

## **Metacarpal torsion in apes, humans, and *Australopithecus*: implications for manipulatory abilities**

Michelle SM Drapeau

Human hands, when compared to that of apes, have a series of adaptations to facilitate manipulation. Numerous studies have shown that *Australopithecus afarensis* and *A. africanus* display some of these adaptations, such as a longer thumb relative to the other fingers, asymmetric heads on the second and fifth metacarpals, and orientation of the second metacarpal joints with the trapezium and capitate away from the sagittal plane, while lacking others such as a mobile fifth metacarpal, a styloid process on the third, and a flatter metacarpo-trapezium articulation, suggesting some adaptation to manipulation but more limited than in humans. This paper explores variation in metacarpal torsion, a trait said to enhance manipulation in humans and apes, as well as in early australopithecines and specimens from Swartkrans. This study shows that humans are different from large apes in torsion of the first, third and fourth metacarpals. Humans are also characterized by wedge-shaped bases of the third and fourth metacarpals, making the metacarpal-base row very arched mediolaterally and placing the ulnar-most metacarpals in a position that facilitate opposition to the thumb in power or cradle grips. The third and fourth metacarpals of *A. afarensis* are very human-like, suggesting that the medial palm was already well adapted for these kinds of grips in that taxon. *A. africanus* present a more intermediate morphology between humans and apes, suggesting a less derived morphology for manipulation in that taxa.

5 Abstract

6 Human hands, when compared to that of apes, have a series of adaptations to facilitate  
7 manipulation. Numerous studies have shown that *Australopithecus afarensis* and *A. africanus*  
8 display some of these adaptations, such as a longer thumb relative to the other fingers,  
9 asymmetric heads on the second and fifth metacarpals, and orientation of the second metacarpal  
10 joints with the trapezium and capitate away from the sagittal plane, while lacking others such as a  
11 mobile fifth metacarpal, a styloid process on the third, and a flatter metacarpo-trapezium  
12 articulation, suggesting some adaptation to manipulation but more limited than in humans. This  
13 paper explores variation in metacarpal torsion, a trait said to enhance manipulation in humans and  
14 apes, as well as in early australopithecines and specimens from Swartkrans. This study shows that  
15 humans are different from large apes in torsion of the first, third and fourth metacarpals. Humans  
16 are also characterized by wedge-shaped bases of the third and fourth metacarpals, making the  
17 metacarpal-base row very arched mediolaterally and placing the ulnar-most metacarpals in a  
18 position that facilitate opposition to the thumb in power or cradle grips. The third and fourth  
19 metacarpals of *A. afarensis* are very human-like, suggesting that the medial palm was already  
20 well adapted for these kinds of grips in that taxon. *A. africanus* present a more intermediate  
21 morphology between humans and apes, suggesting a less derived morphology for manipulation in  
22 that taxa.

## 34 **Introduction**

35 Much of the debate on *Australopithecus* has focused on its locomotor habits and the maintenance  
36 (or not) of an arboreal component. However, manipulatory capabilities in that taxon have also  
37 been argued (e.g., Marzke, 1983, 1997; Susman, 1998; Drapeau, 2012; Skinner et al., 2015).  
38 Marzke (1997, 2005) identified three traits that suggest that the hand of one of the oldest  
39 *Australopithecus* species, *A. afarensis* was modified for better precision grips and handling: a  
40 longer thumb relative to the other fingers, asymmetric heads on the second and fifth metacarpals,  
41 and orientation of the second metacarpal (MC) joints with the trapezium and capitate away from  
42 the sagittal plane. However, Susman (1998) doubts that they indicate significant improvement of  
43 manipulatory skills. Interestingly, they both recognize that the radial torsion of the second and  
44 third MC heads improves manipulatory grips (Susman, 1979; Marzke and Shackley, 1986;  
45 Marzke 1997, 2005), although neither recognizes that trait in *Australopithecus*. Torsion of the  
46 second and third MC head in humans is a trait that is described qualitatively, but has not been  
47 extensively quantified (except in humans; Singh, 1979; Peters and Koebke, 1990) and rarely  
48 statistically compared among humans and great apes (Drapeau, 2009). This paper explores MC  
49 head torsion in these extant species and compares values for *A. afarensis*, *A. africanus* and  
50 Swartkrans specimens.

51

## 52 **Background**

53 Humans and apes have different power grips. Humans hold objects obliquely in the cupped palm,  
54 positioning the thumb in opposition to the other fingers. The fifth digit is the most flexed and the  
55 subsequent lateral fingers, digit 4 to 2, are progressively less flexed (Lewis, 1977, 1989;  
56 Kapandji, 2005). The two ulnar-most MCs are also slightly flexed at the carpometacarpal joint. In

57 addition, the palmar surfaces of the fingers are supinated, i.e., turned toward the thumb. Apes,  
58 instead, flex digits 2 to 5 in a hook-like fashion, with no obvious differences in degree of flexion  
59 among the fingers and no apparent flexion at the carpometacarpal joint (Lewis, 1977, 1989).

60  
61 However, the hand is not used solely for powerful gripping, but is important for fine  
62 manipulation as well, particularly in humans. In precision grips, the thumb is opposed to the other  
63 fingers and objects are often held with the finger pads or palmar surface of the fingers (Napier,  
64 1956). Depending on the size of the object held, the position of the ulnar digits varies. When  
65 manipulating small objects in a pad-to-pad grip, only the second or second and third digits are  
66 opposed to the thumb (Napier, 1956; Marzke and Shackley, 1986). In that position, the second  
67 and third digits are supinated. However, as the size of the object held increases or if the grip  
68 involves the palmar surface of the digits rather than the pads, the third and particularly the second  
69 digit tend to take a more pronated position (Napier, 1956). In addition, the fourth and fifth digits  
70 become involved and take a supinated position (Marzke and Shackley, 1986).

71  
72 Apes are much less dexterous than humans in manipulation (Napier, 1960) and have much more  
73 difficulty in pad-to-pad grips. This is in part a consequence of their relatively long fingers and  
74 short thumbs. They are able to handle small objects between the thumb and the side of the  
75 phalanges of the index (Napier, 1960). This particular grip does not require marked rotation of  
76 the second digit. In contrast to humans, the morphology of the ape hand is most likely strongly  
77 driven by locomotor constraints. All great apes are characterized by a hook grip, which involves  
78 flexing all the fingers in sagittal planes (Lewis, 1977, 1989; Napier, 1993), a position that is  
79 remains the same when using the hand in terrestrial locomotion.

