Here we report a new articulated skeleton of *Yamaceratops dorngobiensis* (MPC-D 100/553) from the Khugenetjavkhlant locality at the Shine Us Khudag (Javkhlant Formation, ?Santonian-Campanian) of the eastern Gobi Desert, Mongolia, which represents the first substantially complete skeleton and the first juvenile individual of this taxon. The specimen includes a nearly complete cranium and large portions of the vertebral column and appendicular skeleton. Its skull is about 2/3 the size of the holotype specimen, based on mandibular length. Its juvenile ontogenetic stage is confirmed by multiple indicators of skeletal and morphological immaturity known in ceratopsians, such as the long-grained surface texture on the long bones, the smooth external surface on the postorbital, open neurocentral sutures of all caudal vertebrae, a large orbit relative to the postorbital and jugal, the low angle of the lacrimal ventral ramus relative to the maxillary teeth row, narrow frontal, and straight ventral edge of the dentary. Osteohistological analysis of MPC-D 100/553 recovered three lines of arrested growth, implying around three years of age when it died, and verifying the immature ontogenetic stage of this specimen. The specimen adds a new autapomorphy of *Yamaceratops*, the rostroventral margin of the fungiform dorsal end of the lacrimal being excluded from the antorbital fossa. Furthermore, it shows a unique combination of diagnostic features of some other basal neoceratopsians: the ventrally hooked rostral bone as in *Aquilops americanus* and very tall middle caudal neural spines about or more than four times as high as the centrum as in *Koreaceratops hwaseongensis*, *Montanoceratops cerorhynchus*, and *Protoceratops andrewsi*. The jugal with the subtemporal ramus deeper than the suborbital ramus as in the holotype specimen is also shared with *Liaoceratops yanzigouensis*, *A. americanus*, and juvenile *P. andrewsi*. Adding 36 new scorings into the recent comprehensive data matrix of basal Neoceratopsia and taking into account the ontogenetically variable characters

recovered *Y. dorngobiensis* as the sister taxon to the Leptoceratopsidae plus Coronosauria. A second phylogenetic analysis with another matrix for Ceratopsia also supported this position. The new phylogenetic position of *Y. dorngobiensis* is important in ceratopsian evolution, as this taxon represents one of the basalmost neoceratopsians with a broad, thin frill and hyper-elongated middle caudal neural spines while still being bipedal.

18 ## ABSTRACT

19 Here we report a new articulated skeleton of *Yamaceratops dorngobiensis* (MPC-D 100/553)
20 from the Khugenetjavkhlant locality at the Shine Us Khudag (Javkhlant Formation, ?Santonian-
21 Campanian) of the eastern Gobi Desert, Mongolia, which represents the first substantially
22 complete skeleton and the first juvenile individual of this taxon. The specimen includes a nearly
23 complete cranium and large portions of the vertebral column and appendicular skeleton. Its skull
24 is about 2/3 the size of the holotype specimen, based on mandibular length. Its juvenile
25 ontogenetic stage is confirmed by multiple indicators of skeletal and morphological immaturity
26 known in ceratopsians, such as the long-grained surface texture on the long bones, the smooth
27 external surface on the postorbital, open neurocentral sutures of all caudal vertebrae, a large orbit
28 relative to the postorbital and jugal, the low angle of the lacrimal ventral ramus relative to the
29 maxillary teeth row, narrow frontal, and straight ventral edge of the dentary. Osteohistological
30 analysis of MPC-D 100/553 recovered three lines of arrested growth, implying around three
31 years of age when it died, and verifying the immature ontogenetic stage of this specimen. The
32 specimen adds a new autapomorphy of *Yamaceratops*, the rostroventral margin of the fungiform
33 dorsal end of the lacrimal being excluded from the antorbital fossa. Furthermore, it shows a
34 unique combination of diagnostic features of some other basal neoceratopsians: the ventrally
35 hooked rostral bone as in *Aquilops americanus* and very tall middle caudal neural spines about or
36 more than four times as high as the centrum as in *Koreaceratops hwaseongensis*,
37 *Montanoceratops cerorhynchus*, and *Protoceratops andrewsi*. The jugal with the subtemporal
38 ramus deeper than the suborbital ramus as in the holotype specimen is also shared with
39 *Liaoceratops yanzigouensis*, *A. americanus*, and juvenile *P. andrewsi*. Adding 36 new scorings

40 into the recent comprehensive data matrix of basal Neoceratopsia and taking into account the
41 ontogenetically variable characters recovered *Y. dorngobiensis* as the sister taxon to the
42 Leptoceratopsidae plus Coronosauria. A second phylogenetic analysis with another matrix for
43 Ceratopsia also supported this position. The new phylogenetic position of *Y. dorngobiensis* is
44 important in ceratopsian evolution, as this taxon represents one of the basalmost neoceratopsians
45 with a broad, thin frill and hyper-elongated middle caudal neural spines while still being bipedal.
46

47 **INTRODUCTION**

48

49   Ceratopsian dinosaurs appeared in the Late Jurassic of Asia and flourished in the Late
50 Cretaceous of North America. In early evolutionary history, basal ceratopsians were small,
51 bipedal dinosaurs without much-elaborated structures (Xu et al., 2006; Han et al., 2016), but in
52 the Late Cretaceous ceratopsoids, they became quadrupedal giants with large horns and frills on
53 their heads (Sues and Averianov, 2009; Wolfe et al., 2010). Intermediate between the non-
54 neoceratopsian ceratopsians and ceratopsoids are the non-ceratopsoid neoceratopsians, referred
55 to as basal neoceratopsians (You and Dodson, 2004).
56   The earliest fossil record of ceratopsian dinosaurs appears to be two Jurassic taxa,
57 *Yinlong* and *Hualianceratops*, both from the Upper Jurassic (Oxfordian) Shishugou Formation
58 (Xu et al., 2006; Han et al., 2015; 2016). The transition from basalmost ceratopsians (represented
59 by *Yinlong*) to ceratopsids (represented by *Triceratops*) has encompassed many anatomical
60 innovations through the transformational and step-wise acquisition of unique traits. These
61 include bony structures such as the enlarged frill and horns related to display (Prieto-Márquez et
62 al., 2020), complex dental battery for food processing (Erickson et al., 2015), and even
63 neomorphic ossifications for keratinous coverings such as the rostral, epijugal, epinasal,
64 episquamosal, and epiparietal (Horner and Goodwin, 2008). Ceratopsian evolution is also
65 interesting in obtaining larger body size, bipedal to quadrupedal transition, and dispersal from
66 Asia to Laramidia, Europe, and Appalachia.
67   Among basal neoceratopsians is *Yamaceratops dorngobiensis* from the Upper Cretaceous
68 Javkhlant Formation of eastern Mongolia (Makovicky and Norell, 2006; Eberth et al., 2009).
69 Although represented by a holotype partial skull and referred disarticulated elements, the exact
70 osteology of *Yamaceratops* was not known yet due to the absence of articulated postcranial
71 skeletons. Thus, the phylogenetic relationships of *Yamaceratops* among basal neoceratopsians
72 have not been entirely solved since its initial description in 2006 (Makovicky and Norell, 2006;
73 Chinnery and Horner, 2007; Makovicky, 2010; Lee et al., 2011; Ryan et al., 2012; Farke et al.,
74 2014; He et al., 2015; Zheng et al., 2015; Han et al., 2018; Knapp et al., 2018; Morschhauser et
75 al., 2018c; Arbour and Evans, 2019; Yu et al., 2020).
76   *Yamaceratops* is the only known ceratopsian from the Javkhlant Formation at the
77 Dornogovi Province and its correlative strata at the Zos Canyon locality (Norell and Barta, 2016)
78 (Fig. 1A). Other ceratopsians from the Dornogovi Province of eastern Mongolia include the
79 "psittacosaurs" from the Dzun Shakhai locality (Watabe et al., 2010) and an indeterminate

80 leptoceratopsid (PIN 4046/11; formerly "*Udanoceratops*") from the Baga Tariach locality
81 (Tereshchenko, 2001; 2020) (Fig. 1B). A *Protoceratops* sp. specimen (MPC-D 100/517) from
82 the Shurg Uul locality is likely from the "Shurguul, Sevrei sum, Omnogovi province," instead of
83 Dornogovi Province (Tsogtbaatar et al., 2019; contra Czepiński, 2020). Some protoceratopsid
84 fossils were reported from the Baga Tariach locality (Watabe et al., 2010), but the specimens had
85 not been described yet.
86   Ontogeny and variation in a few basal neoceratopsian taxa have been extensively studied
87 since early in research history. It was made possible by discovering many well-preserved
88 specimens from Mongolia, as described by Brown and Schlaikjer (1940) for *Protoceratops*
89 *andrewsi* and by Maryańska and Osmólska (1975) for *Bagaceratops rozhdestvenskyi*. Despite
90 these studies, many other names have been proposed for specimens of these taxa of different
91 growth stages, especially for juvenile specimens, which were only recently reviewed and
92 synonymized (Makovicky and Norell, 2006; Czepiński, 2019; 2020).
93   Here we describe a new articulated skeleton of a small individual of *Yamaceratops*
94 *dorngobiensis* (MPC-D 100/553) discovered from the middle Javkhlant Formation (?Santonian-
95 Campanian) at Khugenetjavkhlant locality in 2014 (Fig. 2, 3). Khugenetjavkhlant is identical to
96 the misspelled 'Khugenslavkhant' (Eberth et al., 2009; Tanaka et al., 2019) and
97 'Khugenetslavkant' (Makovicky and Norell, 2006; Balanoff et al., 2008; Nesbitt et al., 2011;
98 Makovicky et al., 2011; Varricchio et al., 2015). This is the same locality where the holotype of
99 *Yamaceratops* was found. We found new diagnostic characters for this taxon and described its
100 articulated postcranial skeleton for the first time. We also examined the chronological age of
101 death of this specimen through histological analysis and reviewed the indicators of skeletal and
102 morphological maturity (Hone et al., 2014; 2016; Griffin et al., 2020). Comparing MPC-D
103 100/553 to the holotype and referred materials, the ontogenetically variable features of
104 *Yamaceratops* were investigated and compared with those in other well-sampled taxa. The well-
105 preserved postcranial anatomy of MPC-D 100/553 offers insight into basal ceratopsian
106 locomotion and evolution as well. We believe that the new osteological characters and inferred
107 patterns of ontogenetic variation in this study can help resolve the phylogenetic position of
108 *Yamaceratops* and understand the character evolution of basal neoceratopsians.
109
110 **MATERIALS & METHODS**
111
112 **Phylogenetic analysis**
113 A strict consensus tree was constructed based on the most recent iteration of the comprehensive
114 character matrix of Morschhauser et al. (2018c). The Morschhauser et al. (2018c) matrix had 41
115 taxa with all 257 characters ordered. Later, in the iteration of this matrix by Arbour and Evans
116 (2019), one additional taxon (*Ferrisaurus*) was added, and all characters were treated as
117 unordered, as we followed in this paper. We compared the ontogenetic variation in
118 *Yamaceratops* based on comparisons of the juvenile specimen (MPC-D 100/553) to adult one

119 (IGM 100/1315) with that of *Protoceratops andrewsi* (Brown and Schlaikjer, 1940) and found
120 generalized patterns. Therefore, we applied them to our analysis, assuming they were widespread
121 in basal neoceratopsians. From these observations, we found additional ontogenetic characters in
122 the Morschhauser et al. (2018c) matrix. They are character numbers 32 and 128, in addition to
123 the previously recognized 8, 53, 58, 59, 98, 162, 177 (Morschhauser et al., 2018c), totaling nine
124 out of 257 characters. Juvenile states in these ontogenetically variable characters were scored as
125 '?' in taxa represented solely by juvenile specimens (*Asiaceratops*, *Aquilops*, '*Graciliceratops*')
126 and *Yamaceratops* (MPC-D 100/553). Although the specimens of *Prenoceratops* were described
127 as immature (Chinnery, 2004b), they were not in the size or morphology that warranted caution,
128 and changing their scores to '?' did not change the resulting topology. The resulting revised
129 scoring of *Yamaceratops* is a total of 36 (character numbers 3, 5, 6, 10, 11, 17, 18, 19, 23, 26, 27,
130 28, 29, 31, 46, 49, 95, 103, 126, 127, 179, 195, 196, 198, 199, 201, 210, 211, 214, 218, 219, 221,
131 222, 228, 231, and 236). Additional changes to the scorings were: '[0 1 2]' to '1' for character
132 number 172, '0' to '1' for 178 in *Yamaceratops*, and '?' to '4' for 198 in *Protoceratops*
133 *andrewsi*. The matrix was analyzed in TNT version 1.5 as parsimony analysis using the
134 Traditional Search (Goloboff and Catalano, 2016). The search followed the method of
135 Morschhauser et al. (2018c) that was iterated in Arbour and Evans (2019), and the parameters
136 are as follows: MaxTrees of 10,000 trees; *Lesothosaurus* as an outgroup taxon; tree bisection
137 reconnection (TBR) swapping algorithm with 1,000 replications.
138

CT scanning

139
140 We made micro-CT scans by using Xradia 620 Versa (Carl Zeiss, USA) for the right jugal
141 (80kV, 127uA, pixel size 56.5881um) and right distal humerus (80kV, 126uA, pixel size
142 46.6794um), and by using Xradia 520 Versa (Carl Zeiss, USA) for the articulated skull (120kV,
143 84uA, pixel size 95.2099um). The images were segmented with Dragonfly (Object Research
144 Systems (ORS) Inc., Canada). The scanned images were used to confirm some morphology that
145 is indistinct from the surface of the specimen. Detailed analysis of the internal structure is
146 outside the scope of this paper and will not be discussed here.
147

Histological analysis

148
149 Photography, photogrammetry, and CT scanning of the humerus were conducted before the
150 sectioning. For histologic analysis, we chose associated humerus. Molding and casting were
151 made from the specimen for later research. The mid-shaft of the humerus was sampled for the
152 examination. The sample was prepared and transversely thin sectioned following Lamm (2013).
153 The slides were examined using Nikon Eclipse E600 POL petrographic polarizing microscope
154 with a lambda 530nm plate. The bone cross-section was photographed using a combination of
155 Nikon DS-Ri2 camera and NIS-Elements BR (ver. 4.13) software. Adobe Photoshop (ver. 21.2)
156 is utilized for image enhancement and tracing LAGs. Bone wall thickness and area of the
157 transverse section were quantified by Image J (ver. 1.53).
158

159 **RESULTS**
160
161 **Systematic paleontology**
162 Dinosauria Owen, 1842 (*sensu* Padian and May, 1993)
163 Ornithischia Seeley, 1887 (*sensu* Sereno, 1998)
164 Marginocephalia Sereno, 1986
165 Ceratopsia Marsh, 1890 (*sensu* Dodson, 1997)
166 Neoceratopsia Sereno, 1986
167 *Yamaceratops dorngobiensis* Makovicky and Norell, 2006
168
169 **Holotype.**   IGM 100/1315, an articulated skull from an adult that lacks the rostral,
170 premaxillae, nasals, the predentary, anterior process of the lacrimal, left elements around the
171 temporal region, left posterior mandible, and the parietal (Makovicky and Norell, 2006).
172
173 **Studied specimen.**   MPC-D 100/553, a nearly complete articulated skeleton with the left
174 proximal femur and partial foot, but no cervical vertebrae, pectoral girdles, left arm, right hand,
175 other parts of the left leg, and the right foot.
176
177 **Locality, horizon, and age.** Upper Cretaceous (?Santonian-Campanian) Javkhlant Formation,
178 Khugenetjavkhlant, Dornogovi Province, Mongolia.
179
180 **Emended diagnosis.** A neoceratopsian possessing the following autapomorphies: unkeeled
181 rostral bone ventrally hooked and posteriorly expanded; the anteroventral margin of the
182 fungiform anterior process of the lacrimal excluded from the antorbital fossa; jugal with its
183 subtemporal ramus deeper than the suborbital ramus with an angle in between at the ventral
184 edge. In addition, *Yamaceratops dorngobiensis* differs from other basal neoceratopsians by the
185 following unique set of shared characters: a ventrally hooked rostral bone as in *Aquilops*
186 *americanus*; a fungiform anterior process on the lacrimal as in *Auroraceratops rugosus*; a jugal
187 with a deeper subtemporal ramus than the suborbital ramus as in *Aquilops americanus*,
188 *Liaoceratops yanzigouensis*, and juvenile *Protoceratops andrewsi*; middle caudal neural spines
189 about or more than four times as high as the centrum as in *Koreaceratops hwaseongensis,*
190 *Montanoceratops cerorhynchus*, and *Protoceratops andrewsi*.
191
192 **Remarks.**   MPC-D 100/553 is identified as *Yamaceratops* based on the unique characters
193 shared with other *Yamaceratops* specimens (IGM 100/1303 and 100/1315), such as the unkeeled
194 and posteriorly expanded rostral bone, jugal with its subtemporal ramus deeper than the
195 suborbital ramus with an angle in between at the ventral edge, and two tubercles on the ventral
196 margin of the angular (Makovicky and Norell, 2006).
197   The lacrimal with a "fungiform expansion of the dorsal end" and a "concave rostroventral
198 margin due to limited participation in the floor of the antorbital fossa" was suggested to exist in

