Background. Localized disturbances within established grasslands alter a suite of biological and chemical properties, leading to shifts in species composition. For example, relatively rare species in established communities may become dominant in successional communities if they exhibit traits that are suited to disturbance conditions. Although the idea that plant species exhibit different trait ‘strategies’ is well established, it is unclear how ecological selection for specific traits may change as a function of disturbance. Further, there is little data available testing whether disturbances select for single trait-characters within communities (homogenization), or allow multiple trait-types to persist (diversification). We investigated how (a) traits and (b) functional diversity of post-disturbance communities compared to those in adjacent undisturbed grasslands, and (c) if changes in functional diversity resulted in the homogenization or diversification of functional traits within local communities.

Methods. Here we emulate the impacts of an extreme disturbance in a mixed grassland site. We measured plant community composition of twelve paired plots in a native grassland within the central parkland of Alberta, Canada. Each pair consisted of one undisturbed plot and one which had all plants terminated two years prior. We used species abundances in conjunction with a local trait database to calculate community weighted means for maximum height, specific leaf area, specific root length, leaf nitrogen percent, and root nitrogen percent. To test the impacts of disturbance on community functional traits, we calculated functional diversity measures and compared them between disturbed and undisturbed local communities.

Results. Within two years, species richness and evenness in disturbed communities had recovered and was equivalent to undisturbed communities. However, disturbed and undisturbed communities had distinct community compositions that differed in functional diversity. Functional divergence was significantly lower in the disturbed plots. Further, disturbance was also linked to increases in community-weighted mean trait values associated with resource-acquisitive traits, such as specific leaf area, and leaf and root nitrogen.

Discussion. Disturbance had lasting effects on the functional traits and diversity of communities, despite traditional measures of biodiversity such as richness and evenness recovering within two years. There was a discrete shift in the trait space of post-disturbance communities compared to undisturbed communities such that post-disturbance communities were dominated by traits that enhance resource uptake and growth rates. Overall, these results show that disturbance fundamentally changes the functional character of communities, even if they superficially appear recovered.

Abstract

24 **Background.** Localized disturbances within established grasslands alter a suite of biological and
25 chemical properties, leading to shifts in species composition. For example, relatively rare
26 species in established communities may become dominant in successional communities if they
27 exhibit traits that are suited to disturbance conditions. Although the idea that plant species
28 exhibit different trait ‘strategies’ is well established, it is unclear how ecological selection for
29 specific traits may change as a function of disturbance. Further, there is little data available
30 testing whether disturbances select for single trait-characters within communities
31 (homogenization), or allow multiple trait-types to persist (diversification). We investigated how
32 (a) traits and (b) functional diversity of post-disturbance communities compared to those in
33 adjacent undisturbed grasslands, and (c) if changes in functional diversity resulted in the
34 homogenization or diversification of functional traits within local communities.

35 **Methods.** Here we emulate the impacts of an extreme disturbance in a mixed grassland site. We
36 measured plant community composition of twelve paired plots in a native grassland within the
37 central parkland of Alberta, Canada. Each pair consisted of one undisturbed plot and one which
38 had all plants terminated two years prior. We used species abundances in conjunction with a
39 local trait database to calculate community weighted means for maximum height, specific leaf
40 area, specific root length, leaf nitrogen percent, and root nitrogen percent. To test the impacts of
41 disturbance on community functional traits, we calculated functional diversity measures and
42 compared them between disturbed and undisturbed local communities.

43 **Results.** Within two years, species richness and evenness in disturbed communities had
44 recovered and was equivalent to undisturbed communities. However, disturbed and undisturbed
45 communities had distinct community compositions that differed in functional diversity.
46 Functional divergence was significantly lower in the disturbed plots. Further, disturbance was

47 also linked to increases in community-weighted mean trait values associated with resource-
48 acquisitive traits, such as specific leaf area, and leaf and root nitrogen.

49 **Discussion.** Disturbance had lasting effects on the functional traits and diversity of communities,
50 despite traditional measures of biodiversity such as richness and evenness recovering within two
51 years. There was a discrete shift in the trait space of post-disturbance communities compared to
52 undisturbed communities such that post-disturbance communities were dominated by traits that
53 enhance resource uptake and growth rates. Overall, these results show that disturbance
54 fundamentally changes the functional character of communities, even if they superficially appear
55 recovered.