80  
81 Morphological adaptations to the different grips observed in humans can be seen in their hands.  
82 First, as mentioned above, digits 2-5 are much shorter relative to the thumb in humans than in  
83 apes. Also, the bases of the second and fifth MCs have been modified to allow for some axial  
84 motion. The base of the second MC has a saddle shape rather than the wedge shape observed in  
85 apes and its base has a continuous articulation with the capitate instead of an articulation that is  
86 bisected in anterior and posterior segments by carpometacarpal ligaments as found in all extant  
87 apes (Lewis, 1973, 1977, 1989; Marzke, 1983; Tocheri et al., 2008; Drapeau, 2012). That  
88 articulation and the articulation between the second and third MCs are curved instead of being  
89 flat as in apes (Lewis, 1973, 1977, 1989; Marzke, 1983; Tocheri et al., 2008; Drapeau, 2012).  
90 Finally, the second MC-trapezium articulation lies in a more transverse plane instead of the  
91 sagittal plane found in apes (Marzke, 1983; Drapeau et al., 2005; Tocheri et al., 2008). Similarly,  
92 the base of the human fifth MC is saddle shaped with a dorsoventral convexity. This morphology,  
93 combined with a retraction of the hook of the hamate, allows for flexion and supination of the  
94 MC (Dubousset, 1981; Marzke, 1983; Lewis, 1989; Buffi et al., 2013). In great apes, the ventral  
95 surface of the base articulates with the hook of the hamate, limiting flexion and axial rotation.  
96  
97 The head shape of MCs 2 and 5 are also modified to allow rotation of the fingers. The MC2 head  
98 has a distal articular surface whose palmo-radial corner projects more proximally (Lewis, 1989;  
99 Drapeau, 2012). In palmar view, the head is slanted radially (Lewis, 1989; Drapeau, 2012). This  
100 morphology, combined with the collateral ligaments, causes the proximal phalanx to deviate  
101 radially and to pronated when flexed (See Lewis, 1989 for details). The extended finger tends to  
102 be supinated when ulnarly deviated and pronated when radially deviated or flexed. The

103 morphology of the third MC head also present some asymmetry, but to a lesser degree than the  
104 second and the rotation and axial deviation of the phalanx are also less marked than in the second  
105 (Lewis, 1989). The morphology of the fifth MC head is the mirror image of the second, causing  
106 movements in opposite directions relative to the second MC (Lewis, 1989). This particular  
107 morphology of the head, combined with the morphology of the base, allows for axial rotation of  
108 the second and fifth fingers and MCs. In contrast, the ape MCs do not have such asymmetrical  
109 heads and movement at these joints function much more as simple hinges (Lewis, 1989; Drapeau,  
110 2012). The human first MC allows for a greater range of thumb opposition because the base has a  
111 less projecting palmar beak than what is seen in chimpanzees and the articulation is flatter in the  
112 dorso-palmar direction (Marzke, 1992; Tocheri et al., 2003). The morphology of the head, with a  
113 palmar elevation radially, allows for some pronation and abduction of the distal segments of the  
114 thumb during flexion, but it is a morphology that appears to be primitive in hominoids (Lewis,  
115 1989).

116  
117 Australopithecines have acquired some of the traits associated with manipulation in humans. For  
118 example, *A. afarensis* is characterized by a continuous and curved MC2-capitate articulation that  
119 is more transversely oriented than in apes, but less than in humans (Marzke, 1983; Drapeau et al.,  
120 2005), a MC2-trapezium facet that is more palmarly oriented than in chimpanzees (Marzke,  
121 1983; Drapeau et al., 2005), asymmetric MC2 and MC3 heads (Lewis, 1977; Susman, 1979;  
122 Marzke, 1997; Drapeau, 2012), and relatively long thumbs (Alba et al., 2003; but see Rolian and  
123 Gordon, 2013 for opposing view), traits that are also found in *A. africanus* (Green and Gordon,  
124 2008; Tocheri et al., 2008; Drapeau, pers. obs.). These traits suggest an adaptation to 3-finger  
125 chuck. However, a volar beak on the MC1 probably limited opposition of the thumb (Marzke,

126 1992) and limited flexion and supination of the MC5 imply that the fossils could not produce  
127 human-like power and cradle grips with a cupped palm (Marzke, 1983).

128  
129 In this study, I contrast MC head torsion in human and great apes to show how it reflects the  
130 differences in grips between these taxa. I also compare *A. afarensis*, *A. africanus* and specimens  
131 from Swartkrans to extant species to evaluate their morphological affinities and possibly identify  
132 additional traits related to manipulation in the fossil specimens.

133  
134 In hominoids, the bases of the MCs are disposed in a mediolateral arch configuration (Fig. 1),  
135 with the concave, palmar side housing the carpal tunnel (although much of the walls of the tunnel  
136 are the result of the projecting hook of the hamate and of the position of the trapezium usually  
137 disposed at an angle from the other distal carpal bones; see Lewis, 1989). Sarmiento (1994) noted  
138 that the radius of curvature of this arch varies among taxa, but did not measure it. Metacarpals are  
139 expected to present torsion values that adjust for the degree of arching. As a result, the ulnar-most  
140 digits will tend to have heads that are more ulnarly twisted, while the radial-most digits (except  
141 the thumb) will tend to have heads that are more radially twisted.

142  
143 More specifically, humans, because of the types of grips described above, are expected to have,  
144 on average, MC 2 to 5 heads that are more radially twisted than apes. However, variation in  
145 arching of the MC row is expected to influence the twisting of the MCs. For example, ulnar digits  
146 may not present as much torsional difference as the more radial digits in a hand that would have  
147 greater arching. In addition, because the base and head morphologies of the second and fifth MCs  
148 of humans allows for axial rotation of the digit to conform to various object sizes and shapes,

149 torsion of these two MCs may not be as different from apes as for the other digits. In humans, the  
150 trapezoid is wider palmarly than that of apes, which pushes the trapezium radially and rotates it  
151 into alignment relative to the rest of the proximal carpal row (Tuttle, 1970; Lewis, 1977, 1989;  
152 Sarmiento, 1994; Drapeau et al., 2005; Tocheri et al., 2005). As a result, the trapezio-MC  
153 articulation lies within an axis comparable to that of the other digits. Therefore, a greater torsion  
154 of the first MC in humans is expected in order to bring the metacarpo-phalangeal joint in an axis  
155 perpendicular to that of the other digits. Apes, particularly chimpanzees, having the base of the  
156 first MC already perpendicularly rotated relative to the other carpo-metacarpal joints, are not  
157 expected to require as much torsion of the first MC to function in opposition to the other digits or  
158 to the palm.

159

## 160 **Materials**

161 The human sample is from archaeological collections and it consists of a mix of euroamericans  
162 from the 19<sup>th</sup> century and of Canadian Amerinds (Table 1). All extant great apes are wild shot and  
163 the *Gorilla* sample includes only western lowland gorillas. All specimens are free of pathologies.  
164 Sample size varies from one MC to the other in function of the availability of each bone in the  
165 osteological collection (Table 2).