199   *Auroraceratops*, *Bagaceratops*, and *Liaoceratops* (Morschhauser et al., 2018c). However, the
200   expansion of the anterior ramus is not extensive in *Liaoceratops* (You et al., 2007) and the
201   ventral ramus participates in the medial wall of the antorbital fossa in *Bagaceratops* (Czepiński,
202   2019). The anterior ramus of the lacrimal is rectangular in *Beg tse* (Yu et al., 2020). Therefore,
203   the fungiform expansion of the anterior ramus of the lacrimal is only distinct in *Auroraceratops*
204   (You et al., 2005) and *Yamaceratops* (MPC-D 100/553). The lacrimal of MPC-D 100/553 differs
205   from *Auroraceratops* and all other basal neoceratopsians. The rostroventral margin of the
206   anterior ramus of the lacrimal neither participates in the floor nor the margin of the antorbital
207   fossa. For these reasons, this character is assigned as an autapomorphy of *Yamaceratops* herein.
208   The presence and number of angular tubercles are plesiomorphic for basal
209   neoceratopsians, although previously thought to be diagnostic for *Liaoceratops* (Xu et al., 2002)
210   and *Yamaceratops* (Makovicky and Norell, 2006). The numbers and position of the tubercles
211   vary among taxa. Three tubercles are present in *Liaoceratops* (Xu et al., 2002), and two tubercles
212   in *Mosaiceratops* are positioned more dorsally than in *Yamaceratops* (Zheng et al., 2015).
213   However, these are variable in *Auroraceratops*, with the holotype specimen bearing two
214   tubercles on the right angular and none on the left (Morschhauser et al., 2018a). Considering that
215   the tubercles are positioned in the area where the attachment of *M. pterygoideus ventralis* is
216   implied (Nabavizadeh, 2020), these tubercles may result from varying degrees of jaw muscle
217   development. In mammals, similar roughened tubercles are often muscle attachment sites (e.g.,
218   Clifford and Witmer, 2004). It is also worth noting that the surangular lateral ridge was
219   suggested as an attachment site of jaw adductor muscle for basal ceratopsians, including
220   *Psittacosaurus* and *Protoceratops* (Haas, 1955; Nabavizadeh, 2020). In *Psittacosaurus* species,
221   the dentary flange well-developed in adults has also been suggested as a site for adductor muscle
222   attachment (Sereno et al., 2010).
223   Although an embayment at the posterior base of the dorsal process of the jugal is present
224   on both the holotype (IGM 100/1315) and the new specimen of *Yamaceratops* (MPC-D
225   100/553), this is likely due to postmortem dorsoventral crushing of the skull resulting in the
226   breakage and displacement of the thin dorsal process of the jugal, judging from the micro-CT
227   images of the jugal in MPC-D 100/553. Another possible example of such displacement of the
228   jugal dorsal process due to crushing can be seen in *Aquilops* (Farke et al., 2014).
229
230   **Ontogenetic Assessment.**   An osteohistological analysis of the humerus indicates a minimum
231   of three years of chronological age for MPC-D 100/553. It is 2/3 the size of the *Yamaceratops*
232   holotype (IGM 100/1315) based on mandibular length (Makovicky and Norell, 2006). Some
233   indicators of skeletal immaturity seen in MPC-D 100/553 are long-grained surface texture on the
234   long bones (femur, tibia, fibula, humerus, ulna, and radius) (Tumarkin-Deratzian, 2009), the
235   smooth external surface on the postorbital (Brown and Schlaikjer, 1940), and open neurocentral
236   sutures of all caudal vertebrae (Hone et al., 2014).
237
238   **Description and comparisons**

239

240 **Preservation.** The MPC-D 100/553 specimen is nearly complete and articulated in a life-like
241 crouched position. It is dorsoventrally compressed, with the jugal situated about 1.5 cm below its
242 original position based on the surangular ridge. Sediments around the skeleton are carbonate-
243 cemented, contrasting with the poorly-cemented reddish sediment farther from the skeleton. A
244 series of tectonic-induced joints occur across the skeleton, mainly in the left posterior mandible
245 through the right squamosal, humerus, femur, and tibia. The gap is wider along the right leg and
246 is filled with reddish silt.

247

248 **Skull.** The skull (Figs. 4, 5) is mainly articulated, but the left skull roof and most of the left
249 lateral elements posterior to the orbit are not preserved. The occipital region, braincase, and
250 palatal elements are embedded in the matrix. The skull is proportionately much narrower than
251 the holotype (IGM 100/1315). The basal skull length (from the rostral to quadrate articulation) is
252 111 mm, and the preserved skull length is 142 mm in the sagittal plane. The width of the skull
253 from the sagittal midline to the lateral tip of the epijugal is 53 mm.
254   Both narial openings, right and partial left orbit, and both antorbital fossa are preserved.
255 The narial opening is oval and anteroventrally oriented 60° to the horizontal plane. It is
256 anteriorly, ventrally, and posteriorly bounded by the premaxilla and dorsally by the nasal. The
257 ventral margin of the narial opening is lower than the anterior tip of the dorsal process of the
258 rostral and the dorsal margin of the antorbital fossa. The posterodorsal end of the narial opening
259 is about the same level as the anteriormost margin of the orbit.
260   The orbit is large and circular in lateral view. It is dorsally bounded by the prefrontal,
261 frontal, and postorbital in equal proportions. The ventral margin of the orbit is bounded by the
262 lacrimal and jugal. The lacrimal makes up about 17% of the ventral margin of the orbit, while the
263 jugal bounds the rest. The ratio of the orbit to preorbital length is 0.78 (32 mm to 41 mm), which
264 is between the percentages reported for juvenile *Aquilops* (OMNH 34557, 0.84), adult
265 *Archaeoceratops* (IVPP V11114, 0.63), and *Auroraceratops* (CAGS-IG-2004-VD-001, 0.64)
266 (Farke et al., 2014).
267   The shape and dimension of the infratemporal fenestra cannot be accurately determined,
268 because the ventral process of the squamosal, which articulates with the quadrate, is missing, and
269 the quadrate is directed medially due to the crushing of the skull.
270   The supratemporal fenestra would have been triangular, given the low curvature of the
271 possible posterior parietal and the squamosal. The right squamosal is medially crushed. The
272 parietal is disarticulated with probable pectoral elements and ribs preserved at the inferred
273 position of the left supratemporal fenestra.
274   The antorbital fossa is subtriangular in lateral view. It is bounded anteriorly, medially,
275 and ventrally by the maxilla and dorsally by the lacrimal. The fungiform anterior process of the
276 lacrimal does not participate in the antorbital fossa. A deep pocket is ventromedially positioned
277 to the ventral margin of the antorbital fossa, as in *Auroraceratops* (Morschhauser et al., 2018a),
278 juvenile *Protoceratops* (Brown and Schlaikjer, 1940), and *Yamaceratops* (Makovicky and

279 Norell, 2006). The suture between the maxilla's posterior margin and the lacrimal shaft
280 comprises the posterior margin of the antorbital fossa. The anterior ramus of the jugal contacts
281 but hardly contributes to the posterior margin of the antorbital fossa, as in *Archaeoceratops*
282 (Sullivan & Xu, 2017).
283
284 Rostral
285   The anterior margin of the rostral is unkeeled, making a smooth curved edge similar to
286 *Liaoceratops* (Xu et al., 2002; but see also You and Dodson, 2003) and *Mosaiceratops* (Zheng et
287 al., 2015) among basal neoceratopsians, and chaoyangsaurids and psittacosaurids. In lateral view,
288 the ventral process of the rostral becomes lower in height towards the ventral terminus and
289 curves posteroventrally, forming an almost vertical angle with the posteroventral margin of the
290 rostral and the maxillary tooth row, as in *Aquilops* (Farke et al., 2014). The width of the ventral
291 process tapers anteriorly but not to the extent of a keel (Fig. 5B). It goes at a more acute angle
292 than at the anterior margin of the dorsal process. The lateral surface is slightly convex. The
293 lateral process of the rostral is dorsoventrally low and extends to half-length of the ventral
294 margin of the premaxilla. The dorsal process is slightly expanded posteriorly. The external
295 surface of the rostral is relatively rugose, if not to the extent of anastomosing ridges and grooves
296 as in adult *Yamaceratops* (Makovicky and Norell, 2006).
297
298 Premaxilla
299   Both premaxillae are preserved. In lateral view, it is subrectangular, higher than long, and
300 anteroposteriorly shorter than the maxilla. A shallow fossa is present on the anterodorsal portion
301 of the premaxilla, which forms the anteroventral portion of the narial opening. The ventral
302 margin is slightly convex. The premaxillary-maxillary suture is vertical and dorsally confluent
303 with the posterodorsally inclined premaxillary-lacrimal suture. Although the tip of the
304 posterodorsal process is not fully preserved on both sides, it seems that the premaxilla may have
305 posterodorsally contacted the prefrontal. In palatal view, the premaxilla is mediolaterally widest
306 at the middle.
307
308 Maxilla
309   Both maxillae are well preserved. In lateral view, the maxilla is bounded anterodorsally
310 by the premaxilla, dorsally by the lacrimal, and posteriorly by the jugal. The maxilla bears the
311 whole antorbital fossa with a deep pocket medial to the jugal process. Anterior to the antorbital
312 fossa, the dorsal process receives the expanded anterior process of the lacrimal. The prominent
313 buccal emargination is present along the ventral portion of the jugal process. The emargination
314 converges with the oral margin at the premaxillary-maxillary suture.
315
316 Jugal
317   Only the right jugal is preserved and relatively complete. Only the dorsal tip of the dorsal
318 ramus is missing. In lateral view, the jugal is about twice the length of the orbit (66 mm vs. 32

319   mm) and comprises the posteroventral corner of the orbit by more than a quarter. The ventral
320   margin of the jugal is convex, with a vertex at about half-length between the anterior and
321   posterior rami.
322   Along the length of the jugal from the tip of the anterior ramus roughly to the base of the dorsal
323   ramus, the suborbital region of the jugal is laterally convex, making a broad rim around the orbit.
324   Dorsal and ventral to this slight curve, the jugal is essentially flat, except for around the
325   dorsolateral ridge on the posterior ramus. The lateral surface of the jugal is textured as shallow
326   strokes of grooves that are horizontal on the anterior process and vertical on the posterior
327   process. The posterodorsal ridge along the posterolateral edge of the posterior process is also
328   rugose, likely associated with the epijugal in contact and covered with a keratinous sheath as a
329   jugal horn in life.
330   The anterior ramus of the jugal is anterodorsally curved and dorsoventrally shallow. The
331   mediolateral width of the anterior ramus increases towards the anterior portion of the jugal. The
332   anterodorsal end of the anterior ramus is forked and overlaps the tip of the ventral ramus of the
333   lacrimal. The anterior ramus also anterolaterally contacts the maxilla and ventrally along half its
334   length. It creates a triple point between the maxilla, jugal, and lacrimal at the posterior vertex of
335   the antorbital fossa.
336   The posterior ramus of the jugal is a bit longer and dorsoventrally deeper than the
337   anterior ramus. The ramus increases in mediolateral width towards the posterior along its suture
338   with the epijugal. The posterior portion of the posterior ramus gently curves downward, as in
339   *Archaeoceratops* (You and Dodson, 2003), *Auroraceratops* (Morschhauser et al., 2018a),
340   juvenile *Bagaceratops* (Czepiński, 2019), *Beg* (Yu et al., 2020), *Liaoceratops* (Xu et al., 2002),
341   *Mosaiceratops* (Zheng et al., 2015), and juvenile *Protoceratops* (Brown and Schlaikjer, 1940).
342   An elongate epijugal is in contact along the posterodorsal ridge on the posterodorsal edge of the
343   posterior ramus. The quadratojugal would have medially met the posterior ramus of the jugal.
344   However, the medial side of the jugal does not show signs of articulation with the quadratojugal.
345   The space between the quadrate and the jugal is occupied by the surangular. It may be due to the
346   dorsoventral crushing of the skull.
347   The dorsal ramus of the jugal is mediolaterally much thinner than the anterior and
348   posterior ramus. The ventral process of the postorbital covers the anterior part of the dorsal
349   ramus as a scarf joint. It is continuous to the anterior ramus and comprises the posterior margin
350   of the orbit. The posterior part of the dorsal ramus is a thin sheet of bone that forms the
351   anterodorsal margin of the temporal fenestra. In MPC-D 100/553, this bone is positioned medial
352   to the anterodorsal margin of the posterior ramus. The preserved anterodorsal edge of the
353   posterior ramus in the main body of the jugal is horizontal in lateral view and positioned lateral
354   to the posterior part of the dorsal ramus, creating an "embayment" or "notch" (Makovicky and
355   Norell, 2006) at the posterodorsal part of the jugal. The interpretation of the thin bone posterior
356   to the postorbital and medial to the main body of the jugal as a part of the dorsal ramus of the
357   jugal is most parsimonious, given that the dorsal portion of the dorsal ramus of the jugal being
358   expanded posteriorly is a synapomorphy for Neoceratopsia (Butler et al., 2008). This thin sheet

359   of bone was likely broken and displaced due to postmortem crushing of the skull, as can be

360   confirmed by the absence of contact with the main body of the jugal seen in CT data.

361

362   <u>Epijugal</u>

363   The epijugal is preserved articulated with the posterodorsal ridge of the right jugal. The

364   jugal-epijugal suture is open. The epijugal is gently crescentic, dorsoventrally low, and

365   anteroposteriorly elongate, ranging from the tip of the posterior ramus of the jugal to about

366   halfway up the posterodorsal edge. It does not reach the ventral margin of the jugal, which

367   differs from *Auroraceratops* (Morschhauser et al., 2018a), *Bagaceratops* (Czepiński, 2019),

368   '*Graciliceratops*' (Sereno, 2000), both juvenile and adult *Protoceratops* (Brown and Schlaikjer,

369   1940), and the holotype specimen of *Yamaceratops* (Makovicky and Norell, 2006). The

370   transverse section of the epijugal is triangular, and its contact with the jugal is concave. The

371   posterolateral tip of the epijugal is rounded. The lateral surface is highly textured, suggesting it

372   was covered with keratin in life as a jugal horn. The jugal horn's posterodorsal position and

373   elongate shape in MPC-D 100/553 are similar to *Leptoceratops, Montanoceratops*, and

374   *Yamaceratops* (Makovicky, 2010).

375

376   <u>Nasal</u>

377   The right nasal is crushed, and the surface is poorly preserved. The nasal comprises the

378   dorsal border of the narial opening and contacts the premaxilla, lacrimal, prefrontal, and frontal.

379   The nasal is flat and mediolaterally wide relative to the frontal. The mediolaterally widest part of

380   the nasal contacts the lacrimal and is almost as wide as the frontal at the contact with the

381   postorbital on the orbital margin (15 mm vs. 16 mm).

382

383   <u>Lacrimal</u>

384   Both left and right lacrimals are preserved. The lacrimal is shaped like a hand ax, with a

385   narrow ventral ramus and greatly expanded anterior ramus. The anterior ramus of the lacrimal is

386   fungiform in lateral view, similar to *Auroraceratops* (You et al., 2005), but unlike the rectangular

387   shape in *Beg* (Yu et al., 2020). It is surrounded by the maxilla ventrally and only meets the

388   premaxilla anterodorsally. Although the point of contact is crushed, the anterior ramus seems to

389   contact the nasal dorsally as in *Archaeoceratops* (You and Dodson, 2003). This condition differs

390   from *Aquilops* (Farke et al., 2014) and *Auroraceratops* (You et al., 2005), which has no contact

391   between the lacrimal and the nasal, and also *Bagaceratops* (Maryańska & Osmólska, 1975),

392   *Leptoceratops* (Sternberg, 1951), and *Protoceratops* (Brown and Schlaikjer, 1940; Lambert et

393   al., 2001), which has an extensive contact between the two bones.