56 **Introduction**

57 Habitat heterogeneity in grasslands is maintained in part by small-scale mortality
58 inducing disturbances, such as fossorial mammal activity (Davidson and Lightfoot, 2008;
59 Davidson, Detling, and Brown, 2012), drought (Godfree et al., 2011), overgrazing (di Virgilio
60 and Morales, 2016), pathogens (Mursinoff and Tack, 2017), and even herbicide drift (Fried,
61 Villers, and Porcher, 2018). In extreme instances, disturbance can result in the total mortality of
62 mature vegetation (e.g. Cahill 2003). Though each of these disturbances have unique
63 characteristics, they all result in the localized death of established vegetation, creating vegetation
64 “gaps” (Suding, 2001). Gaps result in changes to competitive hierarchies and abiotic soil
65 conditions and competitive hierarchies (Suding and Goldberg, 2001; Suding, 2001), leading to
66 changes in species diversity and community composition.

67 Examining traits can shed light on the specific impacts of disturbance on plant
68 communities. Traits are measurable individual morphological, physiological, or phenological
69 characteristics that provide insight into life history strategies and influence plant ranges and

70 species interactions (Viole et al., 2007; Cadotte, Carscadden, & Mirotnick, 2011). “Functional
71 traits” specifically impact growth, reproduction and survival (Viole et al., 2007). At small scales,
72 trait differences can influence local diversity patterns by determining competitive outcomes (Liu
73 et al., 2015). Traits can also provide insight as to species resource acquisition strategies by
74 indicating species location on the fast-slow plant economics spectrum, where “fast” strategies
75 prioritize resource acquisition and growth while “slow” strategies favour stress tolerance and
76 longevity (Reich et al., 2014). Measuring functional traits after a disturbance (such as those
77 which create gaps) can reveal how a community has changed in functional strategies and can be
78 used to examine the resulting community’s functional diversity. Cadotte (2007) describes gap
79 species as prioritizing rapid resource uptake, whereas non-gap species take a slower, tolerance-
80 based approach. For example, specific leaf area (SLA) values are likely to be larger in post-
81 disturbance successional communities as high SLA is correlated to fast growth and low
82 competitive ability (Kunstler et al., 2016). Additionally, Loughnan and Gilbert (2017) found that
83 SLA may be involved with shifts in competitive ability as greater SLA is associated with more
84 sunlight acquisition and thus increased energy acquisition. Thus, changes in communities post-
85 disturbance are likely due to differences in the trait profiles of successional species.

86 It is important to note that these changes in species composition and community-level
87 traits changes may not be reflected in the total number of species in the community (i.e. species
88 richness). Disturbance may change the nature of community assembly in successional
89 communities by altering the process by which species from the regional pool are able to colonize
90 local communities (HilleRisLambers et al., 2012, Escobedo et al., 2021). Disturbance changes
91 the environmental filters which constrain species dispersal and recruitment to communities
92 (Myers et al., 2015; Brown & Cahill, 2020); in this case we would expect the resulting

93 community to contain species that possess functional traits better suited to the new set of
94 environmental filters, changing the community-level traits and functional diversity of the
95 disturbed community. Thus, if taxonomic measures like species richness or evenness remain
96 unchanged after disturbance, they may mask functional differences and result in a mirage of
97 stability when, in fact, the community has undergone great change. This emphasizes the
98 importance of studying functional traits and quantifying functional diversity to understand
99 community drivers.

100 Functional diversity is a subset of biological diversity which measures the traits present
101 in an ecosystem (Tillman, 2001). It is distinct from taxonomic diversity as it reflects the breadth
102 of the functional space occupied by species in a community (Rosenfeld, 2002; Villéger et al.,
103 2008), whereas taxonomic diversity indicates the number of species in a given community
104 separate from any measure of community function (Laliberté and Legendre, 2010). Some
105 functional diversity measures are not greatly influenced by taxonomic measures such as species
106 richness (Laliberté and Legendre, 2010) and can offer a more nuanced approach to understanding
107 community characteristics. Disturbance affects functional diversity (Parreira de Castro, Dolédec,
108 & Callisto, 2018) and can potentially result in functional homogenization, or selection for similar
109 trait-characters in species colonizing in disturbed communities (Olden et al., 2004). However,
110 resource fluxes associated with disturbance (Davis, Grime, & Thompson, 2000) may lead to trait
111 diversification within colonizing species to allow for more efficient utilization of the increased
112 resources available in disturbed communities (Chapman, Childers, & Vallino, 2016; Jentsch &
113 White, 2019). As functional diversity is associated with the provisioning of ecosystem services
114 (Díaz et al., 2007; Roscher et al., 2012; Pakeman, 2014), the homogenizing or diversifying
115 effects of disturbance on functional diversity must be better understood.