166

167 The hominin fossils included in this analysis are all from Hadar, Ethiopia, and from Sterkfontein  
168 and Swartkrans, South Africa (Table 3). Specimens from Hadar are all attributed to *A. afarensis*  
169 (Bush et al., 1982; Drapeau et al., 2005) and date at 3.2 Ma for A.L. 333 and 3 Ma for A.L. 438  
170 (Kimbel, Rak & Johanson, 2004). Although some have argued that there might be more than one  
171 species represented at Sterkfontein (e.g., Clarke, 2013), all four Sterkfontein specimens included

172 are from Member 4 and are assumed to belong to *A. africanus* base on the general morphology,  
173 size and provenience (McHenry and Berger, 1998), and date between 2.6 and 2 Ma (Herries et  
174 al., 2013). At Swartkrans, *Paranthropus robustus* and early *Homo* are present and post-cranial  
175 specimens are difficult to assign to either of these taxa with certainty. SK 84 is from Member 1  
176 and attributed to *Homo* (Susman, 1994, 2004), SKW 2954 is from member 2 and is described as  
177 being human-like (Susman, 2004), and SKW 14147 is not assigned to a member or to a specific  
178 taxa (Day and Scheuer, 1973). Member 1 is dated between 2.2 and 1.8 Ma and Member 2  
179 between 1.8 and 1 Ma (Gibbon et al., 2014). Only specimens that are complete and undistorted  
180 are included in the analysis.

181

## 182 **Methods**

183 Using a Microscribe 3DX portable digitizer with a precision of 0.23 mm, palmodorsal axes of the  
184 base and head of MCs one through five were recorded to measure head torsion. It was the axis of  
185 the whole head that was recorded, irrespective of the asymmetry of the articular surface (Fig.  
186 2A). For the MC2, the palmodorsal axis of the base was determined as the margin of the articular  
187 surface with the capitate, and for the MC3, it was determined as the margin of the articular  
188 surface with the second MC (Fig. 2C). The three-dimensional points were realigned with the  
189 software GRF-ND (Dennis E. Slice, 1992-1994) so that x, y, and z values varied in the  
190 dorsoplantar, proximodistal and radioulnar anatomical axes respectively. The angle between the  
191 lines defining the orientation of the head and of the base in the transverse plane represents the  
192 angle of torsion of the MCs. Values presented are for the left hand, but if the measure was not  
193 available for one specimen, values from the right were reversed. Positive values represent heads  
194 with their palmar side that are twisted ulnarly relative to the base (away from the thumb),

195 negative values represent heads twisted radially (turned towards the thumb), and a value of zero  
196 indicates no torsion relative to the base. In order to estimate the shape of the arch made by the  
197 base of the MCs when articulated together, the wedging of the base was measured. It was  
198 calculated as the ratio of dorsal width relative to the palmar width of the bases of the MC3 and  
199 MC4, the two 'central' bones of the arch composed of the four ulnar MCs.

200  
201 Intraobserver error in angle measurement was estimated with three specimens: *Homo*, *Pan*, and  
202 *Pongo*. All five MCs for each specimen were digitized 10 times over a two-day period. Each  
203 metatarsal was digitized five times the first day. The second day, the metatarsals were  
204 repositioned and recorded another 5 times. The mean interval of confidence of measurement is  $\pm$   
205  $1.6^\circ$  and the average range  $8.3^\circ$  (varied from  $2.4^\circ$  to  $15.4^\circ$ ). The error was, on average, about  
206 twice as high on the pollical MC compared to the others (mean pollical standard error  $2.5^\circ$  vs.  
207  $1.3^\circ$  for the other MCs; mean pollical range  $13.5^\circ$  vs.  $7.0^\circ$  for all other MCs). This error for the  
208 first MC is probably due to the fairly round profile of the base (Fig. 2C), which makes the  
209 definition of the dorsopalmar axis more difficult to define accurately.

210  
211 Species are compared with one-way ANOVA and *Post hoc* multiple comparisons with  
212 Bonferroni adjustments when variances are homogeneous among groups and Tamhane T2 tests  
213 when heterogeneous. Angles are reversed in right MC fossils for direct comparisons with extant  
214 taxa.

215

216

217

218 **Results (Tables 4 & 5)**

219

220 For the MC1, *Homo* and *Pongo* have heads whose palmar surfaces are the most turned towards  
221 the other fingers, while *Pan* has the head that is the least turned towards the other fingers.

222 Gorillas are intermediate between these two groups. *Australopithecus afarensis* (n=1) is most  
223 similar to *Gorilla* but within the range of all taxa and outside the range of only humans.

224 *Australopithecus africanus* (n=1) and the Swartkrans specimen (SK 84) are most similar to  
225 *Gorilla*, but within the range of all species (Fig. 3A).

226

227 For the MC2, as expected, all species are similarly radially turned towards the thumb except for  
228 *Pongo* that has a significantly more turned MC than the other taxa. *Australopithecus afarensis*  
229 (n=2) is variable and does not resemble one taxon in particular. *Australopithecus africanus* (n=1)  
230 is within the distribution of all taxa, but most similar to African apes (Fig. 3B).

231

232 For the MC3, humans have the heads that are the most supinated and are statistically different,  
233 while all apes are not significantly different from each other. *Australopithecus afarensis* (n=2) is  
234 most similar to humans, while *A. africanus* is within the range of all taxa, but most similar to  
235 apes (Fig. 3C).

236

237 For the MC4, again, humans are different from all apes, which form a fairly uniform group. Apes  
238 have relatively untwisted heads, while humans have fourth MCs that have heads that are more  
239 pronated. The *A. afarensis* specimen is most similar to humans while within the distribution of all  
240 taxa. The Swartkrans specimen (SKW 2954) is most similar to apes but within the distribution of

241 humans (Fig. 3D). Although it has no evidence of a healed fracture, Susman (2004) suggested  
242 that this specimen, because of an uncharacteristically AP curved diaphysis and the presence of a  
243 'crook', may have been broken. If so, the torsion value for that specimen may be distorted and  
244 not reflect a normal morphology.

245  
246 Finally, for the MC5, apes and humans have pronated heads (turned away from the thumb)  
247 although humans have more twisted head than *Pan*, while all other taxa do not differ statistically.  
248 *Australopithecus afarensis* (n=3) is variable, but on average, resemble *Pan* and *Pongo* the most,  
249 as does the one Swartkrans specimen (SKW 14147; Fig. 3E).

250  
251 In base shape, humans are characterized by MC3 and MC4 that have pinched bases palmarly,  
252 while apes have bases that are relatively wider palmarly (Tables 6, 7 & 8, Fig. 4). Among apes,  
253 gorillas have a MC4 base that is intermediate in shape between that of humans and chimpanzees,  
254 while their MC3 base is similar to that of the other ape taxa. *Australopithecus afarensis* (n=5) are  
255 characterized by a human-like, pinched MC3 base, while *A. africanus* (n=2) and one specimen  
256 from Swartkrans are characterized by a base that is intermediate between that of apes and humans  
257 (while not being very different from three *A. afarensis* specimens). The MC4 bases are more ape-  
258 like for all fossils, although *A. afarensis* still falls closest to the median of humans.