394   The contact between the premaxilla, nasal, lacrimal, and prefrontal forms a quadruple junction.

395   The anterior ramus of the lacrimal does not contribute to the antorbital fossa. The ventral ramus

396   of the lacrimal is rod-like, similar to *Aquilops* (Farke et al., 2014), *Archaeoceratops* (You and

397   Dodson, 2003), *Auroraceratops* (You et al., 2005), *Leptoceratops* (Sternberg, 1951), and

398   *Liaoceratops* (You et al., 2007). The ventral ramus constitutes the posterodorsal margin of the

399 antorbital fossa but does not contribute to the medial wall of the antorbital fossa extensively as in
400 protoceratopsids (Brown and Schlaikjer, 1940; Czepiński, 2019). The lacrimal also articulates
401 with the supraorbital, posterior to the posterodorsal contact with the prefrontal.
402
403 Prefrontal
404   The prefrontal is small and relatively thick, contributing to about one-third of the dorsal
405 half of the orbit. The ventral process is posterior to the lacrimal and articulates with the
406 supraorbital. The prefrontal differs from *Bagaceratops* (Czepiński, 2019), *Protoceratops* (Brown
407 and Schlaikjer, 1940), and adult *Yamaceratops* (Makovicky and Norell, 2006), which has an
408 extensive ventral process.
409
410 Supraorbital
411   We follow the term supraorbital, as the bone is homologous in ornithischian dinosaurs
412 instead of "palpebral," which originally refers to a metaplastic ossification in crocodilians
413 (Maidment and Porro, 2010; Nesbitt et al., 2012). Only the right supraorbital is wholly
414 preserved. It is large, with its length reaching half of the orbit. It is elongated and triangular. The
415 supraorbital is articulated with the prefrontal and lacrimal at the base. However, it is collapsed
416 with the tip pointing medioventrally into the orbit, ventral to the collapsed sclerotic ring.
417
418 Frontal
419   The frontal is partially preserved on the right side of the skull. The posterior part,
420 including the frontal fossae and the suture with the parietal, is not preserved. The frontal is flat
421 dorsal to the orbit and gently slopes anteriorly in its contact surface with the nasal. The margin
422 and striations for the contact with the nasal are preserved. In dorsal view, the posteriormost
423 contact with the nasal would have been anterior to the contact with the prefrontal.
424
425 Postorbital
426   The right postorbital is triradiate with the three extremities damaged. The anterior and
427 posterior processes are poorly preserved due to the crushing of the skull, and the narrower
428 ventral process was demarcated by a layer of sediment left in the jugal. The dorsal surface of the
429 postorbital is damaged, and only the anterior margin can be traced. The ventral process would
430 have been narrow and pointed anteroventrally, based on the depression left on the jugal. In the
431 posterodorsal corner of the orbit, the postorbital is divided into the dorsal and lateral surfaces
432 without a distinct ridge. The anterior process at the dorsal surface bounds the posterodorsal
433 corner of the orbit and meets the frontal. The posterior contact with the squamosal is
434 indiscernible and probably damaged, but the preserved length of the postorbital is 33 mm, almost
435 equal to the length of the orbit. The lateral surface of the postorbital is flat and smooth. It is
436 excluded from the infratemporal fenestra by the thin and broad dorsal process of the jugal. The
437 posterior margin of the postorbital is slightly concave and converges with the anterior dorsal
438 process of the jugal.

439

440 <u>Squamosal</u>

441   Only the right squamosal is preserved. Its ventral ramus and the contact with the
442 postorbital, quadrate, and parietal are damaged. In lateral view, the dorsoventral height of the
443 anterior process is highest in the preserved anterior margin. The squamosal tapers towards the
444 posterior margin. The lateral surface is flat to slightly concave. In dorsal view, the squamosal is
445 gently convex laterally, although the transverse width is greatest at the anterior margin due to the
446 lateral crushing of the frill.

447

448 <u>Parietal</u>

449   An isolated element located anteroventral to the right distal fibula is tentatively referred
450 to as the partial posterior margin of the parietal (Fig. 4C). It is long, narrow, generally flat, thin,
451 and slightly curved. It has a low ridge at the dorsal surface, along the concave anterior margin.

452

453 <u>Quadrate</u>

454   The right quadrate is preserved. The condyles are probably in contact with the articular,
455 although obscure. The quadrate head is turned medially, and the pterygoid wing is facing
456 laterally, probably due to the deformation of the skull. There is a straight ridge along the
457 posterolateral edge of the shaft, which is slightly pointed at mid-height.

458

459 <u>Braincase</u>

460   Much of the braincase is incased in the matrix, and detailed analyses from CT data will
461 be presented elsewhere.

462

463 <u>Sclerotic ring</u>

464   A portion of the right sclerotic ring is preserved and exposed, lying on top of the tip of
465 the supraorbital. Three segments can be seen, with the posteroventral ones overlapping the
466 anterodorsal ones. Suppose they represent the original lateral surface of the series. In that case,
467 the exposed portion seems to be from the posterodorsal corner of the sclerotic ring as the center
468 of the ring lies anteroventrally.

469

470 **Mandible.** The right mandible is completely preserved except for around the mandibular
471 fenestra. The left mandible is missing the surangular, and much of the lateral surface is broken.

472

473 <u>Predentary</u>

474   The predentary has a sharp tip and an anteroposteriorly narrow oral margin. The anterior
475 margin is straight and gently keeled. The posteroventral process is bifid from about ventral to the
476 anteroventral corner of the posterior process and ends abruptly at the level of the ventral margin
477 of the dentary. The external surface of the predentary is textured with low grooves and ridges
478 longitudinally radiating from the tip.

479

480 <u>Dentary</u>

481   Both sides of the dentary are preserved. In lateral view, the dentary comprises 59% of the
482 mandible length (54 mm out of 92 mm). The ventral margin of the dentary is relatively straight.
483 The dorsal tip of the coronoid process is textured with rostroventrally directed grooves. The
484 dorsal margin of the coronoid process is higher than the dorsal margin of the surangular. The
485 buccal emargination is prominent. The lateral surface of the dentary ventral to the buccal margin
486 is flat and vertical with shallow striations. This condition differs from the laterally flared and
487 striated dentary surface of the holotype of *Yamaceratops* (Makovicky and Norell, 2006).

488

489 <u>Surangular</u>

490   The right surangular is almost complete except for the anteroventral corner. The surangular
491 positions above the angular and behind the dentary. The dorsal margin of the surangular is
492 sinuous with the convex anterior, concave mid-portion, and convex posterior margins. The
493 surangular has a pronounced lateral ridge that is almost horizontal and only slightly inclined
494 posteroventrally. It is laterally highest in the posterior margin and inclines anteriorly. The lateral
495 ridge extends into the dentary, lowering in height. The posteroventral margin of the lateral
496 surface of the surangular is ventrally convex, almost touching the posterior angular tubercle.

497

498 <u>Angular</u>

499   The right angular is almost complete, and the left angular is missing the posterior half of
500 the dorsal and lateroventral portion. It is bifurcate anteriorly along the suture with the dentary
501 and covered by the surangular dorsolaterally. The dorsal margin of the angular is very thin
502 mediolaterally. The lateral surface of the angular is flat and vertical except for the posteriormost
503 part of the angular where the lateral surface faces posteroventrally. The right angular has ventral
504 and posterior tubercles. The ventral tubercle is located dorsolateral to the ventral margin at about
505 mid-length of the angular. The posterior tubercle is located at the posterior quarter, just ventral to
506 the surangular. The ventral tubercle is low and laterally flat, whereas the posterior tubercle is low
507 and dome-shaped. The margin of the mandibular fenestra is damaged but located anterodorsal to
508 the angular.

509

510 **Dentition.** In lateral view, all dentary teeth are covered laterally by the maxillary teeth, and the
511 ventral edges of the maxillary teeth cannot be observed due to the dorsoventral crushing of the
512 skull. However, from the articulated and well-preserved nature of the skull, most, if not all, teeth
513 are likely to be present, as preliminarily seen from the CT images (Fig. 4D). The cingulum is
514 developed on the left maxillary teeth (Jin et al., 2009; *contra* Makovicky and Norell, 2006) (Fig.
515 5A). Judging from the CT data, there seem to be two premaxillary teeth and nine maxillary and
516 eight dentary teeth with well-developed primary ridges. There is a second row of teeth for
517 replacement.

518

519   **Overview of the axial elements.** The preserved axial column is fully articulated (Figs. 2, 6). The
520   cervical series and most of the dorsal vertebrae are lost due to erosion. The posterior dorsal
521   vertebrae are poorly preserved. The sacral vertebrae are mostly complete, although the contacts
522   are hard to interpret. The anterior caudal vertebrae are in place, although the right transverse
523   processes, right half of the centra, and proximal chevrons are missing. In the transition from the
524   anterior to middle caudal vertebrae, the tail is abruptly turned anteroventrally, with the caudal
525   series still in ascending order with wide spacing. The posterior caudal vertebrae are obscured by
526   the matrix but probably lie ventral to the right tibia and fibula.
527
528   Dorsal Vertebrae and Dorsal Ribs
529   The posterior dorsal vertebrae are preserved, articulated but in poor condition. Their neural
530   spines are lower than those of the anterior caudal vertebrae. The exact morphology of the dorsal
531   vertebrae is hard to observe, as they are fragmented and therefore not fully prepared for stability.
532   The anterior and posterior dorsal ribs are preserved without the proximal portions. The ribs on
533   the right side of the body were probably partially articulated from their respective vertebrae,
534   given they are mostly parallel in the series. The rib cage has collapsed and lie on its left side so
535   that the left ribs lie just below the right ribs. The ribs are long and slender, and the cross-section
536   is oval in the preserved portions.
537
538   Sacral Vertebrae and Sacral Ribs
539   Seven sacral vertebrae are present between the ilia (s1-7). The sacrum is composed of
540   one dorsosacral vertebra (s1), four true sacral vertebrae (s2–s5), and two caudosacral vertebrae
541   (s6–s7). Of the four true sacral vertebrae, s2-4 are medial to the acetabulum. The neural spines of
542   the sacral vertebrae are tilted left, although to a less degree in sacral vertebrae 2-5, so that the
543   right side is primarily exposed in dorsal view. The left side is covered in the matrix, roofed by
544   the neural spines and left ilium. Whether the centra of s1-5 are co-ossified cannot be observed,
545   and the centra of s5-7 are not co-ossified. The pre- and postzygapophyses of s1-8 are poorly
546   developed but not co-ossified. The sacral neural spines are low and anteroposteriorly expanded,
547   widest in s2-5, and the anterior margin is sloping in s6-7. The neural spines are not co-ossified,
548   although the neural spines of s3-4 are in close proximity. From the slight displacement and tilting
549   of both ilia, it can be inferred that the distal ends of the transverse processes nor sacral ribs are
550   not co-ossified with the ilium. The distal ends of the transverse processes are covered on top by
551   the tilted ilium on the right side. However, it is unlikely that the distal ends are co-ossified from
552   the low anteroposterior expansion and wide spacing in the proximal portion. The posterior sacral
553   vertebrae are poorly preserved, and the respective sacral ribs are not preserved.
554
555   Caudal Vertebrae, Caudal Ribs, and Chevrons
556   The anterior to middle caudal vertebrae (cd1-19) are preserved in articulation (Fig. 6A).
557   The more posterior caudal vertebrae are not observable due to the overlying right tibia. There is a
558   slight displacement between the eleventh and twelfth caudal vertebrae following the abrupt turn

559   of the caudal series (Fig. 6A). All neurocentral sutures are open. In the anteriormost caudal
560   vertebra (cd1), which is located between the posterior ends of the ilia, the anteroposterior width
561   of the neural spine and the length of the centrum is intermediate between the last caudosacral
562   vertebrae (s7) and the second anterior caudal vertebra (cd2). The overlap of zygapophyses is
563   more extensive at the anterior than the middle caudal vertebrae. Overall, the neural spines of the
564   anterior caudal vertebrae are slightly taller and narrower anteroposteriorly than those from the
565   dorsal vertebrae.
566   The middle caudal vertebrae possess the highest neural spines (preserved in cd13-17) that
567   are much taller and anteroposteriorly narrower than those from the anterior caudal vertebrae (Fig.
568   6B). In the mid-caudal vertebrae cd17, the height of the preserved neural spine (32 mm) is more
569   than five times the height of its corresponding posterior centrum face (6 mm). It cannot be
570   determined whether the tallest neural spine is at the middle portion of the tail or the more
571   posterior part. The neural spines are gently curved posteriorly, with the base nearly vertical to the
572   centra. The neural spines are only slightly expanded distally. The cross-section of neural spines
573   is oval. The zygapophyses meet nearly horizontally, and each neural arch is tall relative to the
574   centrum. The centra of the middle caudal vertebrae are slightly spool-shaped (waisted), with a
575   concave ventral margin in lateral view. The distal ends of the caudal ribs for the anterior caudal
576   vertebrae are preserved, meeting the ischium (Figs. 2, 6A). They are anteroposteriorly wide and
577   rectangular with parallel anterior and posterior margins headed directly laterally rather than
578   posterolaterally. Caudal ribs are not preserved for the middle caudal vertebrae. The facets for
579   articulation with the caudal ribs are present in cd18, and their presence in more posterior caudal
580   vertebrae cannot be verified. The very tall middle caudal neural spines with the neural spine
581   length about or more than four times the height of the centrum is known in *Koreaceratops*
582   *hwaseongensis*, *Montanoceratops cerorhynchus*, and *Protoceratops andrewsi* (Tereshchenko,
583   2008; Lee et al., 2011; Tereshchenko and Singer, 2013). The case for *Bagaceratops* should be
584   taken with caution because the specimen PIN 3143/11, a partial tail, that was referred to and
585   provided data for this taxon (e.g., Tereshchenko, 2007; 2008; Tereshchenko and Singer, 2013)
586   likely instead belongs to *Protoceratops andrewsi* (Czepiński, 2020).
587   The chevrons of cd11-18 are preserved. The chevrons are rod-like and elongated but
588   much shorter and a bit narrower proximally than the corresponding neural spines. They are wider
589   distally, as in *Leptoceratops* and *Protoceratops andrewsi*, but not as much expanded as in
590   *Auroraceratops* and *Koreaceratops* (Morschhauser et al., 2018b). The chevron is twice as long
591   as the height of the respective centrum face in cd17 (12 mm and 6 mm, respectively).
592
593   Ossified Tendons
594   Three ossified tendons are partially preserved on the right dorsal side of the two
595   anteriormost sacral vertebrae (s1-2). The ossified tendons are parallel to each other and do not
596   overlap. The presence or extent of the ossified tendon is known to be not taxonomically
597   diagnostic because they are subjective to taphonomic biases even among a single basal
598   neoceratopsian taxon from a "geographically and stratigraphically restricted area" (Morschhauser

599   et al., 2018b). It has been shown that the ossified tendons in hadrosaurine dinosaurs (*Maiasaura*
600   *peeblesorum* and *Brachylophosaurus canadensis*) were not induced by biomechanical stresses
601   (non-pathologic), and their development began early, as they were even found from a nestling
602   specimen (Adams and Organ, 2005).

603

604   **Overview of the appendicular elements.** Several authors have recently done descriptive and
605   comparative work on the basal ceratopsian appendicular elements for several taxa: they are well
606   described and compared in *Auroraceratops* (Morschhauser et al., 2018b), *Ferrisaurus* (Arbour
607   and Evans, 2019), *Ischioceratops* (He et al., 2015), and *Yinlong* (Han et al., 2018). Juvenile
608   specimens of *Montanoceratops* (Chinnery and Weishampel, 1998) and *Psittacosaurus*
609   *lujiatunensis* (Hedrick et al., 2014) show a general trend in the ontogeny of basal ceratopsian
610   appendicular elements. This pattern was particularly well described for *Protoceratops andrewsi*
611   (Słowiak et al., 2019) and altogether formed the foundation for comparative work between taxa
612   and ontogenetic stages of specific taxa.

613

614   **Forelimb.** The right humerus, radius, and ulna are preserved articulated (Fig. 7A), although the
615   proximal ulna is missing and the glenoid of the radius is indiscernible.

616

617   <u>Humerus</u>
618   The right humerus is preserved articulated with the ulna and radius. The proximal portion
619   of the humerus is fractured at the proximal end of the deltopectoral crest. The humeral head is
620   covered by overlapping dorsal ribs. The humerus is gracile with less expanded proximal and
621   distal ends and a slender shaft than juvenile *Protoceratops andrewsi* and other basal ceratopsian
622   specimens of more advanced growth stages (Słowiak et al., 2019). It is most similar to
623   '*Graciliceratops*' (ZPAL MgD-I/156). The shaft of the humerus is oval in cross-section as the
624   proximally positioned deltopectoral crest does not extend down to the shaft as a ridge. In
625   *Protoceratops andrewsi*, the cross-section of the humeral shaft is triangular in juveniles (Brown
626   and Schlaikjer, 1940) and distally suboval in young adults (Słowiak et al., 2019). The shaft is
627   slightly bowed posteriorly in lateral view, as in all basal neoceratopsians except *Cerasinops*
628   (Słowiak et al., 2019). The deltopectoral crest is low in lateral view and transversely flat. The
629   overall development of the deltopectoral crest is more similar to *Cerasinops* than *Auroraceratops*
630   and *Protoceratops andrewsi*. In posterior view, the ulnar condyle extends more distally and is
631   transversely narrower than the radial condyle.

