted

386  from these tests.

387      In addition to this pre-registered analysis, we also looked at performance of the group

388  with self-reported reading difficulties compared to the control group on the two tests. Overall,

389  this group seemed closely comparable to the control group. The only variable extracted from the

390  ICT-2 and GDT that showed a significant difference was Accuracy on the GDT, i.e. grammatical

391  ability. The group with self-reported reading difficulties had significantly lower scores, $t$

392  (116.16) = 2.24, $p$ = 0.027, $d$ = -0.35.

393  **Testing Hypothesis 2**

394    Please see Table 5 for correlations between variables taken from the ICT-2 and GDT and

395    self-reported communication difficulties on the pragmatic scale of the CC-SR and intolerance of

396    uncertainty as measured by the IUS-12. We hypothesised that confidence on the ICT-2 and

397    scores on the CC-SR and IUS-12 would significantly inter-correlate across the sample. This was

398    the case, $p < .001$. Interestingly, accuracy on the ICT-2 showed similar correlations with these

399    variables too, $p < .001$.

...

400                                        **Discussion**

401            We set out to replicate our previous research that found evidence for a specific difficulty

402     with inferring implied meaning in conversation among autistic people (Wilson & Bishop,

403     2020c). As expected, autistic people were more likely than non-autistic people to give less

404     confident and non-normative (or "inaccurate") responses on the Implicature Comprehension

405     Test, suggesting that neurotypical and autistic people form inferences in conversation in different

406     ways. This was in the context of no significant differences in performance on a grammar test

407     presented in a similar format. Our findings therefore support the view that comprehension of

408     non-literal, implied language can be a specific area of difficulty in autism even where core

409     language skills, such as grammar and vocabulary skills, develop typically (Andres-Roqueta &

410     Katsos, 2017; Baron-Cohen, 1988). Likewise, our findings support the body of literature about

411     comprehension of figurative language and nonliteral language. Although it has been suggested

412     that differences between autistic and non-autistic people on this may be attributable to core

413     language skills (Kalandadze et al., 2018), two meta-analyses have found differences between

414     autistic and non-autistic people in understanding metaphor, proverbs and idioms, even when

415     matching participants on verbal ability (Morsanyi et al., 2020; Morsanyi & Stamenkovic, 2021).

416     This supports the idea that factors other than language skills are involved in the challenges

417     experienced by autistic people in processing nonliteral language, for instance the need to

418     integrate multiple sources of information (Vulchanova et al., 2015).

419            However, it is important to note that the effect size on the Implicature Comprehension

420     Test was relatively small. In absolute terms, the average autistic person only gave a non-

421     normative response one or two more times than the average non-autistic person. A few people

422     were particularly likely to respond "inaccurately" (as shown by the long tail in the distribution

423     for accuracy in the autistic group) but they do not represent the average person. This suggests

424     that autistic people are not so much characterised by an "impairment" in understanding implied

425     meaning, but may on occasion process it in such a way that leads to an incorrect response. Other

426     studies have found that although autistic people may frequently provide accurate responses when

427     processing metaphors, verbal analogies and inferences, they may nonetheless show increased

428     processing time and demonstrate different strategies (Micai et al., 2017; Morsanyi et al., 2021). It

429     is plausible that these processing differences may impact on task accuracy depending, for

430     instance, on whether the response format of the task is more complex. Consistent with this,

431     Morsanyi et al. (2020) found that autistic people obtained lower scores on metaphor

432     comprehension tasks when a verbal response requiring metalinguistic understanding was

433     required rather than a nonverbal response.