259

## 260 **Discussion**

261 The results for the first MC are as expected for humans with a head twisted toward the other  
262 fingers, probably in part to compensate for the reorientation of the trapezium in that species (Fig.  
263 5; Lewis, 1977, 1989; Sarmiento, 1994; Tocheri et al., 2005). As discussed above, the wider

264 palmar aspect of the trapezoid, likely related to the palmar extension of its articulation with the  
265 capitate, results in a trapezium in the human hand that is pushed radially and rotated into  
266 alignment relative to the rest of the proximal carpal row (Lewis, 1977, 1989; Sarmiento, 1994;  
267 Drapeau et al., 2005; Tocheri et al., 2005). This reorientation of the trapezium positions the MC1  
268 articular facet in a position that is more along the radioulnar axis of the other MC bases, in a  
269 position that is less advantageous for MC1 opposability. The strongly twisted head of the human  
270 MC1 reflect that species' particular carpal morphology. The results for *Pongo* are intriguing  
271 given that it does not have developed thenar muscles (Tuttle, 1969) nor particularly large first  
272 MC articular surfaces on the trapezium (Tocheri et al., 2005). That species is the most variable  
273 (Fig. 3A) and that variation may reflect less stabilizing selection for a specific morphology in that  
274 species. It is noteworthy that the strong inversion of the thumb and strong eversion of the second  
275 digit of *Pongo* (Fig. 6) is reminiscent of their value of metatarsal (MT) torsion (Drapeau and  
276 Harmon, 2013). Their MC1-2 and MT1-2 morphology might reflect the importance of a strong  
277 opposing thumb- or hallux-to-palm grip in this highly arboreal taxa (Drapeau and Harmon,  
278 2013). The torsion of the *Australopithecus* and Swartkrans MC1 specimens is similar to apes and  
279 probably reflects the lack of a human-like expansion of the palmar surface of the trapezoid and  
280 the lack of a human-like load distribution on the palmar surface (as suggested by Tocheri et al.,  
281 2008). The Swartkrans specimen (SK 84) is, of all the fossils, the specimen that most closely  
282 approaches the human form and falls within the range of distribution of humans. However, given  
283 its intermediate morphology, this study cannot resolve its taxonomical affinity (see Trinkaus and  
284 Long, 1990; Susman, 1994).

285

286 For the MC2, there is no clear difference among species, extant or fossil. Previously observed  
287 torsion in humans relative to apes, as noted by Susman (1979) may have been an observation of  
288 the asymmetrical shape of the articular surface of the head. The lack of difference in torsion  
289 between dexterous humans and apes does not necessarily signify that the second finger of  
290 humans is used similarly to that of apes. In humans, depending on the grip used and the size of  
291 the object manipulated, the second finger may need to be either ulnarly or radially rotated. Unlike  
292 apes, humans are characterized by an asymmetrical MC2 head (Lewis, 1989), which allows the  
293 finger to axially rotate at the metacarpophalangeal joint. It is therefore possibly more  
294 advantageous to have a head that is only slightly twisted radially, which leaves flexibility to  
295 achieve different degrees of finger rotation for different types of grips. In addition, the human  
296 second MC is capable of some axial rotation while that of apes is much less mobile (Lewis,  
297 1989). Changes in both proximal and distal articular architecture in humans provide rotational  
298 flexibility of the finger necessary for a variation in effective grips. Interestingly, the base and  
299 head morphology of *Australopithecus* is clearly derived toward the human-like configuration  
300 (Marzke, 1983, 1997; Marzke and Shackley, 1986; Drapeau et al., 2005; Tocheri et al., 2008;  
301 Kivell et al., 2011; Drapeau, 2012), which suggest human-like digit rotational capacities for these  
302 species.

303  
304 The difference between humans and apes in torsion for the MC3 was expected and observed  
305 previously by Susman (1979). In apes, the torsion required to bring the head back into alignment  
306 with the other MC heads is minimal. Among apes, knuckle-walkers have the less twisted heads,  
307 which may reflect the habitual use of the hand in terrestrial locomotion, which loads heavily the  
308 third digit (Inouye, 1994). In humans, torsion is required in the power and precision grips.

309 However, unlike the MC2, the third MC base does not allow axial rotation and the head is only  
310 slightly asymmetric compared to the second. As a consequence, the third MC head needs to be  
311 more supinated to allow for proper positioning of the finger during power and precision grips.

312

313 The relatively untwisted MC4 of African apes is not surprising. As for the third MC, these apes  
314 load that digit while knuckle walking (Inouye, 1994), which may favor a digit that flexes and  
315 extends closely to a parasagittal plane. Against expectations, the human MC4 is more pronated  
316 than that of apes. In humans, the fourth finger has an important role in buttressing (Susman,  
317 1979). When buttressing, the fourth digit is flexed in the palm and ulnar torsion may help  
318 position the digit more appropriately. In the left hand, the predominant loading force may be the  
319 buttressing function rather than manipulation. Alternatively, it could be related to the degree of  
320 curvature of the metacarpal-base arch. Our measure of base wedging (Tables 6, 7 and 8; Fig. 4)  
321 have shown that humans have more palmarly wedged MC bases and therefore have a more  
322 arched MC base row than other extant large apes (Fig. 5). The dorsopalmar axis of the MC4 base  
323 is therefore more twisted towards the thumb in humans than in other large apes when in  
324 articulation with the other MCs and carpals. Because of the base orientation, the less radially  
325 twisted head of the MC4 in humans does not necessarily indicate that the whole digit is less  
326 radially twisted towards the thumb (Fig. 5). Further study of the orientation of the hand bones *in*  
327 *vivo* in humans and apes will be needed to measure the actual degree of opposition of the MC and  
328 digits.

329

330 The lack of difference in torsion of the MC5 among humans, gorillas, and orangutans, which all  
331 have ulnarly twisted heads, also requires explanation. In humans, the articular surface of the MC5

332 head is also asymmetrical (Lewis, 1977, 1989; Marzke, 1997), being somewhat a mirror image of  
333 the MC2. As a consequence, the digit is rotated towards the thumb during flexion, which is the  
334 natural position taken by the finger during power grips and some precision grips (Napier, 1956).  
335 Also, the MC itself is free to rotate slightly in humans though not in apes. These mechanisms  
336 may be sufficient during power grips and five-finger holds to produce a rotated digit without the  
337 need of the whole hand to be twisted. Also, if the MC-base row is more arched than in apes, as it  
338 is suggested above, the fifth MC base is rotated radially relative to the thumb (Fig. 5). A  
339 moderate ulnar torsion still leaves the fifth MC head in a radially facing position.

340  
341 *Australopithecus afarensis* has MC3 and MC4 that are clearly more similar to humans, which  
342 suggest use of the hand in the fossil species that resembles humans more than apes. Similarly,  
343 their third and fourth MCs are wedge-shaped most like humans. The morphology of *A. africanus*  
344 is less clearly similar to one species. Although torsion values are within the range of humans,  
345 they are more typical of apes and their MC bases are not as wedged as humans. Together, these  
346 traits suggests that it may have been less adept at the pad-to-pad three-jaw chuck grasp relative to  
347 humans and *A. afarensis*, even though it probably had relative finger lengths comparable to *A.*  
348 *afarensis* (Green and Gordon, 2008; Rolian and Gordon, 2013). Overall, the *A. afarensis*  
349 morphology is human-like, while that of *A. africanus* is less clearly derived towards the human  
350 form, suggesting that the medial palm was less derived toward the human condition than *A.*  
351 *afarensis*.