632

633   <u>Ulna</u>
634   The distal half of the right ulna is preserved. The cross-section of the ulnar shaft is widely
635   ovated, and its distal end is mediolaterally narrow, likely due to its juvenile state. The distal shaft
636   of the ulna is straight in posterior view, as the general configuration of basal neoceratopsians
637   (Chinnery and Horner, 2007) and in contrast to the medially-bending condition in some
638   leptoceratopsids (*Cerasinops* (MOR 300), *Ferrisaurus* (RBCM P900) *Prenoceratops* (TCM

639 2003.1.8), and *Udanoceratops* (PIN 3907/11)) (Chinnery, 2004; Chinnery and Horner, 2007;
640 Arbour and Evans, 2019).
641
642 Radius
643   The right radius is preserved except for the proximal end. The mid-shaft is rounded
644 triangular in cross-section as in *Protoceratops andrewsi* and *Auroraceratops* (Słowiak et al.,
645 2019). The lateral margin of the radius is straight.
646
647 **Pelvic Girdle.** The pelvic girdle is well preserved, other than slight displacement and
648 dorsoventral compression during diagenesis.
649
650 Ilium
651   Both ilia are well preserved (Figs. 7B, 8A), only missing the thin anteriormost portions.
652 The pubic peduncles and ischiadic peduncles are partly covered in the matrix. The iliac blade is
653 low and vertical above the acetabulum. In lateral view, the dorsal margin of the ilium is mainly
654 convex but slightly sigmoidal with the preacetabular portion curved anteroventrally with a pivot
655 point dorsal to the pubic peduncle and the posteriormost portion nearly straight but slightly
656 concave with its end curving dorsally. This overall morphology is in line with the referred
657 *Yamaceratops* left ilium of IGM 100/1303, 62% larger than MPC-D 100/553. The postacetabular
658 process of *Yamaceratops* is more elongate than that of most other basal ceratopsians, only
659 rivaled by adult *Protoceratops andrewsi* (e.g., AMNH 6424). The posterior end of the
660 postacetabular process pointing slightly dorsally in *Yamaceratops* resembles the condition of
661 *Mosaiceratops* (*contra* Zheng et al., 2015) and *Protoceratops andrewsi* (Słowiak et al., 2019).
662 The pre- and postacetabular processes are elongated, and the former would not have been much
663 longer than the latter. The postacetabular process is dorsoventrally slightly taller than the
664 preacetabular process. The postacetabular process tapers posteriorly, although this shows
665 ontogenetic or individual variation in *Yinlong* (Han et al., 2018)). The brevis shelf of the
666 postacetabular process is not pronounced. The lateral surface of the ilium is smooth.
667   The ilium is low above the acetabulum, with the depth of the ilium only half that of the
668 length between the base of the pre- and postacetabular processes. It is unlike other members of
669 Cerapoda but similar to the basal pachycephalosaur ('heterodontosaurid,' Dieudonné et al.,
670 2020), *Abrictosaurus*, and the non-neoceratopsian ceratopsians *Stenopelix* and *Yinlong* (Han et
671 al., 2018). The ilium is relatively deeper in the larger specimen of *Yamaceratops* (IGM
672 100/1303), so this is ontogenetically variable in *Yamaceratops*.
673   In dorsal view, the dorsal margin of the ilium shows a weak sigmoid curvature where the
674 preacetabular process is slightly laterally deflected, and the postacetabular process is slightly
675 convex laterally. The dorsal margin of the ilium is only slightly everted laterally. The lateral side
676 of the postacetabular process is slightly longitudinally concave.
677
678 Ischium

679   The right ischium is exposed, with its medial side facing up, as in dorsoventrally
680   compressed specimens of *Leptoceratops* (CMN 8887; Sternberg, 1951) and juvenile
681   *Protoceratops* (MPC-D 100/530; Fastovsky et al., 2011) (Fig. 7). The end of the pubic peduncle
682   and the iliac peduncle is obscured by the overlying ilium. The ischium is long, dorsoventrally
683   slender, straight, and lacks an obturator process. The ischial shaft is transversely flat, and its
684   medial surface is smooth. The ischial shaft is laterally compressed as in leptoceratopsids such as
685   *Montanoceratops* and *Leptoceratops*, contrary to other basal neoceratopsians where its cross-
686   section is oval (e.g., *Auroraceratops*, *Koreaceratops*, *Mosaiceratops*, and *Protoceratops*
687   *andrewsi*) (Słowiak et al., 2019). The ischium is slightly laterally convex as in *Mosaiceratops*
688   and *Protoceratops*, unlike the straight ischial shaft in *Archaeoceratops* and *Koreaceratops*
689   (Słowiak et al., 2019). The morphology of the ischial shaft is unlikely to be postmortem
690   deformation, as the bone surface shows no sign of breakage from flattening. The distal end is
691   covered in the matrix and lies beneath the caudal vertebrae.
692
693   **Hind Limb.** Both hind limbs are partially preserved (Figs. 2, 7, 8). The right hind limb is
694   preserved articulated and somewhat extended, although the parts distal to the tarsus are not
695   present. The preserved portion of the left hind limb comprises the proximal femur articulated
696   with the ischium and part of the pes.
697
698   Femur
699   The right femur and the proximal one-third of the left femur are preserved. Both femora
700   are articulated with the ilium, so the femoral head could not be seen. The proximal portion of the
701   left femur is only slightly expanded anteroposteriorly. The lesser and greater trochanter is
702   divided by a narrow and shallow groove, but their proximal ends are poorly preserved. The
703   femoral shaft is straight and slender in lateral view. This condition is ontogenetically variable in
704   *Protoceratops andrewsi*, as they are arched in very small juveniles but straight in small to large
705   adults (Słowiak et al., 2019). Only the base of the fourth trochanter is preserved. It is located just
706   proximal to the middle of the femur, facing caudomedially. The existent of fourth trochanter
707   preservation is known to vary with taphonomy among specimens of *Psittacosaurus lujiatunensis*
708   (Hedrick et al., 2014; Persons and Currie, 2019). The inner and outer condyles are obscured by
709   the matrix.
710
711   Tibia
712   Only the right tibia is preserved and is articulated with the fibula and femur. Its posterior
713   surface is exposed in dorsal view. The middle portion of the shaft is missing. The tibia is long
714   and slender, with only modestly expanded ends. At the proximal end, the inner condyle is cut
715   apart by the joint. The distal end of the tibia is laterally expanded to meet the fibula. The distal
716   end of the tibia does not angle medially, as in *Auroraceratops* and *Ischioceratops*, as noted as an
717   exceptional case among non-ceratopsid ceratopsians by Słowiak et al. (2019).
718

719   Fibula

720   The right fibula is articulated with the tibia and is also missing the middle portion of the

721   shaft. The proximal end is anteroposteriorly expanded and mediolaterally compressed. The distal

722   fibula is narrow with an oval cross-section. Its distal end curves anteriorly to meet the anterior

723   surface of the distal tibia.

724

725   Pes

726   Only the left pes is preserved and articulated (Fig. 8). The preserved elements are digit

727   Ⅰ to Ⅲ, with only the distal portions of metatarsal Ⅰ to Ⅲ preserved in articulation. The pedal

728   ungual is preserved in digit Ⅲ. The surfaces are broken in the proximolateral surface of phalanx

729   Ⅰ 1, the lateral surface of phalanges Ⅰ 1 and 2, and the dorsal surfaces of metatarsals Ⅰ to Ⅲ.

730   The first phalanx of digit Ⅰ is longer than that of digit Ⅱ, similar in length to that of digit Ⅲ.

731   The phalanx of digit Ⅰ is narrower than the phalanges of digits Ⅱ and Ⅲ. The second phalanx

732   of digit Ⅱ is shorter than the first but longer than the second phalanx of digit Ⅲ. The phalanx

733   Ⅲ2 is subequal in length but slightly shorter than Ⅲ3.

734   As in MPC-D 100/553, length of phalanx Ⅱ1 is longer than Ⅱ2 in *Auroraceratops*

735   (Morschhauser et al., 2018b), *Cerasinops* (Gilmore, 1939; Chinnery and Horner, 2007),

736   '*Graciliceratops*' (Maryańska and Osmólska, 1975), *Koreaceratops* (Lee et al., 2011),

737   *Leptoceratops* (Sternberg, 1951), *Montanoceratops* (Chinnery and Weishampel, 1998),

738   *Protoceratops andrewsi* (Brown and Schlaikjer, 1940), *Psittacosaurus amitabha* (Napoli et al.,

739   2019), and indeterminate leptoceratopsid PIN no. 4046/11 (Tereshchenko, 2008; Słowiak et al.,

740   2019),. However, the length of phalanx Ⅱ1 is shorter than Ⅱ2 in *Archaeoceratops* (You and

741   Dodson, 2003) and *Yinlong* (Han et al., 2018).

742   As in MPC-D 100/553, the length of phalanx Ⅲ2 is subequal to Ⅲ3 in *Ferrisaurus*

743   (Arbour and Evans, 2019), '*Graciliceratops*' (Maryańska and Osmólska, 1975), *Koreaceratops*

744   (Lee et al., 2011), *Protoceratops andrewsi* (Brown and Schlaikjer, 1940), and an indeterminate

745   leptoceratopsid PIN 4046/11 (Tereshchenko, 2008; Słowiak et al., 2019; Arbour and Evans,

746   2019). The Ⅲ2 are longer than or subequal in length to Ⅲ3 with variable relative lengths in

747   specimens of *Auroraceratops* (Morschhauser et al., 2018b), *Cerasinops*, and *Leptoceratops*

748   (Arbour and Evans, 2019).

749   The morphology of the pedal ungual is intermediate between hoof-like and claw-like,

750   although its medial and lateral edges and the tip are broken. The proximal end of the pedal

751   ungual is about the same width as the distal end of the preceding pedal phalanx. The relative

752   width of the pedal ungual is known to be ontogenetically variable in *Protoceratops andrewsi*

753   (Słowiak et al., 2019) and even in the ceratopsid *Chasmosaurus belli* (Currie et al., 2016): pedal

754   unguals are relatively longer and narrower in small juveniles than adult-sized individuals. The

755   pedal unguals of two ontogenetic stages of *Yamaceratops* (MPC-D 100/553; IGM 100/1303) are

756   not as elongate as those in some leptoceratopsids (*Cerasinops*, *Ferrisaurus*, *Leptoceratops*), nor

757   are they broad as those of adult *Protoceratops andrewsi* (Słowiak et al., 2019; Arbour and Evans,
758   2019).
759
760   **Bone histology**
761
762   The humerus of MPC-D 100/553 was examined for histological study (Fig. 9).
763   The cortex of the humerus exhibits longitudinal, reticular, and plexiform vascularization. Four
764   zones are observed. The endosteal region contains a small amount of trabecular bone and
765   plexiform bone matrix with large bone resorption cavities. A small number of radial vessels are
766   observed. Bone vascularity shifts from longitudinal to laminar toward the periosteal region. Bone
767   wall ranges between 2.98-3.64 mm in thickness. The cortex does not contain secondary osteons
768   and active bone remodeling.
769   The tissue mainly consists of fibro-lamellar. The density of lacunae is less dense in the
770   outer two zones than inside. A total of three lines of arrested growth (LAG) are preserved. In
771   some regions of the cortex, LAGs are obliterated due to taphonomic or diagenetic alterations.
772   The endosteal bone in the humerus is not completed, as in juvenile to sub-adult *Psittacosaurus*
773   *lujiatunensis* (Zhao et al., 2019). Primary bone remodeling from individuals with three LAGs is
774   also reported from *Psittacosaurus lujiatunensis* and *Psittacosaurus sibiricus* (Zhao et al., 2019;
775   Skutschas et al., 2021), of which erosion bays, the first sign of primary bone remodeling,
776   appeared from this stage.
777   Instances where the distance between LAGs is decreased in the place where it is expected
778   to increase have been reported for *Psittacosaurus lujiatunensis* (Zhao et al., 2013; 2019). MPC-D
779   100/553 shows a shorter spacing between the second and third LAG than the first and second
780   LAG like a fibula of *Psittacosaurus lujiatunensis* IVPP V14341.1 with three LAGs (Zhao et al.,
781   2013).
782
783   **Body size and completeness**
784
785   MPC-D 100/553 is the smallest and most complete among *Yamaceratops* specimens and
786   the first articulated skeleton (Makovicky and Norell, 2006). Although the presence of additional
787   *Yamaceratops* materials has been mentioned in the literature, they were not described (Eberth et
788   al., 2009; Nesbitt et al., 2011).
789   Although no detailed measurements were given for other *Yamaceratops* specimens (IGM
790   100/1315; IGM 100/1303; IGM 100/1867), from the figure, MPC-D 100/553 is 67% the size of
791   the holotype IGM 100/1315 based on the mandibular length and is 62% the size of the referred
792   specimen IGM 100/1303 based on postacetabular length of the ilium. MPC-D 100/553 is slightly
793   smaller than 'Graciliceratops' ZPAL MgD-I/156 based on the lengths of appendicular elements.
794   Estimation of total body mass of MPC-D 100/553 based on the corrected equation for bipedal
795   animals by Campione et al. (2014) recovered a body mass of 3.5 kg.
796

Phylogenetic analysis

In the analysis of Arbour and Evans (2019), unordered characters resulted in an extensive polytomy of most non-protoceratopsid basal neoceratopsians without a monophyletic Leptoceratopsidae. The new analysis with updated scorings (42 taxa and 257 characters) that are all unordered recovered both Leptoceratopsidae (except for *Helioceratops* and *Koreaceratops*) and Ceratopsoidea as a monophyletic clade. However, the Protoceratopsidae had collapsed into a polytomy with some of the other basal neoceratopsians.

Removing one unstable taxon, *Helioceratops*, represented by fragmentary materials, resolved this polytomy, yielding a resolved Coronosauria (Protoceratopsidae and Ceratopsoidea) that is a sister clade to Leptoceratopsidae (except *Koreaceratops*), even in the unordered setting. The phylogenetic analysis of 41 taxa and 257 characters produced a strict consensus tree (1160 most parsimonious trees, tree length (TL) = 689 steps) with a topology similar to that of Morschhauser et al. (2018c) but with all characters unordered and no additional steps taken except for removing one unstable taxon (*Helioceratops*). It means that the extensive polytomy from the unordered matrix of Morschhauser et al. (2018c) and Arbour and Evans (2019) has been much resolved. The new analysis for the phylogenetic relationships of *Yamaceratops* within basal neoceratopsians recovered *Yamaceratops* as a sister taxon to the Leptoceratopsidae and Coronosauria combined as suggested by Morschhauser et al. (2018c). The main difference between the two strict consensus trees is the unresolved positions at the base of the tree and the positons of *Asiaceratops*, *Mosaiceratops*, and *Koreaceratops*. The unresolved position between *Hypsilophodon*, *Stegoceras*, and Ceratopsia, and between the Psittacosauridae, Chaoyangsauridae, and Neoceratopsia are expected to some extent since the relevant characters were not the main focus of the matrix by Morschhauser et al. (2018c), and the phylogeny of Cerapoda has not reached a consensus yet (Han et al., 2018; Dieudonné et al., 2020). In a cladogram of Morschhauser et al. (2018c), *Asiaceratops* and *Mosaiceratops* formed a clade with *Yamaceratops* that is a sister clade to the Leptoceratopsidae and Coronosauria combined. In the new analysis, however, only *Yamaceratops* retained this position, and *Asiaceratops* and *Mosaiceratops* are in a position that is more derived than *Liaoceratops* and more basal than *Archaeoceratops*. In addition, in Morschhauser et al. (2018c), *Aquilops* formed a clade with *Auroraceratops* and '*Graciliceratops*' (ZPAL MgD-I/156) between *Archaeoceratops* and the clade including *Yamaceratops*. But in our analysis, the clade has collapsed with the inclusion of *Koreaceratops*.

Removing two taxa, *Helioceratops* and *Koreaceratops* (only known the low body), improved resolution and recovered the previously established monophyletic groups of Leptoceratopsidae, Coronosauria, Protoceratopsidae, and Ceratopsoidea (Fig. 10). The phylogenetic analysis of 40 taxa and 257 characters produced a strict consensus tree (730 most parsimonious trees, tree length (TL) = 688 steps) with a topology again similar to that of Morschhauser et al. (2018c) but with polytomies among basal neoceratopsians resolved. In this iteration, *Asiaceratops* and *Mosaiceratops*, and *Auroraceratops,* and '*Graciliceratops*' (ZPAL

837   MgD-I/156) formed a clade in their position, and *Aquilops* was recovered as a more derived

838   taxon than the clade of *Auroraceratops* and '*Graciliceratops*' (ZPAL MgD-I/156) and more

839   basal than *Yamaceratops*.