116 If species in post-disturbance areas are more likely to possess traits which support faster
117 resource acquisition (e.g. Cadotte, 2007; Kunstler et al., 2016), then shifts in trait distributions
118 after disturbance may alter functional diversity by changing the success of different trait suites to
119 favor “fast” traits prioritizing resource acquisition at the local scale. However, it is unclear which
120 traits differ between plants in disturbed and undisturbed areas, and how these different strategies
121 are reflected in functional diversity. To resolve these outstanding questions, we ask:

- 122 1. How do functional traits of a grassland community change after disturbance?
- 123 2. How does functional diversity change after disturbance?
- 124 3. If functional distributions do change, will it result in the homogenization or
125 diversification of community-level traits?

126 If disturbance causes shifts in habitat filters, then we expect to observe shifts in the functional
127 trait space of the resulting community. If disturbance constrains the competitive strategies that
128 succeed in successional communities (for instance, favouring plants with resource-acquisitive
129 traits), we would expect changes in trait values (i.e. community-weighted means) and potentially
130 the homogenization of community-level traits. Alternatively, if species turnover after disturbance
131 drives shifts in community traits, we then expect to observe both taxonomic and functional trait
132 shifts, which could in turn diversify community-level traits.

133 **Methods**

134 **Study site**

135 Our study site was located in the Roy Berg Kinsella Research Ranch in Kinsella, AB,
136 Canada (53°5' N, 111°33' W). Data collection took place in a native grassland dominated by
137 *Hesperostipa curtiseta* (Hitc.) Barkworth, *Festuca hallii* (Vasey) Piper and *Poa pratensis* (L.)
138 (Brown and Cahill, 2019). The site is part of the Aspen Parkland ecoregion, a savanna-type

139 habitat characterized by a mosaic of mixed-grass prairie and trembling aspen (*Populus*
140 *tremuloides* Michx.). The field site is periodically grazed by cattle with a heavy grazing event in
141 October 2019 and a light grazing event occurring in May 2020.

142 **Study design**

143 We sampled twenty-four plots (50 cm x 50 cm), arranged in twelve pairs, which were
144 originally established in 2016 (Brown & Cahill, 2020). Each pair contained an undisturbed plot,
145 where no standing vegetation was terminated, and a disturbed plot, where all standing vegetation
146 was terminated. Disturbed plots were created in May 2016, by having all biomass trimmed to the
147 soil surface and a glyphosate herbicide (Roundup©) applied to the remaining stems to ensure
148 death of the resident vegetation. This treatment was maintained through August 2018 with any
149 regenerating plant materials trimmed and painted with herbicide during the growing seasons.
150 This treatment does not represent any specific natural event, and instead is testing the extreme
151 event of complete removal of the resident vegetation. Additionally, this treatment does not
152 remove the seed bank present at the site (Brown and Cahill, 2020) and thus does not affect
153 community regeneration from seed (see Grubb, 1977).

154 Plant community composition was measured in July 2018 by visually estimating percent
155 cover of all species present within each plot. Two years post-treatment, in July 2020, plot pairs
156 were revisited, by which time vegetation had regenerated in the disturbed plots. Community
157 composition was measured using percent cover estimation of each species. Sedges were unable
158 to be identified to species and were recorded as “*Carex* spp.”.

159 *Plant traits*

160 Disturbance can alter abiotic conditions (Suding and Goldberg 2001); however, here we
161 focus on its impacts on vegetative traits. Plant trait data came from a database developed

162 principally at this field site (Cahill, 2020), thus representing local trait data. Details of trait
163 measures are found in Cahill (2020), but largely follow the methods outlined in Cornelissen et al.
164 (2003) and Pérez-Harguindeguy et al. (2013). Here we focused on five traits which encompass
165 aspects of plant structure and above- and belowground resource acquisition: maximum height,
166 specific leaf area (SLA), specific root length (SRL), leaf nitrogen percentage (N %), and root N
167 %. See Cahill (2020) for trait definitions. These traits were chosen to provide a holistic scope of
168 above and below ground functional strategies with reference to trait groups described by Cadotte
169 (2017). Site-specific trait data was available in the database for all species except for *Cirsium*
170 *vulgare* (Savi) Tenore, *Collomia linearis* Nuttall, *Gentianella amarella* (Linnaeus) Börner,
171 *Sonchus arvensis* Linnaeus, and two unidentified forbs. Trait data was obtained for species that
172 represent at least 93% of total composition, which exceeds the 80% threshold standard for trait
173 studies (Pakeman & Quested 2007).