352  
353 In contrast, the morphology of *A. afarensis* fifth MC suggests, on average a morphology that is  
354 more *Pan*-like, with untwisted heads. Also, the morphology of the base in that species suggests

355 less mobility in flexion and supination at that joint than in humans (Marzke, 1983; Marzke and  
356 Shackley, 1986; Marzke, Wullstein & Viegras, 1992). However, as for the second, the head is  
357 asymmetric (Bush et al., 1982; Marzke, 1997; Drapeau, 2012). This mosaic of ape and human  
358 traits in the fossils species indicates a transitional state, in which the human-like involvement of  
359 the fifth finger in manipulation might be limited to the phalangeal segment of the digit. This  
360 sequence of evolutionary events (involvement of the phalanges first, then followed by the  
361 mobility of the MC) may have been similar in the second digit, but occurred earlier in a form  
362 ancestral to *A. afarensis*, a hypothesis that can be tested with the discovery of slightly older  
363 fossils that would preserve the MC2 head.

364  
365 The curved MC base arch of humans orients the ulnar MC bases with their palmar surface toward  
366 the thumb. As a consequence, when the fifth and, to a lesser degree, fourth MC are flexed in  
367 humans, it produces the typically human cupping of the palm that is used in power grips of large  
368 objects (Peters and Koebke, 1990). The greater arching of the MC bases might then be an  
369 adaptation of such movement in humans and pronation of the MC4 head is only a consequence of  
370 the reoriented base. If so, this would indicate that *A. afarensis*, with its wedged bases, has begun  
371 the reorientation of the medial aspect of the palm of the hand despite probably not being able to  
372 flex the MC4 and MC5 like humans (Marzke, Wullstein & Viegras, 1992). Combined with the  
373 asymmetry of the fifth MC head, *A. afarensis* was probably capable of a power and cradle grips  
374 that were not completely human but approached it significantly.

375  
376 The torsion of Swartkrans MCs can be characterized, as a whole, as being more ape-like than  
377 human-like. However, of all the three Swartkrans specimens available for analysis, the MC4 is

378 the only one that is clearly ape-like by being more radially twisted. This morphology is rather  
379 surprising (if it is not due to a healed fracture), considering that the MC3 base tends to be pinched  
380 suggesting a fairly deeply arched MC-base row. As a whole, the Swartkrans specimens do not  
381 suggest human-like adaptations to manipulation although some traits, such as moderate base  
382 wedging, does point toward some adaptations for that behavior.

383

### 384 **Conclusions**

385 Metacarpal head torsion is different between humans and apes, particularly in the first, third and  
386 fourth MCs. For the MC2 and MC5, articular morphology, including head asymmetry, may be  
387 better indicator of human-like manipulation and rotational capacity of the digits. Differences in  
388 head torsion among species are broadly as expected, except for the fourth and fifth MCs that are  
389 generally less radially twisted in humans. These unexpected results for the ulnar part of the hand  
390 might relate to the how the MC bases are positioned relative to each other and to the degree of  
391 curvature of the proximal metacarpal arch, a curvature that is greater in humans than in apes.  
392 Further work needs to document the *in vivo* MC torsion when in anatomical articulation.

393

394 An overall view of the *A. afarensis* and *A. africanus* MCs is consistent with previous analyses of  
395 the hand in these species. The lack of ulnar twist in the pollical MC suggest that these species  
396 were probably not characterized by a palmarly expanded trapezoid that positioned the trapezium  
397 in line with the rest of the carpals and allowed for load dissipation through the palmar aspect of  
398 the palm. These fossil species likely had a primitive configuration similar to apes with a  
399 trapezium positioned more perpendicular to the rest of the distal carpal row. Previous studies had  
400 shown that the second MC of *Australopithecus* was modified from the assumed primitive

401 morphology, with a base and head allowing for some axial torsion of the digit, but the third  
402 lacked the human-like styloid process, suggesting only a partial transition towards a human-like  
403 grip. This study has shown that the human-like orientation of the third and fourth fingers was  
404 achieved in *A. afarensis*, indicating the possibility of adequate three- or four-jaw chucks in these  
405 species (although possibly with less ulnar deviation of the thumb than in humans; Marzke, 1992).  
406 More ulnarly, there is little evidence of a human-like grip, but for the asymmetry of the fifth MC  
407 head that allow for phalangeal axial rotation, suggesting that active involvement of the fifth digit  
408 in a five-jaw chuck was probably limited to the phalanges. However, the shape of the MC3 and  
409 MC4 bases suggest a configuration of the MC bases that was human-like in *A. afarensis*,  
410 allowing for more opposition of the fifth MC than is possible in large apes. As a consequence,  
411 although *A. afarensis* has not developed a completely human grip, it showed significant derived  
412 traits that suggest that there was directional selection for improved dexterity and strength in  
413 various grips in these early hominins. In contrast, *A. africanus* presents MC3 torsion more typical  
414 of apes, a MC3 base shape that is more intermediate between apes and humans, and a MC4 base  
415 that is more ape-like. This suggests that *A. africanus* may have been less dexterous in the three-  
416 jaw chuck than *A. afarensis* despite thumb-to-fingers proportions that were probably similar  
417 (Green and Gordon, 2008; Rolian and Gordon, 2013) and evidence of some human-like loading  
418 in the trabecular patterns of the base of the first and head of the second and third MCs (Skinner et  
419 al., 2015). The weakened human-like signal in the trabeculae of the MC4 (Skinner et al., 2015)  
420 concurs with this study's observation that *A. africanus* has a less derived hand ulnarly as reflected  
421 by base shapes that are more ape-like and keep the orientation of the palm and palmar surface of  
422 the digits oriented more anteriorly and less towards the thumb.  
423

424 Overall, this study supports previous studies on *A. afarensis* and *A. africanus* that these taxa had  
425 derived hand morphology that suggest increase finesse and strength in pad-to-pad, two- and  
426 three-jaw chucks grips and some adaptation to human-like power grips and support the  
427 hypothesis that tool making and use predated *Homo* (McPherron et al., 2010; Harmand et al.,  
428 2015).

## Figures

Figure 1: Metacarpal 2 to 5 of a left hand in distal view illustrating the arch formed by the metacarpal bases (modified from Peters and Koebke, 1990).