840   For the conformation of the phylogenetic position of *Yamaceratops*, a second analysis

841   was conducted using the character matrix of Knapp et al. (2018) as iterated by Yu et al. (2020),

842   with only scorings for *Yamaceratops* revised, for 71 taxa with 350 unordered characters using

843   the new technology search algorithm (Fig. 11). The Knapp et al. (2018) matrix encompasses

844   most of the ceratopsid taxon in addition to basal ceratopsians, as opposed to the Morschhauser et

845   al. (2018c) matrix, which is exclusively focused on basal neoceratopsians, with minimal

846   ceratopsids. However, because the Knapp et al. (2018) matrix focused on ceratopsids, many of

847   the characters are on the elaborated frills and horns that are only applicable in ceratopsids.

848   Testing the phylogenetic hypothesis for *Yamaceratops* with the Yu et al. (2020) matrix, the

849   resulting topology is consistent with that of Yu et al. (2020), with paraphyletic

850   Chaoyangsauridae, Psittacosauridae, and Protoceratopsidae. Noticeable differences in the

851   neoceratopsian topology are *Asiaceratops* recovered as a leptoceratopsid, and *Yamaceratops*

852   recovered as the sister taxon to the clade of leptoceratopsids and coronosaurs in the new analysis,

853   both of which were placed as being much basal in the previous result. Compared with our results

854   from the Arbour and Evans (2019) matrix (reiteration of the Morschhauser et al. (2018c) matrix),

855   our new cladogram from the Yu et al. (2020) matrix (reiteration of the Knapp et al. (2018)

856   matrix) recovered a more basal position for *Aquilops* and a more derived position for

857   *Asiaceratops* and '*Graciliceratops*.' Given that these three taxa are known only from juvenile

858   specimens, it seems likely that their positions are subject to changes when ontogenetic variations

859   are considered in the character scorings in the Yu et al. (2020) matrix. Considering juvenile

860   features in scoring the characters from the Knapp et al. (2018) matrix is more complicated

861   because the ontogenetic trajectories of basal neoceratopsians differ from those of ceratopsids,

862   with heterochronic development of derived features (Prieto-Márquez et al., 2020) and should be

863   further studied in the future.

864   Both of our phylogenetic analyses recovered *Yamaceratops* as the sister taxon to

865   Leptoceratopsidae and Coronosauria combined.

866

DISCUSSION

868

Phylogenetic relationships of *Yamaceratops* with other basal neoceratopsians

870

871   A new comprehensive phylogenetic analysis including new MPC-D 100/553 recovered

872   *Yamaceratops* as a sister taxon to the Leptoceratopsidae plus Coronosauria.

873   The thin, narrow, and only slightly curved parietal bar is significant in that in non-

874   ceratopsid ceratopsians, such parietals, indicating the presence of a large parietal foramen, are

875   only known in *Cerasinops* (Chinnery and Horner, 2007) and '*Graciliceratops*' (Sereno, 2000)

876   other than juveniles of more derived protoceratopsids *Protoceratops* (Brown and Schlaikjer,

877   1940; Handa et al., 2012) and *Bagaceratops* (Czepiński, 2019). The posterior parietals are not
878   thin, and the parietal foramen is small in the more basal *Liaoceratops* (Hu et al., 2002) and
879   *Auroraceratops* (Morschhauser et al., 2018a). The "very slender median and posterior parietal
880   frill margin" similar to MPC-D 100/553 was suggested as a unique character of
881   '*Graciliceratops*' by Sereno (2000) but is known to be ontogenetically variable in *Protoceratops*
882   (Brown and Schlaikjer, 1940; Handa, 2012) and *Bagaceratops* (Czepiński, 2019). From our
883   phylogenetic hypotheses, the presence of a fenestrated frill could have been ancestral for the
884   Leptoceratopsidae and Coronosauria and later lost in leptoceratopsid evolution.
885   *Yamaceratops* is the basalmost taxon with the maximum height of the caudal neural spine
886   about or more than four times the height of the associated centrum among basal neoceratopsians,
887   as the phylogenetic position of *Koreaceratops* likely falls within the Leptoceratopsidae
888   (Morschhauser et al., 2018c). It indicates that the tall leaf-shaped tail was perhaps prevalent in
889   leptoceratopsids and protoceratopsids, and later lost in ceratopsids. From the patterns of
890   ontogenetic variation that are concordant in *Yamaceratops* and *Protoceratops*, similar patterns
891   could be expected for other basal neoceratopsians, assuming that they had not diverged, and
892   juvenile specimens could be more reliably incorporated into phylogenetic analyses (Bhullar,
893   2012).
894   Bipedalism of *Yamaceratops* (MPC-D 100/553) was predicted based on overall body
895   proportions with long hindlimbs and tested from the quantitative method of Chapelle et al.
896   (2019) using humeral and femoral circumferences. The measured minimum circumference of the
897   humeral shaft is 23 mm, and that of the femoral shaft is 34 mm. Plotting the data to the database
898   of Chapelle et al. (2019) recovered a bipedal to equivocal position close to a juvenile
899   *Psittacosaurus lujiatunensis*. This taxon went from quadrupedal to bipedal during ontogeny. The
900   humeral shaft of MPC-D 100/553 is well preserved, but as the femur had been laterally crushed
901   due to sediment compaction, its circumference is thought to have been slightly shortened.
902   Therefore, assuming the actual minimum femoral circumference was longer than measured,
903   *Yamaceratops* (MPC-D 100/553) fits into the range of bipedal animals. In a recent review,
904   Słowiak et al. (2019) concluded that many skeletal features of *Yinlong*, *Psittacosaurus*,
905   *Liaoceratops*, *Mosaiceratops*, *Archaeoceratops*, and '*Graciliceratops*' were indicative of
906   bipedality, while *Auroraceratops*, *Protoceratops*, and leptoceratopsids were likely mainly
907   quadrupedal, with a possible ontogenetic shift from facultative bipedalism to quadrupedalism in
908   *Protoceratops andrewsi*. Our phylogenetic tree and bipedalism in *Yamaceratops* are mainly
909   congruent with this conclusion.
910
911   **Ontogenetically variable features in *Yamaceratops***
912
913   The number of LAG suggests the relative age of this individual is at least three years old.
914   The humerus contains mainly longitudinal and a small number of reticular and plexiform vessels.
915   Blood vessel organization suggests that bone is mainly growing along its long axis but not very
916   active. Bone circumferential expansion is lagged. The tissue mainly consists of fibro-lamellar, as

917   observed in modern vertebrates (Horner and Padian, 2004). Based on the absence of the External
918   Fundamental System (Castanet et al., 1988; Ponton et al., 2004; Klein et al., 2009; Woodward et
919   al., 2011), this individual was not somatically mature and was still growing, probably
920   temporarily slowed down.
921   Although a hierarchical analysis of the ontogeny in *Yamaceratops* is limited at this stage
922   due to the small sample size of two skulls, the new skull offers a glimpse into the indicators of
923   morphological maturity in basal neoceratopsians, as well as features diagnostic for this taxon.
924   MPC-D 100/553 is about 67% the size of the holotype specimen of *Yamaceratops* (IGM
925   100/1315) based on the mandibular length. Ontogenetically variable features in MPC-D 100/553
926   concordant with juvenile archosaurs that can be used in Marginocephalia (Griffin et al., 2020)
927   include a relatively large orbit, long-grained surface texture on the femur, tibia, fibula, humerus,
928   ulna, and radius (Tumarkin-Deratzian, 2009), open neurocentral sutures in every caudal vertebra
929   (Brochu, 1996; Hone et al., 2014), ends of the humerus, femur, and tibia composed of poorly-
930   defined, spongy bone (Fastovsky et al., 2011).
931   Juvenile features of MPC-D 100/553 shared with juvenile specimens of *Yinlong* (Han et
932   al., 2016), *Liaoceratops* (Xu et al., 2002), *Auroraceratops* (You et al., 2012; Morschhauser et al.,
933   2018a; Zhang et al., 2019) *Protoceratops andrewsi* (Brown and Schlaikjer, 1940; Handa et al.,
934   2012; Hone et al., 2014) and *Bagaceratops* (Maryańska and Osmólska, 1975; Czepiński, 2019)
935   include the relatively low angle of the lacrimal ventral ramus relative to the maxillary teeth row,
936   a nasal that is flat and broad relative to the frontal, a relatively small jugal that does not flare
937   laterally with its posterior ramus pointed posteroventrally, postorbital lateral surface smooth,
938   short predentary relative to the dentary length, dentary with a straight ventral edge and flat lateral
939   surface ventral to the buccal emargination, the lateral ridge on the surangular low, and posterior
940   parietal thin and narrow.
941   The holotype skull of *Yamaceratops* (IGM 100/1315) was described as being from a
942   mature individual, from "closure of the sutures among the occipital and basicranial braincase
943   elements" (Makovicky and Norell, 2006). However, they also noted a possible indicator of
944   immaturity: "the epijugal is not fused to the jugal, a feature that appears to be related to advanced
945   maturity in *Protoceratops andrewsi* and ceratopsids" (Makovicky and Norell, 2006). Compared
946   to MPC-D 100/553, IGM 100/1315 certainly shows features of a more advanced ontogenetic
947   stage: the high angle of the lacrimal ventral ramus relative to the maxillary teeth row; a relatively
948   large jugal that flares laterally, with its posterior ramus pointed posteriorly; postorbital lateral
949   surface rugose; dentary with a ventral edge that is convex in lateral view and curved laterally
950   below the buccal emargination in anterior view; the lateral ridge on the surangular pronounced.
951   It should be noted that the lateral surangular ridge is well-developed in *Archaeoceratops*,
952   *Bagaceratops*, *Beg*, *Cerasinops*, *Leptoceratops*, *Protoceratops*, and *Yamaceratops* (Makovicky
953   and Norell, 2006; Tanoue et al., 2010; Yu et al., 2020) but very low to absent in *Auroraceratops*,
954   *Liaoceratops*, *Prenoceratops*, *Udanoceratops*, and ceratopsids (Chinnery, 2004a; Makovicky &
955   Norell, 2006; Morschhauser et al., 2018a).

956   Another variable feature in *Yamaceratops* that is related to ontogeny includes the shape
957   and extent of the epijugal: the epijugal in IGM 100/1315 is crescentic and covers the posterior
958   edge of the jugal to the ventral side (Makovicky and Norell, 2006), whereas the epijugal of
959   MPC-D 100/553 is less curved and only covers the posterodorsal edge of the jugal and does not
960   reach the ventral margin of the jugal. We hypothesize a similar pattern of jugal horn expansion
961   during growth in other ceratopsians with epijugals, although specimens with articulated epijugals
962   are relatively rare.
963   Many distinctive features in basal neoceratopsian taxa were acquired early in their
964   developmental history, as can be seen from the presence of the additional antorbital fenestra, the
965   edentulous premaxilla, the fused nasals with a distinct bump, and the V-shaped buccal crest in
966   the very immature skull of *Bagaceratops* (ZPAL MgD-I/123) with a medial length of 47 mm
967   (Maryańska and Osmólska, 1975; Czepiński, 2020), all of which are distinguishing features of
968   this taxon. From assessing the maturity of basal neoceratopsian specimens based on comparisons
969   of the two *Yamaceratops* specimens, we decided that the character scorings for *Asiaceratops*,
970   *Aquilops*, and '*Graciliceratops*' had to be revised, following their probable immature status.
971   However, no changes could be made for *Asiaceratops* because no ontogenetically relevant
972   characters had been scored.
973   Ontogenetic variation in ceratopsians has been described in *Psittacosaurus lujiatunensis*,
974   *Liaoceratops*, *Montanoceratops*, *Protoceratops*, and *Bagaceratops*, but they are either far away
975   from the *Yamaceratops* 'grade' or too fragmentary. Although multiple specimens from a range of
976   ontogenetic stages have been recovered for *Yinlong*, *Psittacosaurus mongoliensis*, and
977   *Auroraceratops*, they had not been studied in detail regarding ontogeny. The discovery of an
978   additional specimen of *Yamaceratops* from an even earlier or much later ontogenetic stage will
979   provide information on the postnatal skeletal development of *Yamaceratops* and add insight into
980   the general patterns of growth in basal neoceratopsian dinosaurs.
981
982   **Taphonomy**
983
984   Taphonomic features of MPC-D 100/553 are as follows: (1) stage 0 degree of abrasion
985   with unabraded bones (Fiorillo, 1988; Cook, 1995); (2) stage 1 weathering with bone-cracking
986   from desiccation most apparent on the left lower jaw (Behrensmeyer, 1978; Fiorillo, 1988); (3)
987   absence of root traces, borings, and gnaw/bite marks; (4) transverse/compression fracture
988   breakage pattern (Haynes, 1983) that is most apparent on the right ilium, femur, and tibia; (5)
989   plastic deformation and crushing present; (6) gleying around the skeleton present (Jackson et al.,
990   2018).
991   The skeletal articulation, crouching posture, and the size of grains in the surrounding
992   matrix (Fig. 2, 12) indicate rapid perimortem to postmortem burial of MPC-D 100/553 (Rogers
993   and Kidwell, 2007) with no transport, and that the carcass did not even float on water (Syme and
994   Salisbury, 2014). A low degree of weathering of the bones and teeth preserved in jaws also

995 supports limited surface exposure times (Hill, 1980). The bone surfaces show no direct evidence
996 of scavenging.
997   It is most likely that MPC-D 100/553 was preserved in this state by rapid burial following
998 desiccation upon death. This interpretation is from a series of observations (Fig. 12). MPC-D
999 100/553 is notable in that: 1) the skeleton lies above a trough cross-bedding of fine- to coarse-
1000 grained sandstone with pebbles. 2) The dorsal side of the skeleton is facing the top of the strata.
1001 3) The skeleton is articulated in a life-like crouching or sprawling position with its elbow
1002 pointing up. 4) The upper body is curved to the right, and the tail is strongly curved to the right,
1003 perpendicular to the pelvis and anterior portion of the tail. 5) The sclerotic ring and the
1004 supraorbital have collapsed but are still inside the orbit. 6) An isolated thin and narrow element,
1005 likely the posterior portion of the parietal bar, is preserved anteroventral to the distal fibula. 7)
1006 The right squamosal is medially compressed with the ribs and probable pectoral elements placed
1007 where the left portion of the frill is expected to be, and the cervical series is missing. 8) The
1008 ribcage is collapsed, with the right ribs lying above the left ribs, with the ribs above the humeral
1009 head. 9) Gleying and carbonate cementation are present around the skeleton. 10) The skeleton is
1010 dorsoventrally crushed so that the maxillary teeth cover the dentary teeth, the jugal covers the
1011 surangular lateral ridge, the dorsal process of the jugal broken and displaced medially, the
1012 postorbital is facing dorsally rather than laterally, legs sprawling with transverse fractures on the
1013 femur, ilium disarticulated with its lateral surface facing up, ischium overturned with its medial
1014 surface facing up, and the right side of the tail is facing up. 11) Some conjugate tectonic joints
1015 cut across the skeleton and the surrounding matrix.
1016   These indicate a taphonomic scenario of death at the lateral accretionary margin of a
1017 channel (1, 2, 3), followed by a short period of decay and desiccation of the body leading to
1018 breakage of the frill (4, 5, 6, 7, 8), subsequent rapid burial and post-burial microbial activities
1019 decomposing the skeleton (9) (Allison, 1988), compression of the skeleton during sediment
1020 compaction and diagenesis (10), and final tectonic processes (11). These processes conform to
1021 the semi-arid seasonal environment of the middle Javkhlant Formation (Eberth et al., 2009).
1022   MPC-D 100/553 is unlikely to have been preserved inside a burrow because the
1023 underlying fine- to coarse-grained sandstone with pebbles and trough cross-bedding (Fig. 12) are
1024 indicative of a fluvial deposit that had not been disturbed from burrowing. However, the laterally
1025 curved tail of MPC-D 100/553 may have resulted from drying of the carcass during
1026 mummification, as has been suggested to have preserved *Auroraceratops* skeletons inside
1027 burrows (Suarez et al., 2018). The possibility of miring is also unlikely because of the underlying
1028 stratified sandstone without extensive mudstone layers, although MPC-D 100/553 shows the
1029 articulation of the skeleton in a life-like crouched posture with flexed hind limbs as in many
1030 skeletons preserved from miring (Sander, 1992; Hungerbühler, 1998; Varricchio et al., 2008;
1031 Eberth et al., 2010).
1032   The death pose and preservation of MPC-D 100/553 showing dorsoventral compression
1033 of the body with the tail turned laterally is likely due to the basal ceratopsian body plan, as can
1034 be seen in articulated skeletons of *Psittacosaurus* (SMF R 4970; Mayr et al., 2002),