434        In addition, we did not find the substantial difference in confidence that we expected. We

435     hypothesised that pragmatic difficulties would be driven by much reduced confidence in

436     processing implied meaning, whereas accuracy would only be somewhat reduced. This

437     hypothesis was influenced by our previous study that found that autistic people gave "don't

438     know" responses when asked about the presence of an implied meaning much more frequently

439     than non-autistic people (Wilson & Bishop, 2020c). In the present study, we aimed to optimise

440     the response format so we could measure accuracy and confidence at the same time. However,

441     this response format gave only a modest difference in confidence between groups. In both

442     groups, the average person only gave a confident response to half the items. While the autistic

443     group reported somewhat lower confidence in interpreting implied meaning overall, it was

444     common for both groups to report uncertainty, perhaps because implicature intrinsically is

445     uncertain and statements could mean different things in different contexts. In addition, there was

446    considerable variability in confidence ratings across both groups. This suggests that people

447    generally vary in how sensitive they are to uncertainty in conversation and/or how prepared they

448    are to report feeling uncertain.

449        Our second hypothesis linked reduced confidence on the ICT-2 to IU and self-reported

450    communication difficulties on the CC-SR. There were significant correlations (at around the 0.3

451    level) between these variables, supporting the hypothesis. It seems that if an individual feels

452    uncomfortable with uncertainty, they are more likely to report general communication troubles

453    (as measured by the CC-SR questionnaire) and also more likely to have difficulties with making

454    inferences in conversation. Previous studies have linked IU to various characteristics of autism,

455    including social difficulties, sensory sensitivities, insistence on sameness and repetitive

456    behaviours (Hwang et al., 2020; Vasa et al., 2018; Wigham et al., 2015). This study extends

457    these findings to link IU to communication and pragmatic language difficulties as well. Notably,

458    IU related to both accuracy and confidence on the ICT-2. This suggests that discomfort with

459    uncertainty impacts not only the subjective experience of interpreting uncertain information in

460    conversation (i.e. confidence) but also the outcome of pragmatic processing (i.e. whether the

461    person arrives at the normative interpretation). In addition to IU, it is also worth noting that the

462    ICT-2 variables did correlate with self-reported communication difficulties (on the CC-SR),

463    suggesting that reduced accuracy and confidence the ICT-2 does relate in a meaningful way to

464    real-life communication difficulties.

465        As part of our study, we recruited a group of adults reporting reading difficulties. This

466    group performed similarly to the control group on the Implicature Comprehension Test,

467    suggesting that both groups processed inferences in conversation similarly. On the grammar test,

468    there was a subtle difference in terms of accuracy. The group with reading difficulties seemed

469 less sensitive to grammaticality compared to the control group, although both groups responded

470 to the test with a similar degree of confidence. In this sense, the group with self-reported reading

471 difficulties demonstrated an inverse pattern to the autistic group. While the autistic group showed

472 some cognitive differences in their processing of implied meaning in conversation and showed

473 intact grammatical awareness, the group with self-reported reading difficulties showed some

474 difficulties with grammar (i.e. an aspect of core language processing) but no differences in

475 pragmatic processing.

476       There are a couple of issues to bear in mind when interpreting this study. The two key

477 tests used in this study were both meta-linguistic in nature. In the ICT-2, participants were

478 responding to comprehension questions about an exchange as a third party, rather than directly

479 responding to implicatures directed at them. It is unclear whether the same skills are required for

480 both these activities. It should be noted that ICT-2 scores did correlate with scores on the

481 pragmatic scale of the CC-SR, which suggests that the ICT-2 does pick up problems relevant to

482 day-to-day conversation. The GDT was also meta-linguistic in nature, as participants needed to

483 make grammatical judgements about stimuli. Again, this test may be assessing skills somewhat

484 distinct from those required in comprehension and production of grammatical speech in day-to-

485 day contexts. The advantage of using a meta-linguistic task to measure grammatical ability in

486 this study was that it was closely matched to the ICT-2 in terms of its response format and task

487 demands. This meant that we could be reasonably confident in inferring that reduced

488 performance on the ICT-2 compared to the GDT was due to some issue with processing non-

489 literal, implied language.