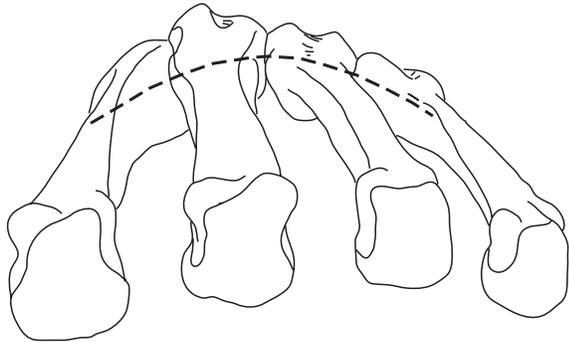

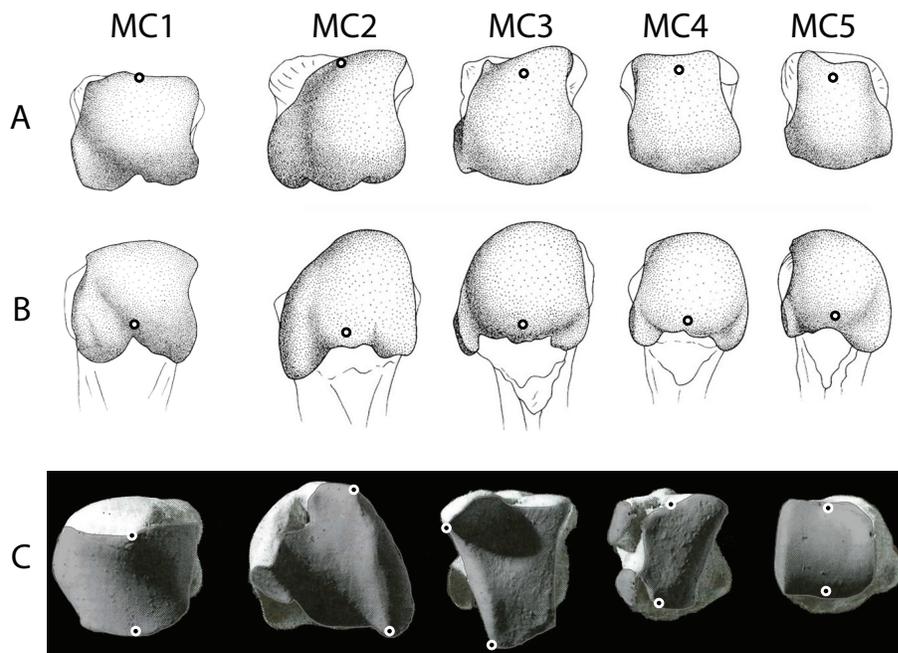

Figure 2: Distal (A) and palmar (B) view of human MC heads, and proximal view of the bases (C). The points show how the palmodorsal axis of the head and base were recorded with a 3D digitizer (see text for details). A, B are modified from Lewis, 1977, and C is modified from White and Folkens, 2000.

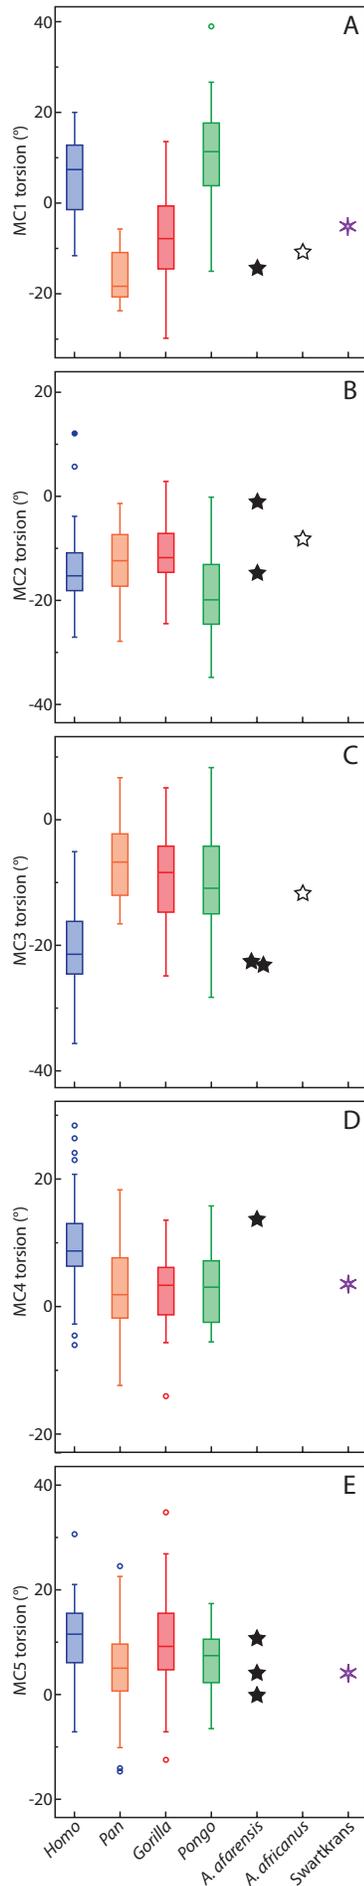

Figure 3: Boxplot of the torsion of MC 1 to 5. The box represent the 25-75 quartiles, the horizontal line the median, the whiskers the range, and open and close circles represent outliers and extreme outliers (more than 1.5 and 3.0 standard deviation from the mean).

Figure 4: Ratio of dorsal to palmar width of the base of MC3 and MC4. Higher ratios indicate a base that is more wedge-shaped, while a ratio of 1 indicates a base that is rectangular.