1035 *Koreaceratops* (KIGAM VP 200801; Lee et al., 2011), *Leptoceratops* (CMN 8887 and CMN
1036 8888; Sternberg, 1951), *Protoceratops* (e.g., AMNH 7417; Gregory and Mook, 1925), and
1037 *Bagaceratops* (MPC-D 100/535; Saneyoshi et al., 2011). *Psittacosaurus sinensis* (IVPP V738)
1038 was even preserved in a crouching position with the tail curved (Young, 1958). But in this case,
1039 the tail is on top of the leg, unlike the case in MPC-D 100/553, where the right leg is stretched
1040 over the curved tail. Such specimens offer insights into post-mortem effects in perfectly
1041 articulated specimens.
1042   The state of preservation in MPC-D 100/553 is reminiscent of an articulated
1043 *Protoceratops* skeleton (GI SPS 100/512) from the "Fighting Dinosaur" specimen. The
1044 *Protoceratops* skeleton GI SPS 100/512 is articulated in a crouching position with its posterior
1045 dorsal vertebral column and tail strongly curved and the humeral head placed beneath the ribs
1046 (Barsbold, 1974; 2016) as in MPC-D 100/553. Another example of an articulated skeleton with a
1047 humeral head placed beneath the dorsal ribs is a partial *Bagaceratops* KID 196 (Kim et al.,
1048 2019), although in this case, the scapula and coracoid are articulated with the humerus, all
1049 beneath the dorsal ribs. The taphonomy of MPC-D 100/553, GI SPS 100/512, and KID 196
1050 leading to their ribcage over forelimb can mainly be explained through the ventral collapse of the
1051 ribcage following decomposition while the shoulder girdle and the forelimb remained relatively
1052 in position, resulting in the axial skeleton below the level of articulation with the appendicular
1053 skeleton (Carpenter, 1998; Hone et al., 2014). In GI SPS 100/512, from the maxillary teeth
1054 preserved below the alveoli and femur disarticulated from the acetabulum, it can be inferred that
1055 decay had taken place to a considerable degree (Behrensmeyer and Boaz, 1980) and that the
1056 displacement happened after burial, to minimize displacement of disarticulated elements. It is
1057 worth noting that the holotype skull of *Yamaceratops* ((IGM 100/1315) also preserves a
1058 maxillary tooth outside the alveolus, implying similar taphonomic processes.
1059   A feature listed by Sereno (2010) as an autapomorphy of *Psittacosaurus sinensis* is
1060 shared with MPC-D 100/553: "short lower jaw that positions the anterior margin of the
1061 predentary in opposition to the premaxilla rather than the rostral." However, the lower jaw in
1062 MPC-D 100/553 is more posteriorly positioned relative to the skull than in another
1063 *Yamaceratops* specimen IGM 100/1315, and this is likely due to deformation by the dorsoventral
1064 compaction of the skull in MPC-D 100/553, while IGM 100/1315 is less deformed (Makovicky
1065 and Norell, 2006). There seems to be variation among *Psittacosaurus sinensis* specimens (e.g.,
1066 IVPP V738 and BNHM BPV149, Sereno, 2010). Moreover, such posteriorly positioned
1067 predentary in life is unlikely to have been functionally advantageous for *Psittacosaurus sinensis*,
1068 especially given that the premaxillae of *Psittacosaurus* species were edentulous (Sereno, 2010),
1069 while in *Yamaceratops,* the premaxillary teeth occluded with the rhamphotheca of the predentary
1070 (Figs. 4, 5; Makovicky and Norell, 2006). Therefore, the predentary of *Psittacosaurus sinensis*
1071 specimens positioned posterior to the general condition in ceratopsians may also be due to their
1072 taphonomy rather than a genuine taxonomic signal.
1073
1074 **CONCLUSIONS**

1075

1076   A new specimen of *Yamaceratops dorngobiensis* (MPC-D 100/553) was collected at the
1077 Khugenetjavkhlant locality from the Upper Cretaceous Javkhlant Formation. MPC-D 100/553
1078 provides essential information on the anatomy of *Yamaceratops,* including autapomorphies
1079 which were unknown from the holotype (IGM 100/1315) and referred (IGM 100/1303; IGM
1080 100/1867) specimens of *Yamaceratops*.
1081   The holotype is about 50% larger than the new specimen based on mandibular length.
1082 The differences between the holotype and the new specimen, likely representing ontogenetic
1083 variation in *Yamaceratops*, were concordant with patterns of ontogenetic variation known in
1084 *Protoceratops andrewsi* (Brown and Schlaikjer, 1940). Therefore, MPC-D 100/553 was
1085 confirmed as a juvenile. The ontogenetically variable features present in both *Protoceratops* and
1086 *Yamaceratops* could be inferred to be shared in basal neoceratopsians or at least in the group that
1087 is of intermediate phylogenetic position between *Yamaceratops* and *Protoceratops*.
1088   Histological analysis of the humerus of MPC-D 100/553 recovered three LAGs,
1089 indicating around three years old when it died, and confirmed the immature ontogenetic stage of
1090 the animal.
1091   The new information on *Yamaceratops* and ontogenetically variable features in basal
1092 neoceratopsians recovered from MPC-D 100/553 were used in the new phylogenetic analysis.
1093 The analysis recovered *Yamaceratops* as a sister taxon to the Leptoceratopsidae and
1094 Coronosauria combined, meaning that *Yamaceratops* is the basalmost taxon with the much-
1095 elongated caudal neural spines. During the evolution of ceratopsian dinosaurs, a change occurred
1096 in tail morphology, where the neural spines of the middle caudal vertebrae were elongated in
1097 basal neoceratopsians, reaching a peak in leptoceratopsids and protoceratopsids, and shortened
1098 back in ceratopsids.

1386

1387 **Figure 1 Maps of the locality where the new skeleton of *Yamaceratops dorngobiensis* (MPC-**
1388 **D 100/553) was discovered.** (A) Map of Mongolia. Stars represent the outcrops of the
1389 Javkhlant Formation and its correlative strata; green star indicates the Zos Canyon
1390 locality and red star the Khugenetjavkhlant locality; (B) Map of Dornogovi Province.
1391 Red stars indicate ceratopsian localities. Yellow stars represent the main localities of the
1392 Bayanshiree Formation. Dashed lines represent province boundaries.

1393

1394 **Figure 2 Skeleton of *Yamaceratops dorngobiensis* (MPC-D 100/553) in right dorsolateral**
1395 **view.** (A) Photograph; (B) Interpretive drawing. Bones are bounded by solid lines and
1396 colored beige; matrix is gray. Shaded areas represent the broken surface of bones.
1397 Abbreviations: cd, caudal vertebrae; dr, dorsal ribs; dv, dorsal vertebrae; f, femur; fi,
1398 fibula; h, humerus; L, bone on the left side; p, isolated parietal; pp, pedal phalanges; R,
1399 bone on the right side; ra, radius; sk, skull; sv, sacral vertebrae; ti, tibia; u, ulna; il,
1400 ilium; is, ischium.

1401

1402 **Figure 3 Skeletal reconstruction of juvenile *Yamaceratops dorngobiensis* (MPC-D 100/553)**
1403 **in right lateral view.** (A) Reconstruction of the skeleton with preserved parts colored in
1404 white and missing bones in gray; (B) Reconstruction of the complete skeleton, restored
1405 based on other basal neoceratopsian skeletons.

1406

1407 **Figure 4 Skull of *Yamaceratops dorngobiensis* (MPC-D 100/553).** (A) Photograph and (B)
1408 interpretive drawing in right lateral view; (C) isolated parietal fragment in dorsal view;
1409 (D) posterior mandible in right lateral view; (E) longitudinal micro-CT cross section of
1410 the skull. Abbreviations: a, angular; aof, antorbital fossa; at, angular tubercle; d,
1411 dentary; dr, dorsal ribs; ej, epijugal; fr, frontal; j, jugal; L, bone on the left side; la,
1412 lacrimal; mx, maxilla; mxt, maxillary tooth; n, nasal; p, isolated parietal; pd, predentary;
1413 pmt, premaxillary tooth; pmx, premaxilla; po, postorbital; prf, prefrontal; q, quadrate;
1414 R, bone on the right side; r, rostral.

1415

1416 **Figure 5 Skull of *Yamaceratops dorngobiensis* (MPC-D 100/553) in (A) left lateral and (B)**
1417 **anterior view.** Abbreviations: a, angular; aof, antorbital fossa; d, dentary; f (R), right
1418 femur; fr, frontal; h, humerus; j, jugal; la, lacrimal; mx, maxilla; n, nasal; pd,
1419 predentary; pf, prefrontal; pmt, premaxillary tooth; pmx, premaxilla; po, postorbital;
1420 prf, prefrontal; r, rostral; ra, radius; sq, squamosal; sa, surangular; scl, sclerotic ring; so,
1421 supraorbital; u, ulna.

1422

1423 **Figure 6 Axial skeleton of *Yamaceratops dorngobiensis* (MPC-D 100/553).** (A) dorsal to
1424 anterior caudal vertebrae in right lateral view; (B) middle caudal vertebrae with very tall

1425   neural spines in right lateral view. Abbreviations: cd, caudal vertebra; cr, caudal ribs;
1426   dv, dorsal vertebrae; s: sacral vertebra; ti, tibia; is, ischium.
1427

1428 **Figure 7 Right appendicular skeleton of *Yamaceratops dorngobiensis* (MPC-D 100/553).** (A)
1429   Forelimb in ventrolateral view; (B) Pelvic girdle and hind limb in lateral view.
1430   Abbreviations: dpc, deltopectoral crest; f, femur; fi, fibula; ft, fourth trochanter; gt,
1431   greater trochanter; h, humerus; ra, radius; u, ulna. L, bones on the left side; lt, lesser
1432   trochanter; R, bones on the right side; ti, tibia; ico, inner condyle of the tibia; il, ilium;
1433   is, ischium.
1434

1435 **Figure 8 Left appendicular skeleton of *Yamaceratops dorngobiensis* (MPC-D 100/553).** (A)
1436   Ilium and pes in lateral view; (B) Pes in dorsal view. Abbreviations: f, femur; ft, fourth
1437   trochanter; gt, greater trochanter; L, bones on the left side; lt, lesser trochanter; mt,
1438   metatarsal; R, bones on the right side; il, ilium; Ⅰ, pedal digit Ⅰ; Ⅱ, pedal digit Ⅱ; Ⅲ,
1439   pedal digit Ⅲ.
1440

1441 **Figure 9 Histological section of the right humeral shaft of *Yamaceratops dorngobiensis***
1442   **(MPC-D 100/553).** Three LAGs are traced in white lines.
1443

1444 **Figure 10 Phylogenetic relationships of *Yamaceratops dorngobiensis* among ceratopsians**
1445   **using the Arbour and Evans (2019) matrix.** Strict consensus tree constructed by using
1446   the character matrix of Arbour and Evans (2019) (iteration of the Morschhauser et al.
1447   (2018c) matrix) with updated scorings for *Yamaceratops dorngobiensis* and
1448   ontogenetically variable characters unscored in taxa represented solely by juvenile
1449   specimens. Taxa with middle caudal neural spines about or more than four times longer
1450   than the centrum height are highlighted as red color. Numbers at each node indicate
1451   Bremer support values.
1452

1453 **Figure 11 Phylogenetic relationships of *Yamaceratops dorngobiensis* among ceratopsians**
1454   **using the Yu et al. (2020) matrix.** Strict consensus tree constructed by using the
1455   character matrix of Yu et al. (2020) (iteration of the Knapp et al. (2018) matrix) with
1456   updated scorings for *Yamaceratops dorngobiensis*. *Yamaceratops dorngobiensis* is
1457   highlighted as red color. Numbers at each node indicate Bremer support values.
1458

1459 **Figure 12 Taphonomy of MPC-D 100/553.** (A) Photograph of the outcrop at the fossil locality.
1460   Red star indicates the position where MPC-D 100/553 was found; (B) Photograph of
1461   MPC-D 100/553 exposed at the flank of a hill as found, during the excavation; (C)
1462   MPC-D 100/553 (skull removed) and its underlying matrix with bedding preserved. The
1463   white lines mark the boundary between coarse- and fine-grained sandstone.
1464

Figure 1

Maps of the locality where the new skeleton of *Yamaceratops dorngobiensis* (MPC-D 100/553) was discovered.

(A) Map of Mongolia. Stars represent the outcrops of the Javkhlant Formation and its correlative strata; green star indicates the Zos Canyon locality and red star the Khugenetjavkhlant locality; (B) Map of Dornogovi Province. Red stars indicate ceratopsian localities. Yellow stars represent the main localities of the Bayanshiree Formation. Dashed lines represent province boundaries.
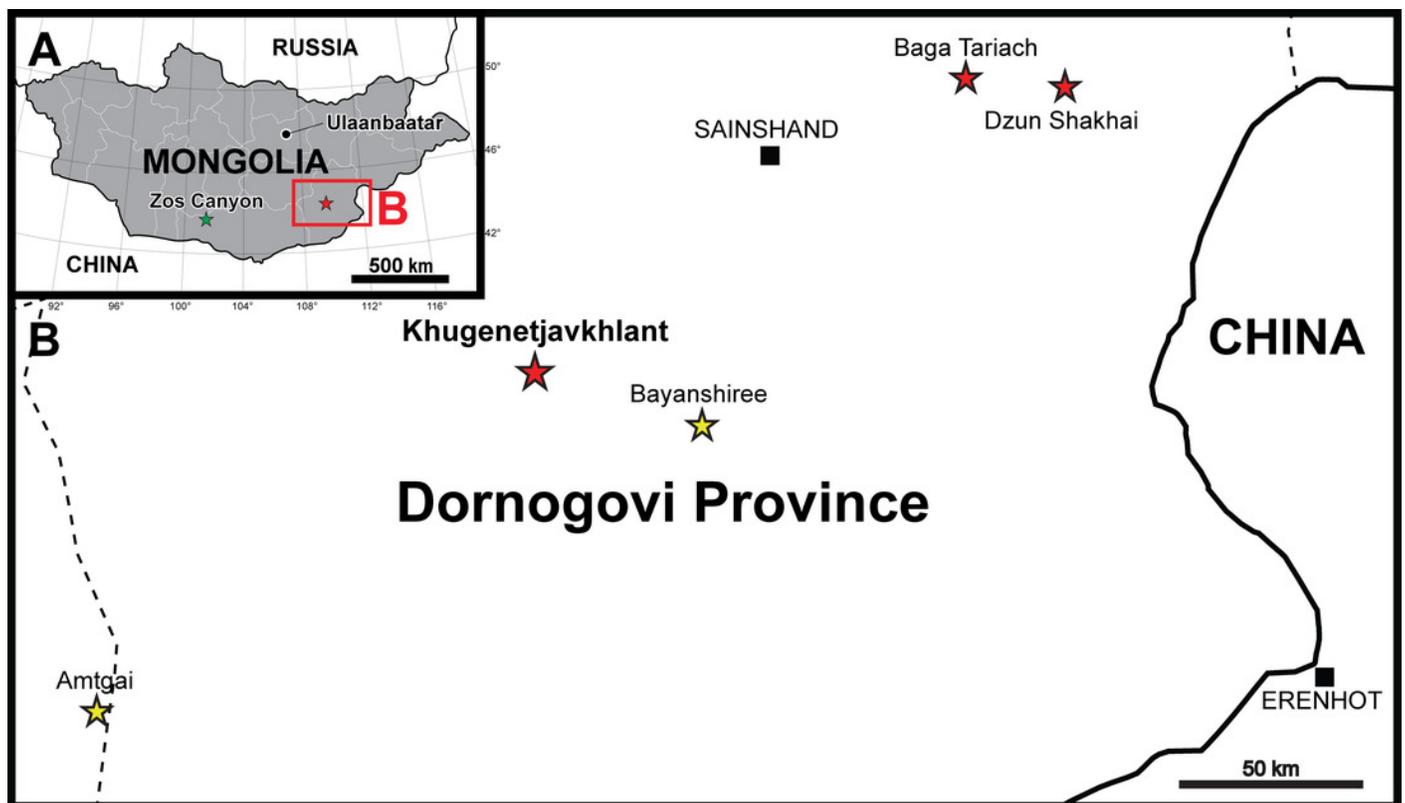

Figure 2

Skeleton of *Yamaceratops dorngobiensis* (MPC-D 100/553) in right dorsolateral view.

(A) Photograph; (B) Interpretive drawing. Bones are bounded by solid lines and colored beige; matrix is gray. Shaded areas represent the broken surface of bones. Abbreviations: cd, caudal vertebrae; dr, dorsal ribs; dv, dorsal vertebrae; f, femur; fi, fibula; h, humerus; L, bone on the left side; p, isolated parietal; pp, pedal phalanges; R, bone on the right side; ra, radius; sk, skull; sv, sacral vertebrae; ti, tibia; u, ulna; il, ilium; is, ischium.