490       In addition, there were possible limitations with the sample recruited in this study. As it

491 was fully online, we could not validate the clinical presentation of the autistic group and relied

492   on self-report. In addition, the autistic sample was not representative of the autistic population at

493   large. Whereas autism is diagnosed approximately three times more often in males, over half our

494   sample was female. However, gender did not affect performance on the ICT-2, so the gender

495   balance in the sample may not be a significant issue. In addition, participants often had advanced

496   education, with almost three-quarters of autistic adults either having or studying for a degree.

497   This is not representative of the broader autistic population, which includes many individuals

498   with co-occurring learning difficulties/disabilities. The pattern of results reported in this study

499   may not apply to individuals with learning difficulties/disabilities, who may be more likely to

500   have general challenges with using and understanding language rather than a specific difficulty

501   with pragmatics.

502         In this registered report, we tested whether the communication difficulties in autism are

503   linked to problems in forming confident, normative inferences during conversation. Our results

504   supported this hypothesis, as autistic adults showed some subtle differences in performance on

505   the Implicature Comprehension Test. We did hypothesise that reduced *confidence* in making

506   inferences would be the key differentiator between autistic and non-autistic people. However,

507   this was not the case, as *both* accuracy and confidence were moderately reduced on the

508   Implicature Comprehension Test. Autistic people did not differ from non-autistic people in terms

509   of their confidence or accuracy on a grammar test, indicating that differences were specific to

510   inference-making rather than a more general language difficulty. By contrast, a dyslexic group

511   showed reduced accuracy on the grammar test, but did not differ from the control group in terms

512   of their inference-making, demonstrating a reverse pattern to the autistic group. Lastly, we found

513   that individuals who reported discomfort with uncertainty were less likely to make confident,

514   normative inferences in conversation and more likely to report more day-day communication

515   difficulties. This adds to the wealth of literature around IU and autism, by demonstrating that

516   discomfort with uncertainty also plays a role in pragmatic language and communication

517   challenges in autism.

Table 1. Planned analyses.

1    Table 1. Planned Analyses.

| Research Question | Hypothesis | Statistical Analysis | Power Analysis |
|---|---|---|---|
| Do autistic people show reduced confidence in understanding implied meanings in conversation? | Autistic adults will score lower on the Implicature Comprehension Test-2 when responses are coded in terms of confidence (number of yes and no responses, regardless of polarity) than when responses are coded in terms of accuracy (with yes and maybe yes, and maybe no and no responses, combined according to polarity), compared to adults without any neurodevelopmental diagnosis, but will not show this same disparity between accuracy and confidence on the Grammaticality Decision Test. | A mixed model will be run including the following effects: task (Implicature Comprehension Test-2 or Grammaticality Decision Test), group (autistic or no neurodevelopmental diagnosis), and response (confidence or accuracy) as fixed effects; the interactions between these fixed effects; and participant as a random effect. The significance level of the three-way interaction will offer a test of the hypothesis. | A sample of 200 people is powered at over 98% to detect the three-way interaction. |
| Do individual differences in confidence in interpreting meaning, intolerance of uncertainty and self-rated communication difficulties inter-correlate? | The number of less confident responses (maybe responses) on the Implicature Comprehension Test-2, the score on the Intolerance of Uncertainty Scale, and self-reported social communication difficulties on the CC-SR will significantly intercorrelate across the full sample. | Pearson's correlations will be computed to quantify the relationships between these three variables across the whole sample. | A sample of 200 people is powered at over 99% to detect correlations of .3. |

Table 2. Demographic information.

Table 2.

*Demographic Information.*

|  | Group 1, Autistic (N=102) | | Group 2, Reading Difficulties (N=49) | | Group 3, Control (N=109) | |
|---|---|---|---|---|---|---|
|  | N | | N | | N | |
| Women | 52 | | 33 | | 79 | |
| Men | 43 | | 15 | | 30 | |