174 *Trait profiles and functional diversity*

175 To characterize communities by their traits, we first calculated community weighted
176 means (CWMs) for five traits: SLA, maximum height, leaf N %, root N %, and SRL. CWMs are
177 the average value of a given trait in a community weighted by the abundance of all species
178 possessing said trait (Lavorel et al., 2008), and are useful for understanding community
179 properties and dynamics, as well as quantifying community change (Garnier et al., 2004, 2007;
180 Louault et al., 2005). CWMs were calculated at the species-level. While disturbance is likely to
181 result in intraspecific variability in functional traits, here we focus on species-level values as a
182 first-level test to detect if disturbance does result in persistent change to community functional
183 traits. We encourage future studies to collect trait data from individual plants across species to
184 quantify how intraspecific trait variation changes with disturbance regimes. Outlier trait values

185 (values more than three standard deviations away from the species' mean) were removed prior to
186 calculating CWM. We then quantified the functional diversity of communities using functional
187 richness (FRic), functional evenness (FEve), functional divergence (FDiv), and Rao's quadratic
188 entropy (Q) (Villéger, Mason, & Mouillot, 2008; Mouchet et al., 2010; Table 1). These metrics
189 allow us to characterize the volume (via FRic), evenness (via FEve), and spread (via FDiv and
190 Q) of the communities' functional traits in multidimensional space. By using these multivariate
191 descriptors of communities, we are able to compare communities' character before and after
192 disturbance, as well as to determine if community traits become more or less homogenous as a
193 result of disturbance. We used package *vegan* (Oksanen et al., 2017) in program R (v 4.0.0; R
194 Core Team, 2020) to compute species richness and evenness, using methods from Oksanen
195 (2020). We used package *FD* (Laliberté, Legendre, & Shipley, 2014) to compute CWMs. We
196 also computed FRic, FDiv, FEve, and Rao's Q using package *FD*.

197 **Statistical analysis**

198 To determine if community traits differed between control and disturbed treatments after
199 recovery, we used five separate linear mixed models (LMMs). The CWM's for SLA, height, leaf
200 N %, root N %, and SRL were used as response variables, plot type (disturbed or undisturbed)
201 was a fixed effect and plot pair (i.e., disturbed and undisturbed plot location) was a random
202 effect. "Pair" was included as a random effect in models to account for spatial autocorrelation in
203 community data as disturbed and undisturbed plots were adjacent. All LMMs were run using an
204 underlying normal distribution with the *lme4* (Bates et al., 2015) and *lmerTest* (Kuznetsova,
205 Brockhoff, & Christensen, 2017) packages. We also used four separate LMMs to quantify how
206 functional diversity measures, namely FRic, FDiv, FEve, and Rao's Q, differed between
207 disturbance types. FRic, FDiv, FEve, and Rao's Q were used as response variables, plot pair was

208 included as a random effect and plot type (disturbed or undisturbed) was a fixed effect in all
209 models. Functional richness was log-transformed to fit assumptions of normality. To determine
210 whether disturbed and undisturbed communities had different community compositions, we
211 conducted a permutational multivariate analysis of variance (PERMANOVA), with plot as a
212 strata, using packages *vegan* and *RVAideMemoire* (Hervé, 2021).

213 **Results**

214 Between 2018 and 2020, total species richness in undisturbed plots decreased from 55 to
215 52 while average species richness in disturbed plots increased from 0 in 2018 to 53 in 2020
216 (Table S1). Six species were found only in disturbed communities (*Androsace septentrionalis*,
217 *Cirsium arvense*, *Mulgedium pulchellum*, *Thalictrum venulosum*, an unidentified *Brassicaceae*
218 plant, and an unidentified herbaceous dicot; Table S1). *Androsace septentrionalis*, *Cirsium*
219 *arvense*, and *Mulgedium pulchellum* are commonly found in disturbed areas (Tannas, 2004). In
220 particular, *Cirsium arvense* is associated high rates of reproduction and dispersal. 15 species
221 were found only in undisturbed communities (Table S1). These species, except *Fallopia*
222 *convolvulus*, are all native to Alberta (Desmet and Brouilet, 2013).