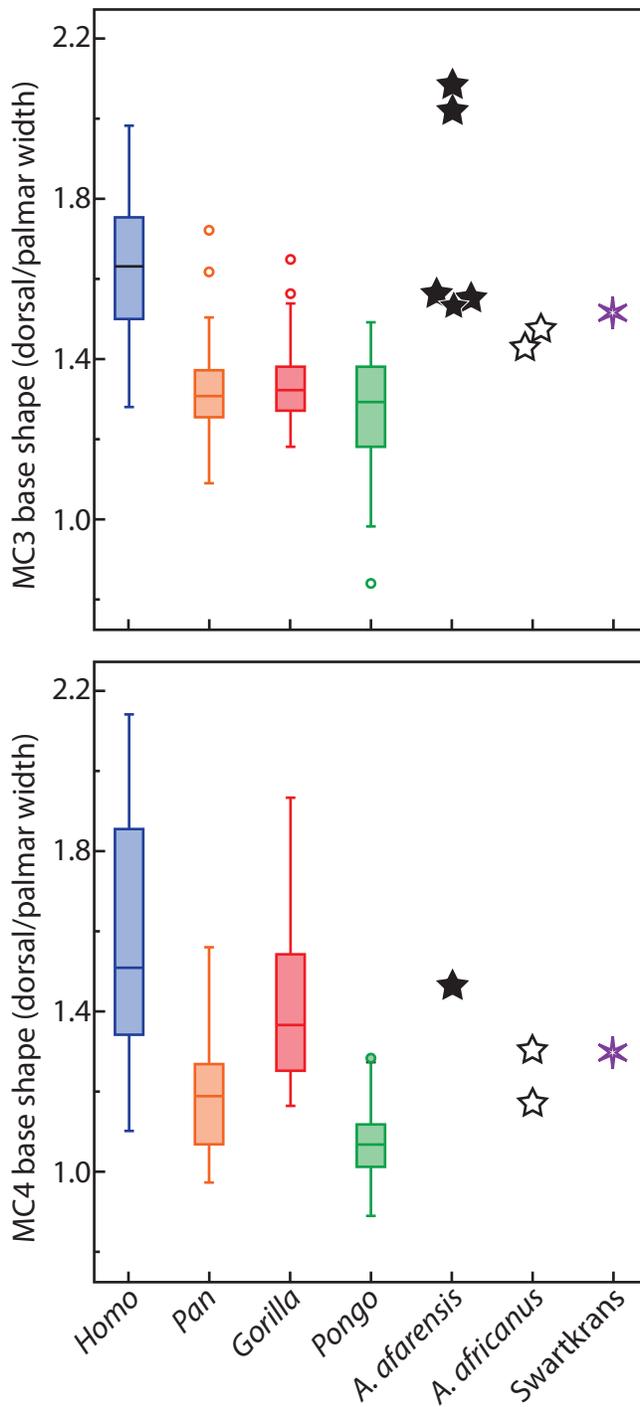

Figure 5: Metacarpal head (pale grey ovals) torsion relative to the base (dark grey quadrangles) in distal view of a left hand. The wedging of the MC3 and MC4 bases is drawn from result in Table 6. All drawings are aligned relative to the MC2-MC3 articulation. Relative orientation of the MC1 base (drawn for humans and chimpanzees only) is estimated from the orientation of the trapezio-MC articulation (from Fig. 20 in Sarmiento 1994). Because of the strong wedging of the MC3 and MC4 bases, the dorso-palmar axis of the bases of the ulnar-most MCs of humans are more turned toward the thumb than in other taxa.

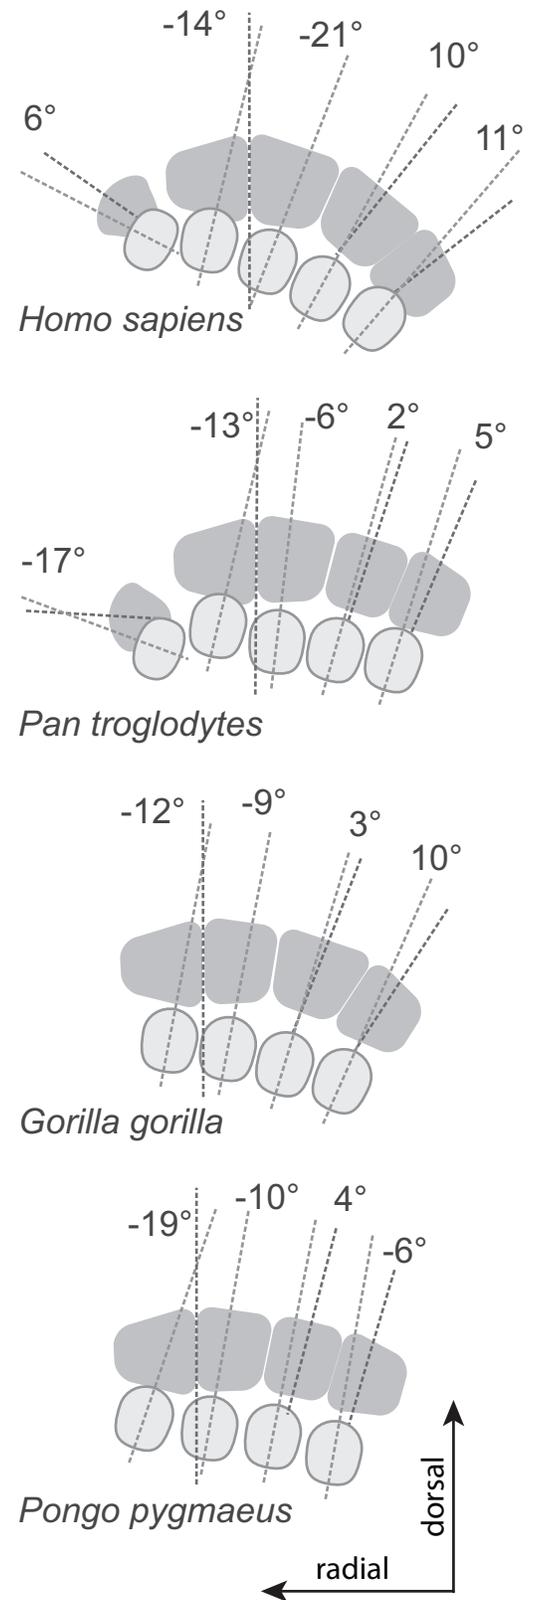

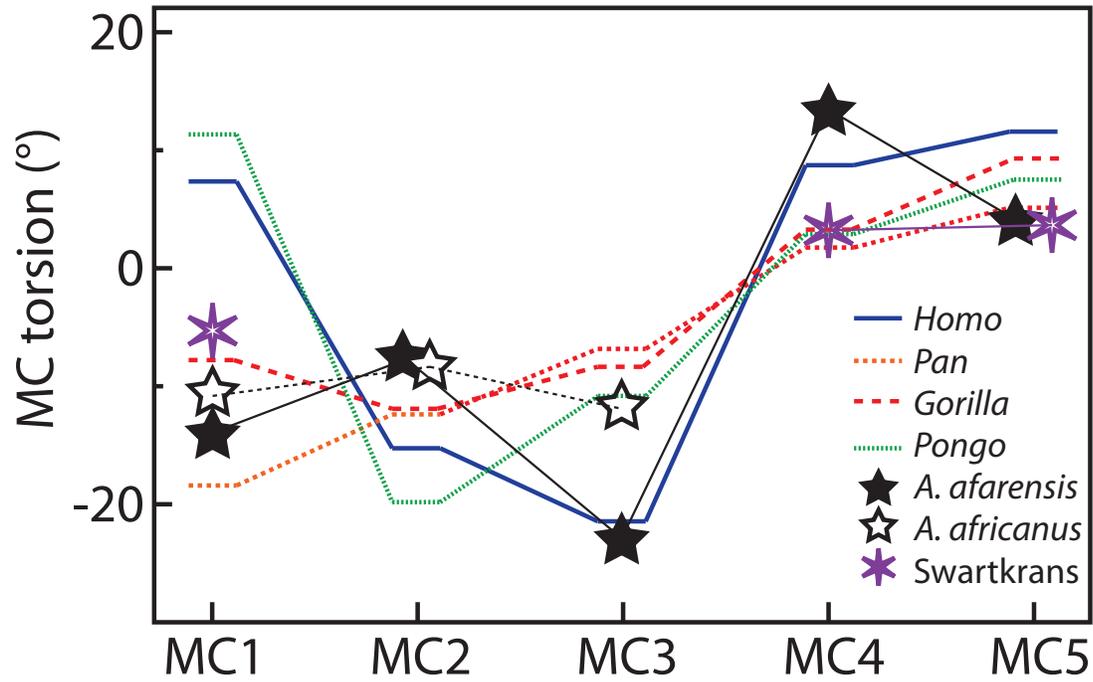

Figure 6: Patterns of torsion for all MCs (median values for samples of  $n > 1$ ).