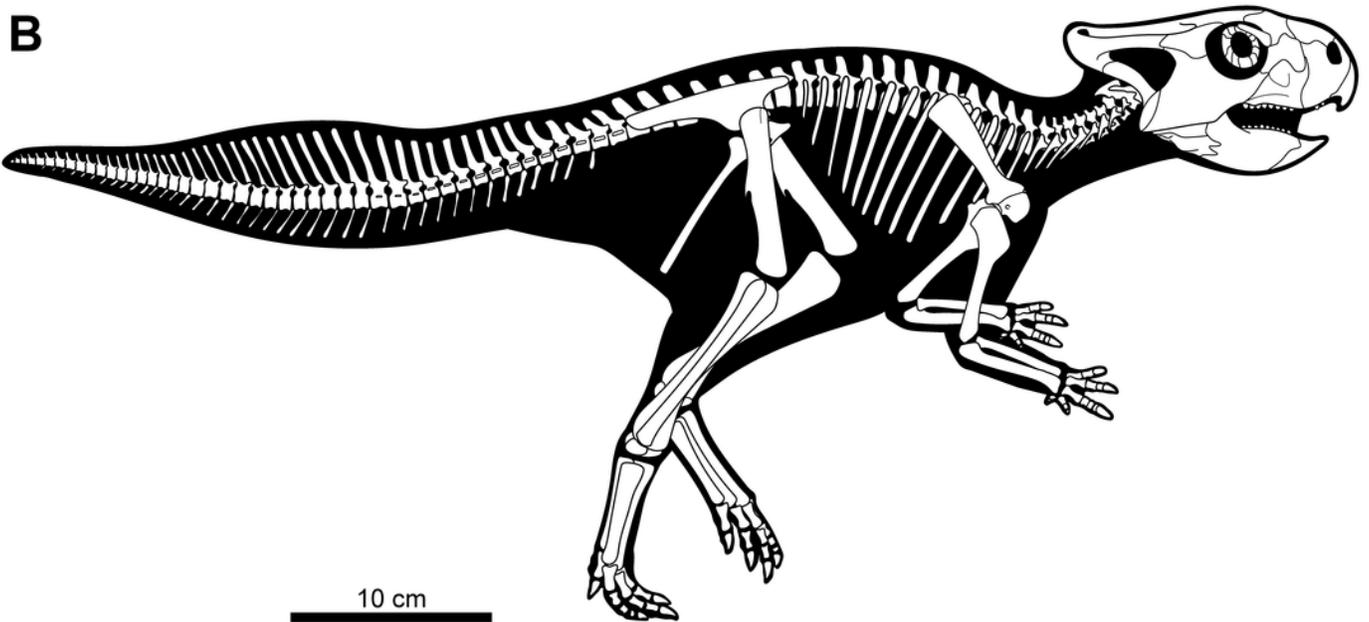

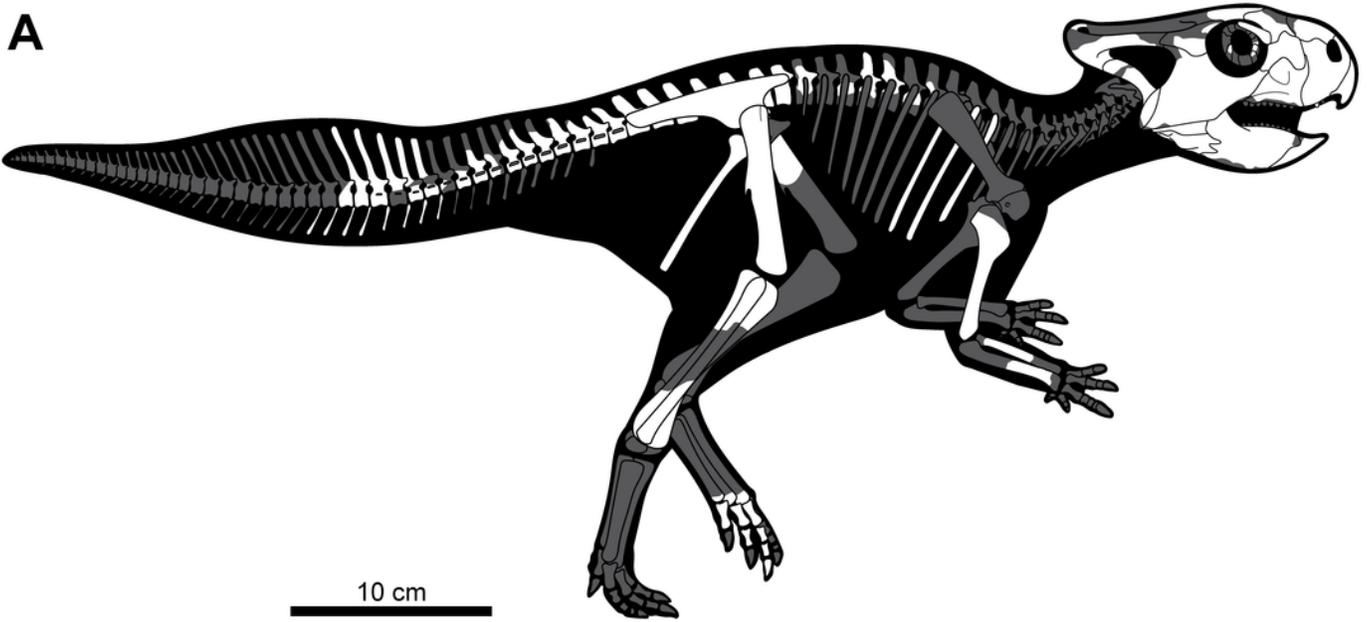

Figure 4

Skull of *Yamaceratops dorngobiensis* (MPC-D 100/553).

(A) Photograph and (B) interpretive drawing in right lateral view; (C) isolated parietal fragment in dorsal view; (D) posterior mandible in right lateral view; (E) longitudinal micro-CT cross section of the skull. Abbreviations: a, angular; aof, antorbital fossa; at, angular tubercle; d, dentary; dr, dorsal ribs; ej, epijugal; fr, frontal; j, jugal; L, bone on the left side; la, lacrimal; mx, maxilla; mxt, maxillary tooth; n, nasal; p, isolated parietal; pd, predentary; pmt, premaxillary tooth; pmx, premaxilla; po, postorbital; prf, prefrontal; q, quadrate; R, bone on the right side; r, rostral.
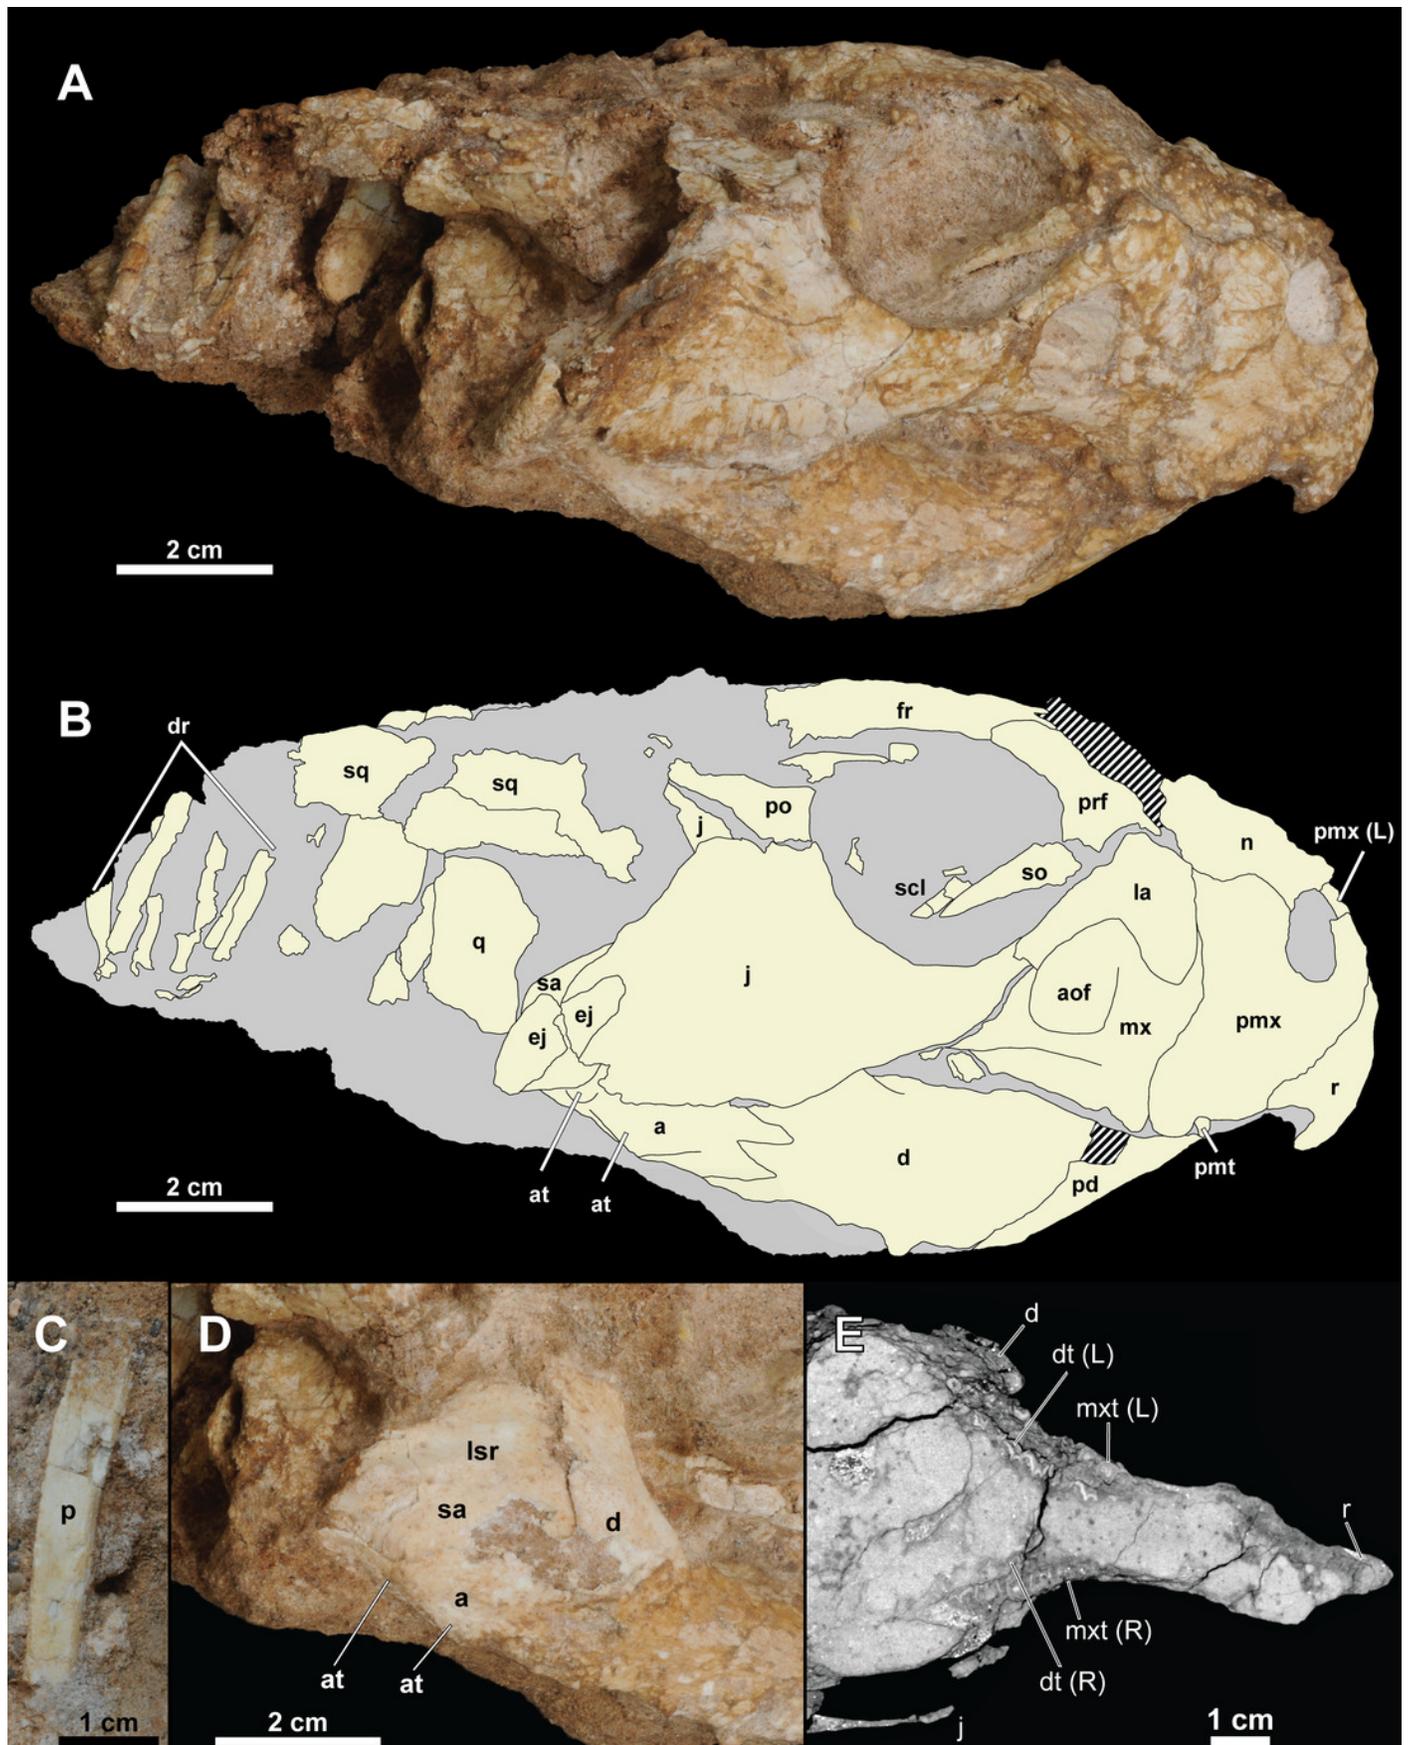

Figure 5

Skull of *Yamaceratops dorngobiensis* (MPC-D 100/553) in (A) left lateral and (B) anterior view.