223 Despite persistent effects on local diversity, and although disturbed plots began with zero
224 species present in 2018, within two years there was no significant difference between plot-level
225 (alpha) richness and evenness between disturbed and undisturbed plots (richness = 17, evenness
226 = 0.82; Fig.1). However, underlying this similarity are differences in species composition ($R^2 =$
227 0.24, $F = 7.06$, $p = 0.001$; Fig. 2), with one third of plant species unique to either treatment type
228 (Fig. 1, Table S1). Post-disturbance communities were segregated from undisturbed communities
229 in multivariate space, with the exception of one disturbed/undisturbed pair (pair #12) (Fig. 2).

230 Community weighted means of SLA, leaf N %, and root N % differed between disturbed
231 and undisturbed plots, with disturbed plots typically having trait values more consistent with the
232 ‘fast’ end of the leaf economics spectrum. Specifically, disturbed plots had significantly larger
233 CWM for SLA, leaf %N, root %N, and there was a trend towards larger root SRL (Fig.3; Table
234 2). There was no difference in CWM of maximum height, indicating a more rapid recovery to
235 overall physiognomy relative to other functional characteristics of the communities.

236 Post-disturbance communities were functionally distinct from undisturbed communities
237 after two years of recovery. Undisturbed communities showed higher FDiv values ($FDiv = 0.08 \pm$
238 0.02 , $p = 0.0020$; Fig.4). FEve ($FEve = 0.07 \pm 0.02$, $p = 0.0129$; Fig.4), FRic (difference = $1.07 \pm$
239 1.16 , $p = 0.376$; Fig.4), and Rao’s Q (difference = 0.004 ± 0.002 , $p = 0.0733$; Fig.4) were not
240 significantly different among the two treatments (Table 3).

241 Discussion

242 Although local communities recovered in species richness after only two years, there
243 were a number of legacies of disturbance found in functional traits. There are persistent effects of
244 disturbance on local diversity, suggesting successional communities are shaped by a combination
245 of local dispersal and niche conditions. However, given competition can be reduced by
246 disturbance (Wilson & Tilman, 1993), dispersal most likely limits recruitment in post-
247 disturbance communities. At the same time, at the plot level we find there is great stability in
248 species richness and evenness, suggesting the local structure of communities in this system is
249 highly stable but the species who fill each “role” are variable. Thus, the functional differences
250 we observe are not due to fundamental changes in the dominance structure (i.e. evenness) of
251 successional communities, but rather due to species filtering.

252 Traits after disturbance

253 Consistent with *a priori* expectations, we show disturbance leads to functional shifts
254 favouring species with higher SLA, leaf N %, and root N %, which are important for the rapid
255 acquisition of resources. SLA and leaf nitrogen content are widely viewed as indicative of a fast-
256 growing, rapid nutrient acquisition strategy (Wright et al., 2004; Liu et al., 2017). Greater leaf
257 nitrogen content works in concert with high SLA to increase energy exploitation through
258 improved photosynthetic capacity, as high leaf N content is necessary for photosynthetic protein
259 functioning (Wright et al., 2004). High root N is also indicative of quick resource acquisition as
260 it is related to high root respiration, high foraging ability, and low root longevity (Craine et al.,
261 2002; Reich, 2014; Roumet et al., 2016; McCormack et al., 2017). SRL, while higher in post-
262 disturbance communities, was not significantly different between plot types. Typically SRL
263 indicates potential resource uptake per root mass investment (Reich, 2014), and high SRL is
264 associated with quick growth, high foraging capacity, and lower root longevity (Comas and
265 Eissenstat, 2004; Roumet et al., 2016); as such, that disturbed communities did not show
266 significantly higher SRL is contrary to our expectations. Overall, the higher levels of SLA, leaf
267 N %, and root N % among the disturbed plots signal post-disturbance conditions permit the
268 success of quick-growing plants that can quickly access resources. Thus, it is likely that the
269 spatial variability of disturbances in this system are an important means to create functional
270 variation across the landscape.

271 Height variation in grasslands is a significant predictor of species richness and
272 community productivity (Brown and Cahill, 2019), yet we found that maximum height recovers
273 quickly (within two years) after disturbance and is not significantly different among successional
274 and undisturbed communities. This is surprising as greater height is thought to be indicative of
275 greater competitive ability (Givnish, 1995; Cornelissen et al., 2003; Falster and Westoby, 2003).