## Tables

Table 1: Comparative sample.

Species	Male	Female	Indet.	Total
<i>Homo sapiens</i> (total)	20	11	17	48
Euroamericans	8	1	5	14
Amerinds	12	10	12	34
<i>Pan troglodytes</i>	16	25		41
<i>Gorilla gorilla</i>	27	20		47
<i>Pongo pygmaeus</i>	13	17		30

Table 2: Extent species descriptive statistics<sup>1</sup> for torsion angles<sup>2</sup>.

Taxon	MC1	MC2	MC3	MC4	MC5
<i>H. sapiens</i>	6.5	-14.0	-21.2	9.6	10.9
	8.1	7.2	6.8	7.6	7.0
	43	46	43	42	38
<i>P. troglodytes</i>	-16.7	-12.9	-6.5	2.4	5.5
	5.7	6.7	6.3	7.1	9.1
	27	39	40	40	39
<i>G. gorilla</i>	-7.9	-11.5	-9.4	2.7	10.1
	8.9	5.8	7.7	5.7	8.7
	39	42	44	44	44
<i>P. pygmaeus</i>	10.8	-18.6	-9.8	3.5	6.2
	10.6	8.8	8.2	6.4	6.0
	29	29	29	29	29

<sup>1</sup>The mean is presented on the first line, standard deviation on the second, and sample size on the third.

<sup>2</sup>In degrees.

Table 3: *Australopithecus afarensis*, *A. africanus* and Sterkfontein fossil sample and torsion values.

Fossil	Element	Side	Torsion angle
A.L. 333w-39	MC1	R	14.3
A.L. 333-48	MC2	L	-1.3
A.L. 438-1e	MC2	L	-15.0
A.L. 438-1f	MC2	R	17.5
A.L. 438-1d	MC3	L	-22.9
A.L. 333-16	MC3	L	-23.3
A.L. 333-56	MC4	L	13.3
A.L. 333-14	MC5	R	0.3
A.L. 333-89	MC5	L	10.5
A.L. 333-141	MC5	R	-4.0
Stw418	MC1	L	-10.8
Stw382	MC2	L	-8.5
Stw68	MC3	R	11.8
SK84	MC1	L	-5.2
SKW2954*	MC4	D	-3.5
SKW14147	MC5	L	4.0

\*possible healed fracture

Table 4: Results for the one way ANOVA comparing MC torsion.

Metacarpal	F	Significance
MC1	68.1	<0.001
MC2	6.0	0.001
MC3	33.8	<0.001
MC4	10.6	<0.001
MC5	4.4	0.005

Table 5: Post hoc comparison with Bonferroni adjustment<sup>1</sup> when comparing torsion.

Metacarpal	Taxa	<i>H. sapiens</i>	<i>P. troglodytes</i>	<i>G. gorilla</i>	<i>P. pygmaeus</i>
MC1	<i>Homo sapiens</i>		23.2	14.4	-4.3
	<i>Pan troglodytes</i>	<b>&lt;0.001</b>		-8.8	-27.5
	<i>Gorilla gorilla</i>	<b>&lt;0.001</b>	<b>&lt;0.001</b>		-18.7
	<i>Pongo pygmaeus</i>	0.2	<b>&lt;0.001</b>	<b>&lt;0.001</b>	
MC2	<i>Homo sapiens</i>		-1.1	-2.4	4.6
	<i>Pan troglodytes</i>	1		-1.3	5.7
	<i>Gorilla gorilla</i>	0.7	1		7.1
	<i>Pongo pygmaeus</i>	<b>0.04</b>	<b>0.007</b>	<b>&lt;0.001</b>	
MC3	<i>Homo sapiens</i>		-14.7	-11.7	-11.4
	<i>Pan troglodytes</i>	<b>&lt;0.001</b>		2.9	3.3
	<i>Gorilla gorilla</i>	<b>&lt;0.001</b>	0.4		0.3
	<i>Pongo pygmaeus</i>	<b>&lt;0.001</b>	0.4	1	
MC4	<i>Homo sapiens</i>		7.2	7.0	6.2
	<i>Pan troglodytes</i>	<b>&lt;0.001</b>		-0.2	-1.0
	<i>Gorilla gorilla</i>	<b>&lt;0.001</b>	1		-0.8
	<i>Pongo pygmaeus</i>	<b>0.001</b>	1	1	
MC5	<i>Homo sapiens</i>		5.4	0.8	4.7
	<i>Pan troglodytes</i>	<b>0.02</b>		-4.6	-0.7
	<i>Gorilla gorilla</i>	1	0.06		3.9
	<i>Pongo pygmaeus</i>	0.1	1	0.2	

<sup>1</sup>Values above the diagonal are mean differences (row - column), values below are significance of the test (values at 0.05 or less are in bold).

Table 6: Dorsal to palmar medio-lateral width ratio of the third and fourth MC (first line: mean; second line: standard deviation).

Taxa	MC3	MC4
<i>H. sapiens</i> (n=29)	1.62 0.18	1.58 0.30
<i>P. troglodytes</i> (n=36)	1.32 0.12	1.20 0.15
<i>G. g. gorilla</i> (n=36)	1.34 0.11	1.45 0.26
<i>P. pygmaeus</i> (n=37)	1.37 0.22	1.32 0.28
AL 333-16	1.55	
AL 333-65	1.53	
AL 333-153	1.56	
AL 333w-6	2.08	
AL 438-1	2.02	
AL 333-56		1.46
Stw64	1.43	
Stw68	1.46	
Stw65		1.17
Stw330		1.30
SKX 3646	1.52	
SKX 2954		1.30

Table 7: Tamhane T2 post-Hoc comparisons of the dorsal to palmar medio-lateral width ratio for the MC3 (p-values).

	<i>H. sapiens</i>	<i>P. troglodytes</i>	<i>G. g. gorilla</i>
<i>P. troglodytes</i>	<b>&lt;0.001</b>		
<i>G. g. gorilla</i>	<b>&lt;0.001</b>	0.94	
<i>P. pygmaeus</i>	<b>&lt;0.001</b>	0.58	0.14

Table 8: Table 2: Tamhane T2 post-Hoc comparisons of the dorsal to palmar medio-lateral width ratio for the MC4 (p-values).

	<i>H. sapiens</i>	<i>P. troglodytes</i>	<i>G. g. gorilla</i>
<i>P. troglodytes</i>	<b>&lt;0.001</b>		
<i>G. g. gorilla</i>	0.09	<b>&lt;0.001</b>	
<i>P. pygmaeus</i>	<b>&lt;0.001</b>	<b>0.001</b>	<b>&lt;0.001</b>