Abbreviations: a, angular; aof, antorbital fossa; d, dentary; f (R), right femur; fr, frontal; h, humerus; j, jugal; la, lacrimal; mx, maxilla; n, nasal; pd, predentary; pf, prefrontal; pmt, premaxillary tooth; pmx, premaxilla; po, postorbital; prf, prefrontal; r, rostral; ra, radius; sq, squamosal; sa, surangular; scl, sclerotic ring; so, supraorbital; u, ulna.
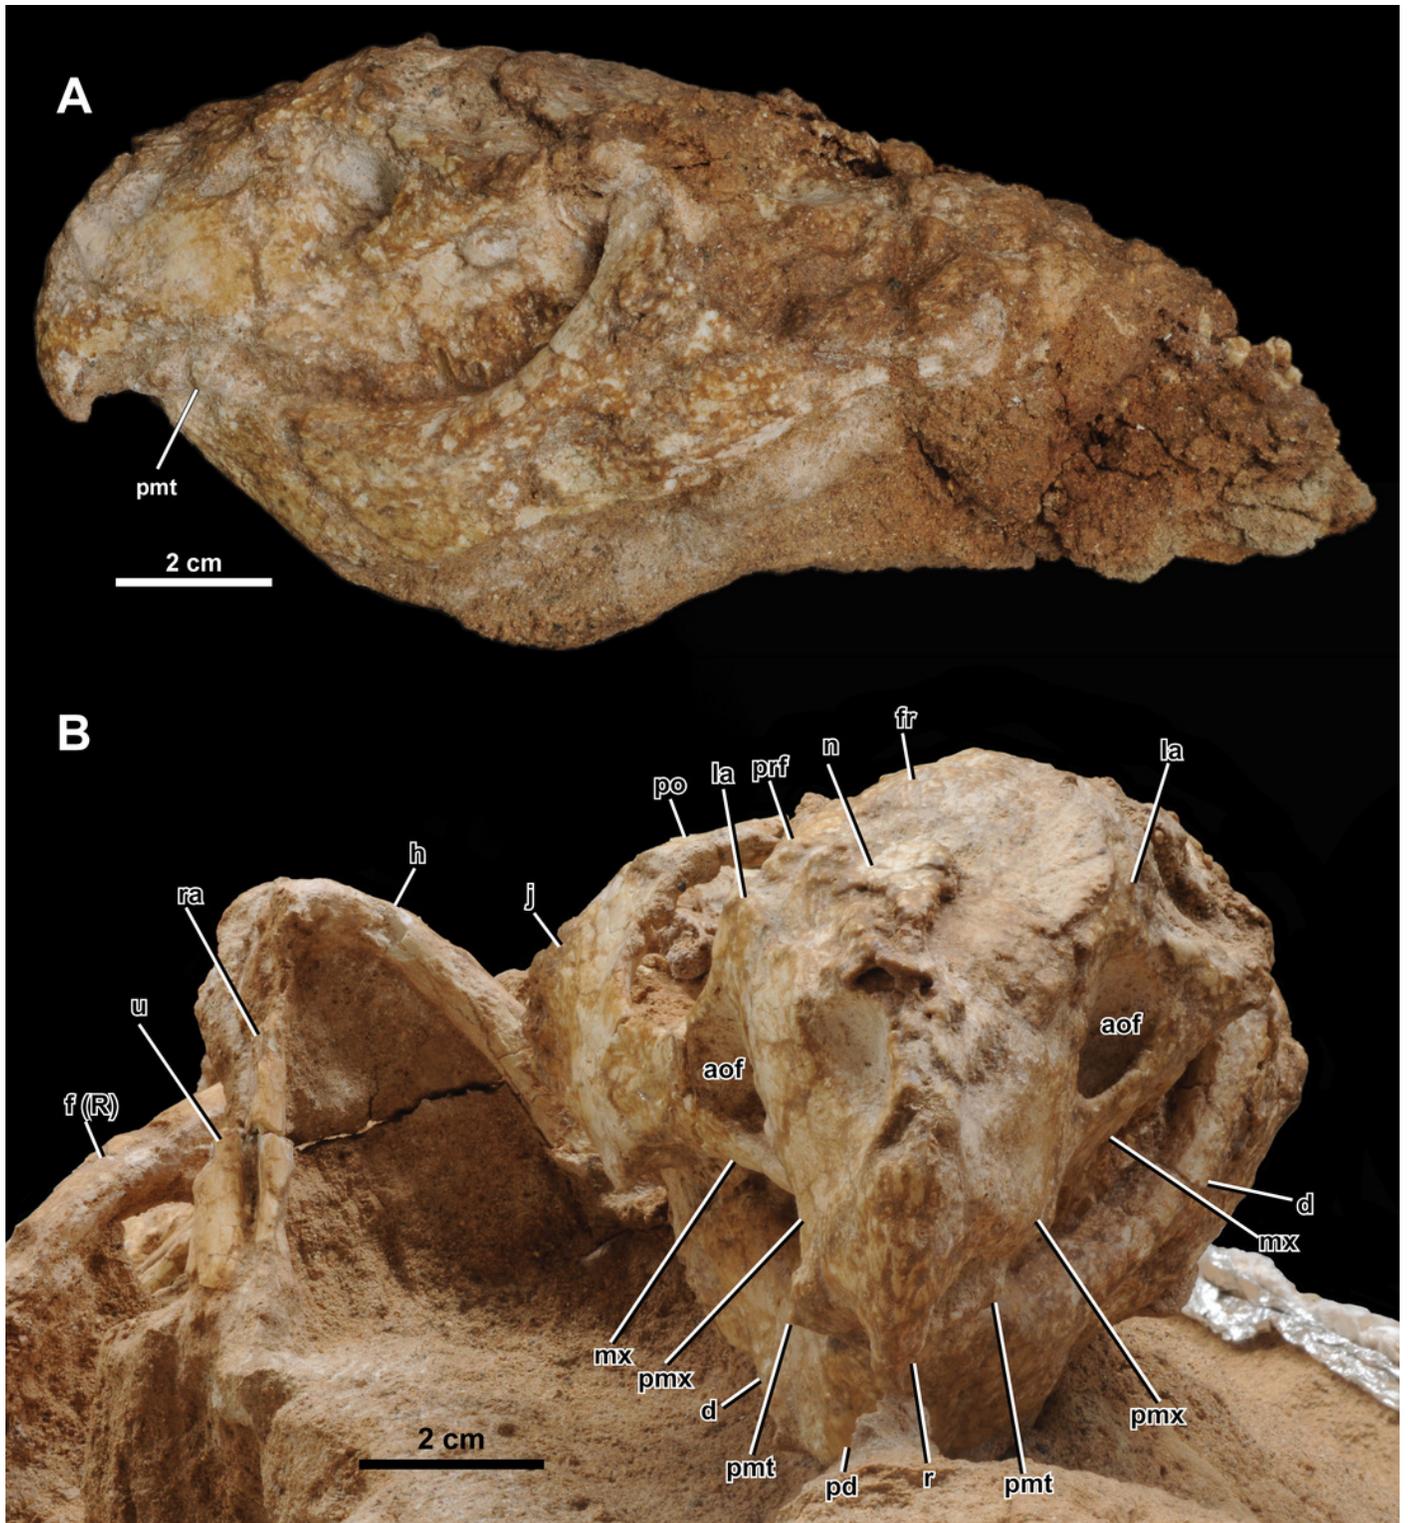

Figure 6

Axial skeleton of *Yamaceratops dorngobiensis* (MPC-D 100/553).

(A) dorsal to anterior caudal vertebrae in right lateral view; (B) middle caudal vertebrae with very tall neural spines in right lateral view. Abbreviations: cd, caudal vertebra; cr, caudal ribs; dv, dorsal vertebrae; s: sacral vertebra; ti, tibia; is, ischium.
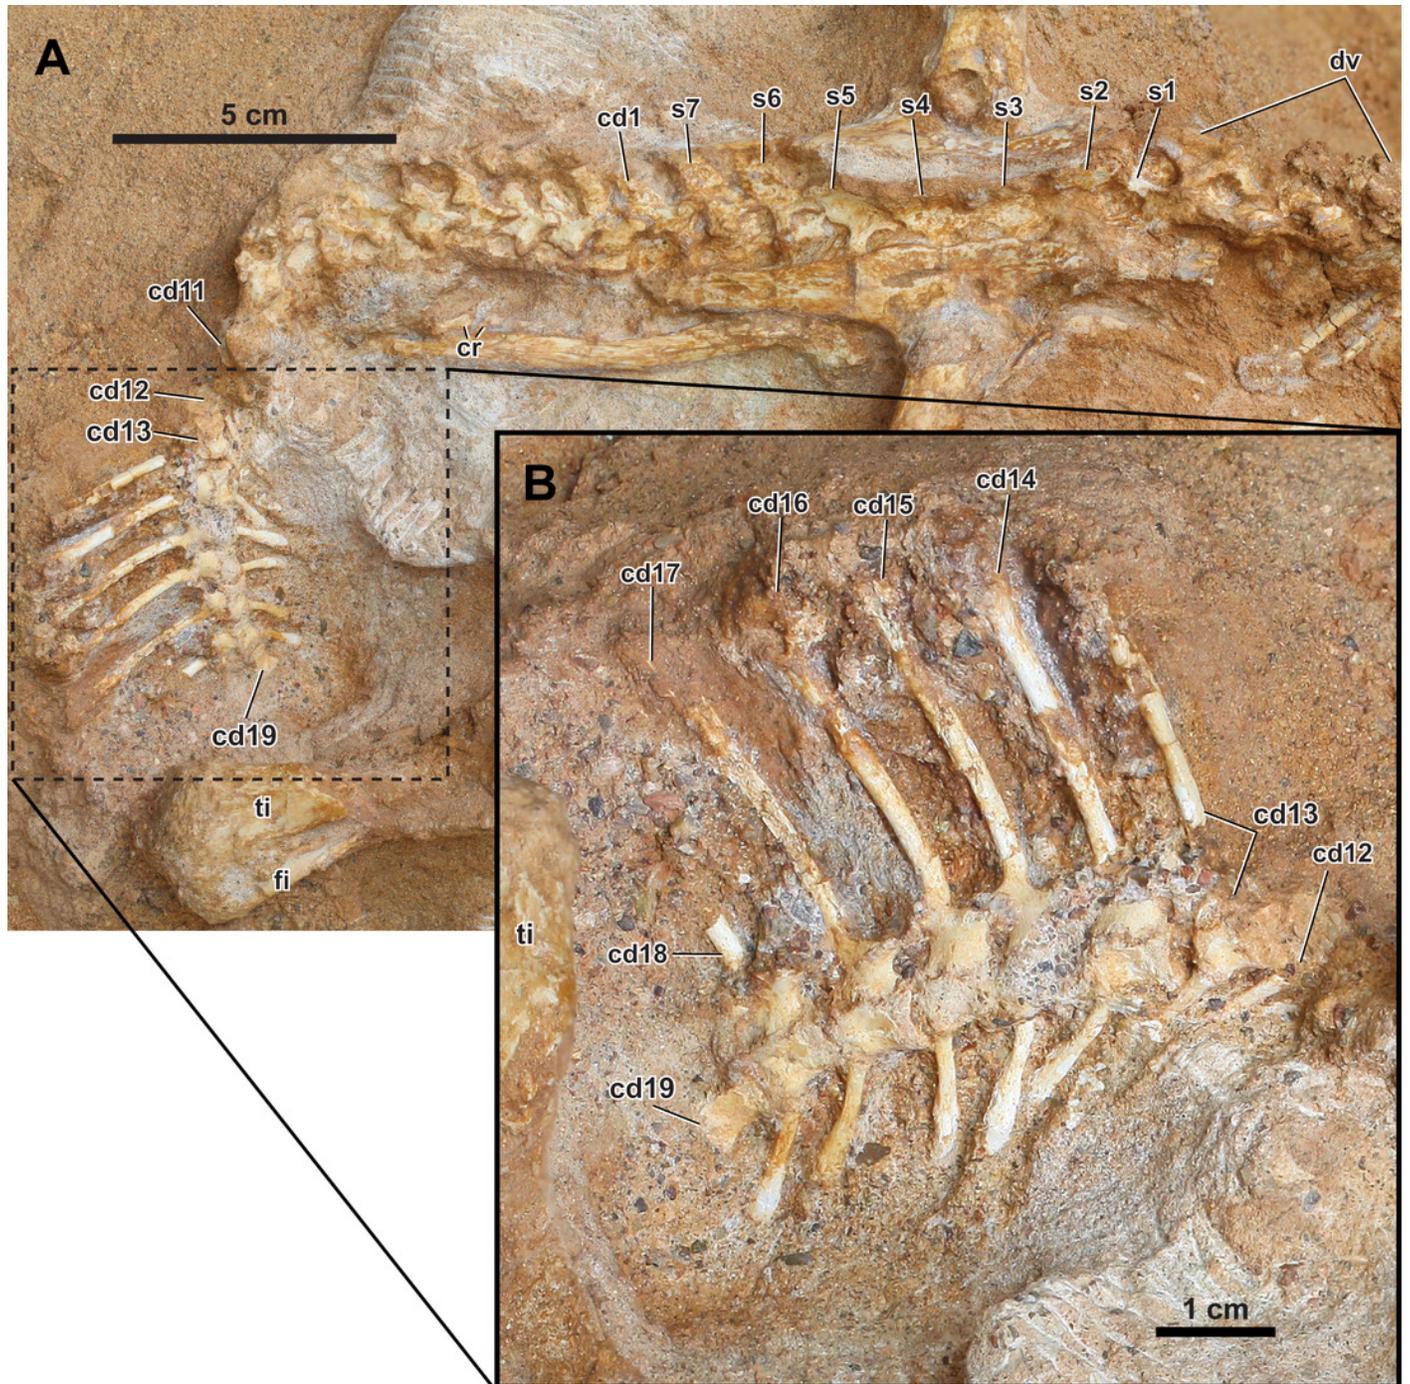

Figure 7

Right appendicular skeleton of *Yamaceratops dorngobiensis* (MPC-D 100/553).

(A) Forelimb in ventrolateral view; (B) Pelvic girdle and hind limb in lateral view. Abbreviations: dpc, deltopectoral crest; f, femur; fi, fibula; ft, fourth trochanter; gt, greater trochanter; h, humerus; ra, radius; u, ulna. L, bones on the left side; lt, lesser trochanter; R, bones on the right side; ti, tibia; ico, inner condyle of the tibia; il, ilium; is, ischium.
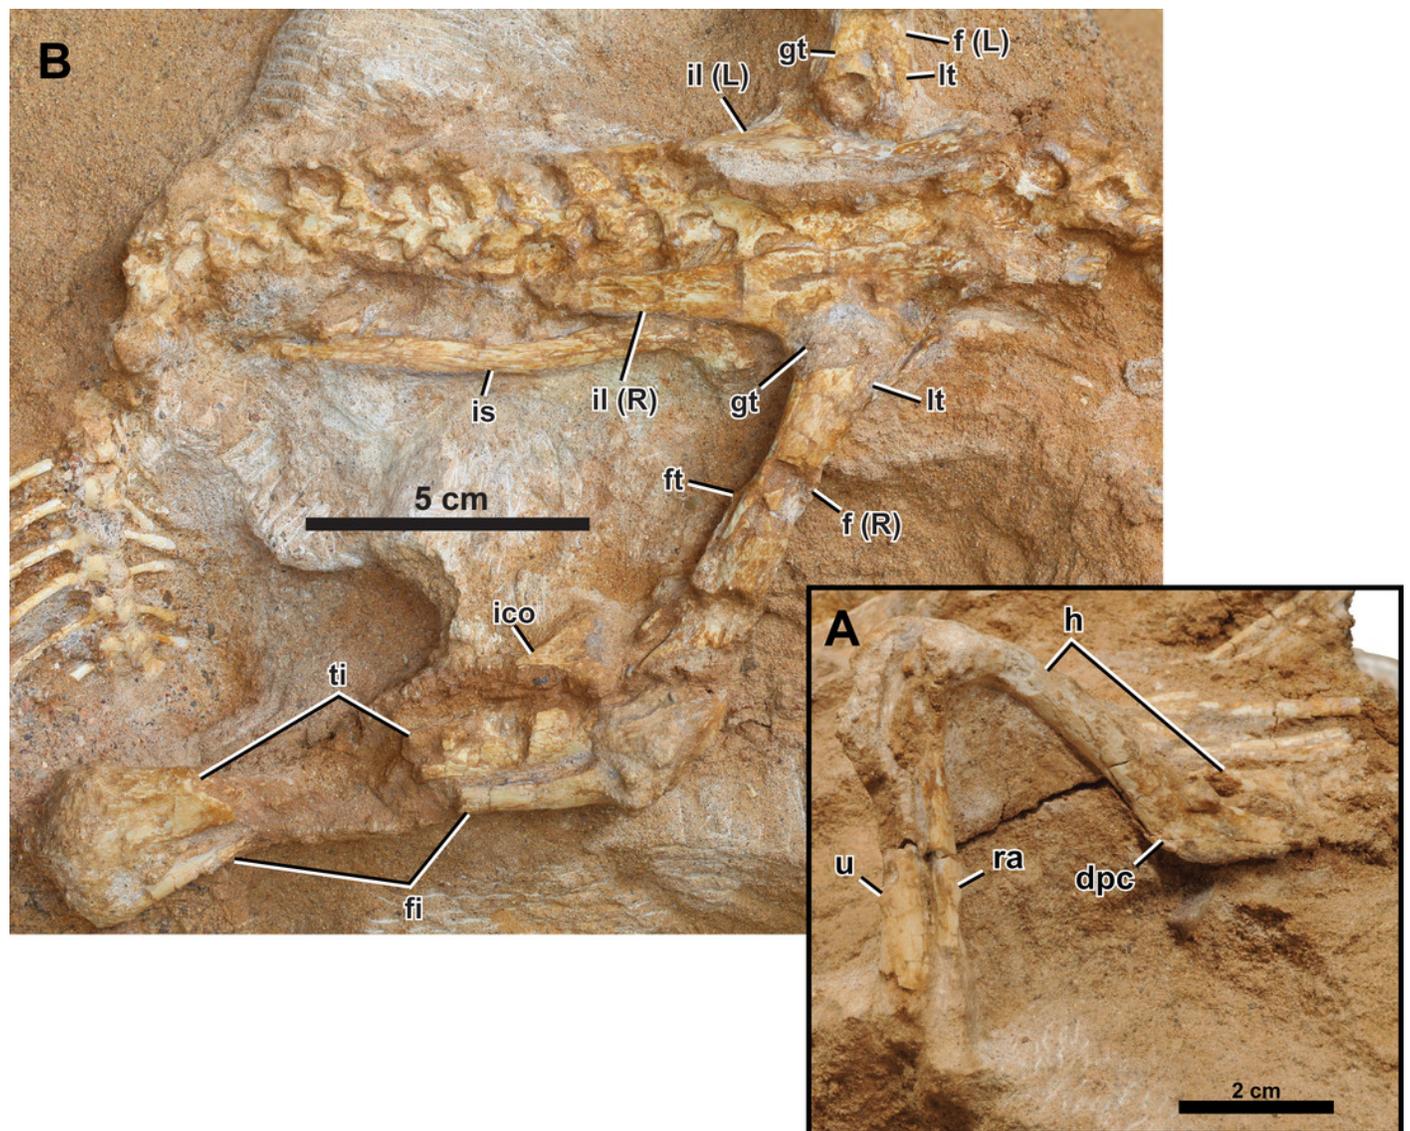

Figure 8

Left appendicular skeleton of *Yamaceratops dorngobiensis* (MPC-D 100/553).

(A) Ilium and pes in lateral view; (B) Pes in dorsal view. Abbreviations: f, femur; ft, fourth trochanter; gt, greater trochanter; L, bones on the left side; lt, lesser trochanter; mt, metatarsal; R, bones on the right side; il, ilium; I, pedal digit I; II, pedal digit II; III, pedal digit III.