276 **Functional diversity after disturbance**

277 Disturbance causes a number of changes to functional diversity, with functional diversity
278 typically increasing in post-disturbance communities (Purschke et al., 2013; Eler et al., 2018).
279 However, we observed that disturbance either decreased or did not affect functional diversity
280 measures. There was no difference in FRic values between the disturbed and undisturbed plots,
281 indicating both treatments filled the same amount of functional niche space (Schleuter et al.,
282 2010). Similarly, FEve did not differ between treatments, denoting that species abundances
283 and/or the functional distances between species were equally even in disturbed and undisturbed
284 plots. However, FDiv values were significantly higher in undisturbed communities. Lower FDiv
285 values in the disturbed plots signify that the most abundant species in disturbed plots had more
286 homogenous trait ranges. Thus, while disturbance does not affect the breadth or evenness of
287 community functional traits, it does lower FDiv, promoting homogenization of functional
288 diversity.

289 **Conclusions**

290 Overall, we found while traditional metrics of community composition such as species
291 richness and evenness recovered within two years of disturbance, there were persistent impacts
292 of disturbance on community-level traits and functional diversity. SLA, leaf N %, and root N %
293 values were significantly larger in the disturbed condition, supporting the conclusion that species
294 in post-disturbance areas are more likely to possess traits that support faster resource acquisition.
295 The prevalence of individuals possessing these “fast” traits was reflected in distinct differences
296 in community membership among undisturbed and post-disturbance communities. Disturbance
297 also impacted functional diversity by promoting homogenization of community’s functional
298 traits. In all, this work suggests functional trait shifts from small disturbances are a critical

299 mechanism for maintaining spatial heterogeneity in grassland systems, even as species richness
300 and evenness recover.

Table 1 (on next page)

Functional diversity metric definitions.

| Functional diversity metric definitions | |
|---|--|
| Functional diversity (FD) | The functional space occupied by species, where axes are functional features (Rosenfeld, 2009; Vileger et al. 2008). The functional differences between a group of species (Tillman, 2001) |
| Functional richness (FRic) | The breadth of functional space filled by a communities (Villegger et al. 2008) |
| Functional evenness (FEve) | The evenness of the distribution of abundances and functional features of species (Villegger et al. 2008) |
| Functional divergence (FDiv) | The average distance of species abundances from the centre of functional space (Mouchet et al. 2010) |
| Rao's quadratic entropy (Q) | The average functional distance between two randomly selected species in a group (Mouchet et al. 2010). |

Table 2 (on next page)

Results of the linear mixed models (LMM) for traits.

Community weighted means for specific leaf area (SLA), height, shoot percent nitrogen (shoot N %), root percent nitrogen (root N %), and specific root length (SRL) were used as response variables in separate models. Plot pair (i.e., disturbed and undisturbed plot location) was a random effect and plot type (disturbed or undisturbed) was used as the fixed effect. SE stands for standard error and df denotes degrees of freedom. Bold type indicates significant results.

1

| | Disturbed plot mean \pm SE | Undisturbed plot mean \pm SE | df | <i>p</i> -value |
|--|---------------------------------|-----------------------------------|----|-------------------------------|
| Maximum height (cm) | 35.78 (\pm 1.05) | 36.30 (\pm 1.16) | 11 | 0.66 |
| Specific leaf area (cm ² /g) | 139.96 (\pm 2.99) | 119.34 (\pm 2.99) | 11 | 2.64 x 10⁻⁵ |
| Specific root length (cm/g) | 5612.82 (\pm 448.19) | 4550.30 (\pm 570.50) | 11 | 0.09 |
| Leaf nitrogen (%) | 1.92 (\pm 0.04) | 1.74 (\pm 0.06) | 11 | 0.01 |
| Root nitrogen (%) | 1.05 (\pm 0.03) | 0.95 (\pm 0.04) | 11 | 0.02 |

Table 3(on next page)

Results of the linear mixed models (LMM) for functional diversity.

Functional richness (FRic), functional divergence (FDiv), functional evenness (FEve), and Rao's Q were used as response variables in separate models. Plot pair (i.e., disturbed and undisturbed plot location) was a random effect and plot type (disturbed or undisturbed) was a fixed effect. SE stands for standard error and df denotes degrees of freedom. Bold type indicates significant results.

1

| | Disturbed plot mean \pm SE | Undisturbed plot mean \pm SE | df | <i>p</i> -value |
|---------------------------|---------------------------------|-----------------------------------|----|-----------------|
| FRic (log transformed) | -39.96 (\pm 0.92) | -38.75 (\pm 1.22) | 11 | 0.345 |
| FEve | 0.66 (\pm 0.02) | 0.69 (\pm 0.02) | 11 | 0.218 |
| FDiv | 0.73 (\pm 0.02) | 0.81 (\pm 0.02) | 11 | 0.003 |
| Rao's Q | 0.02 (\pm 0.001) | 0.02 (\pm 0.002) | 11 | 0.078 |

Figure 1

Average species evenness and richness of disturbed and undisturbed plots in 2018 and 2020.

In disturbed plots, all biomass was trimmed to the soil surface and a glyphosate herbicide (Roundup©) applied to the remaining stems to ensure death of the resident vegetation from 2016 - 2018. Plots were allowed to regenerate from 2018 - 2020. Undisturbed plots had no standing vegetation removed. Species evenness and richness was recorded in the summer of 2020. Error bars represent standard error.

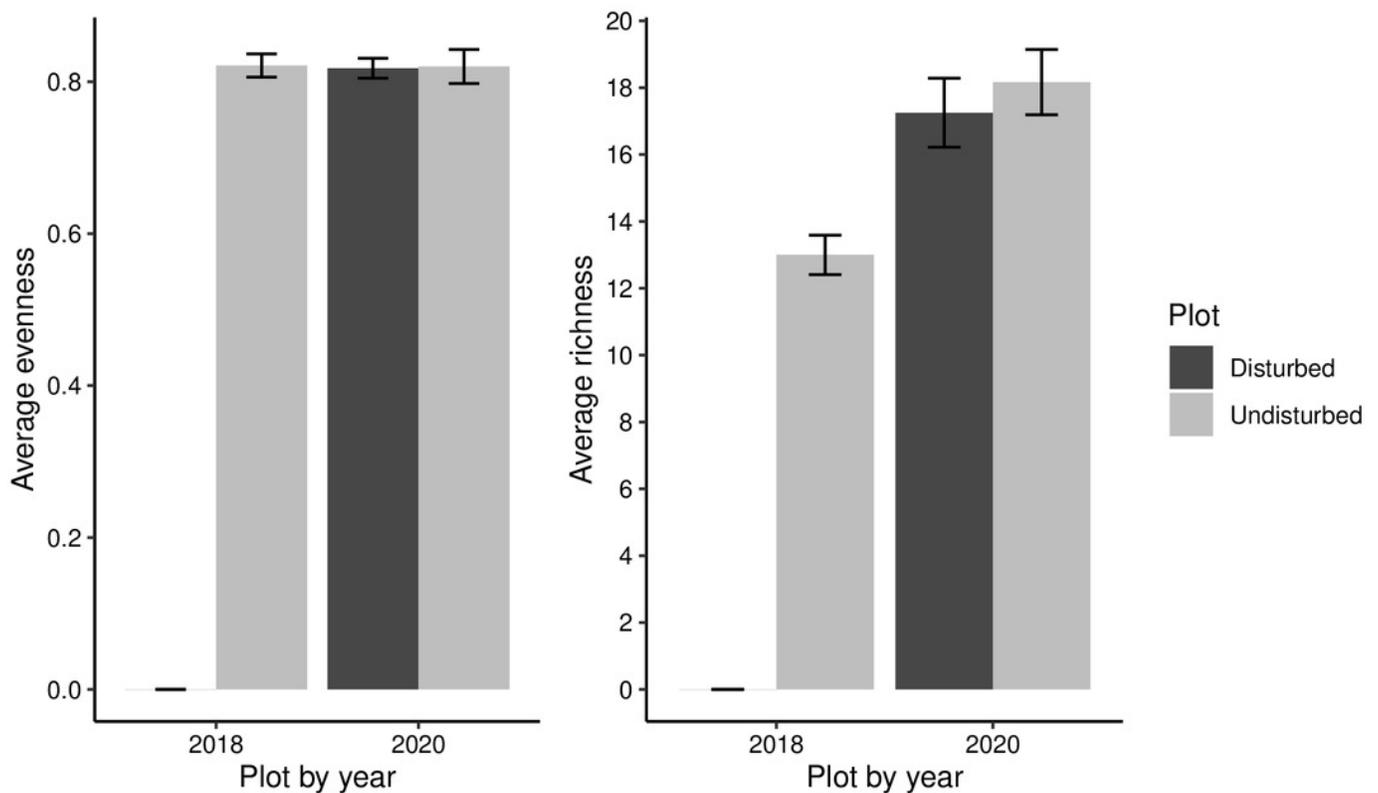

Figure 2

Metric multidimensional scaling (MDS) of disturbed and undisturbed community composition.

Data points denote 2020 plant community composition in disturbed and undisturbed plots. In disturbed plots, all biomass was trimmed to the soil surface and a glyphosate herbicide (Roundup©) applied to the remaining stems to ensure death of the resident vegetation from 2016 - 2018. Plots were allowed to regenerate from 2018 - 2020. Undisturbed plots had no standing vegetation removed. Community composition was assessed in the summer of 2020.

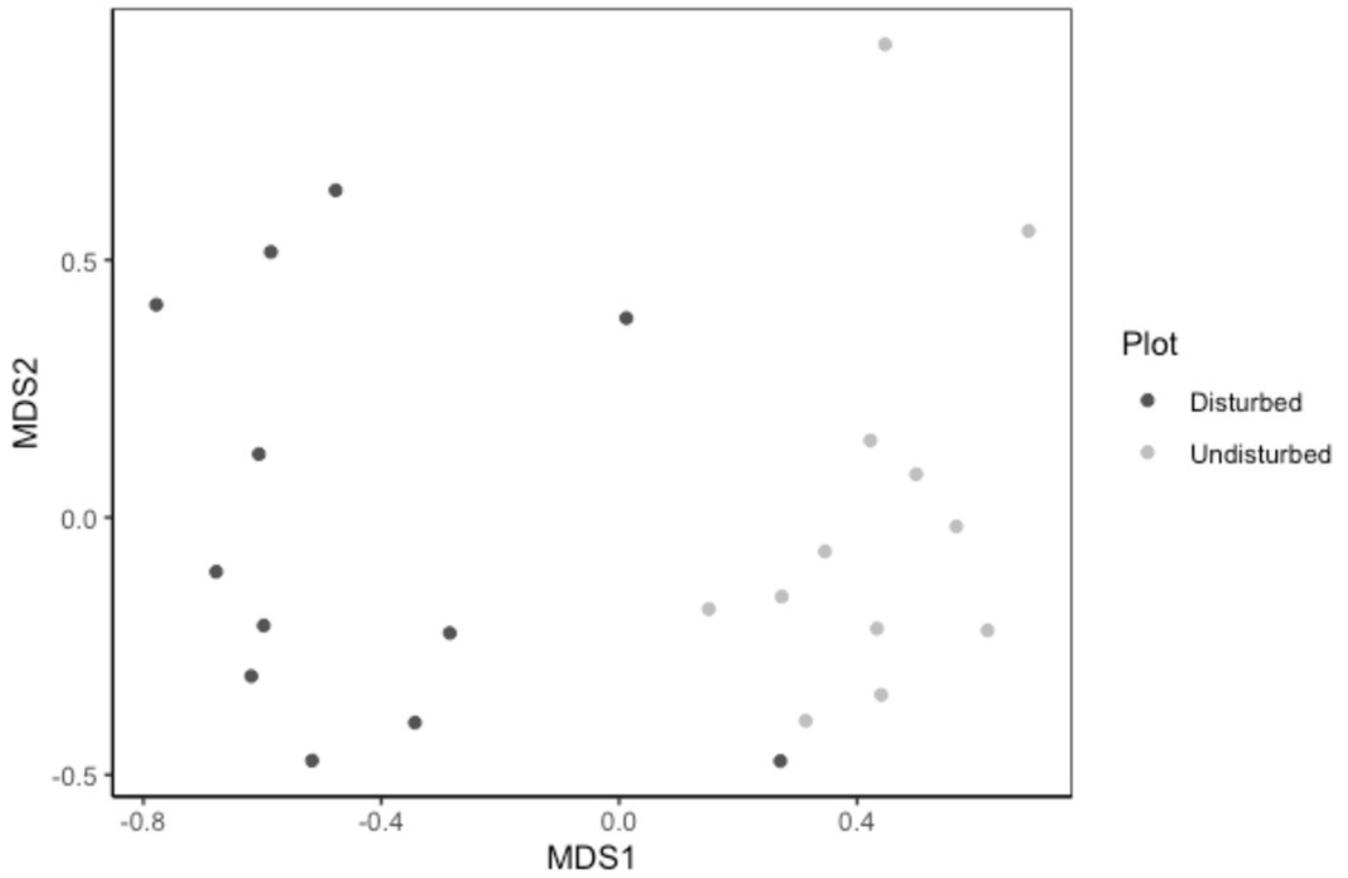

Figure 3

Mean trait values in 2020 disturbed and undisturbed communities.

Comparisons of specific root length, maximum height, specific leaf area, root nitrogen, and leaf nitrogen between disturbed and undisturbed communities. Error bars represent standard error. Associated statistics are found in Table 2.

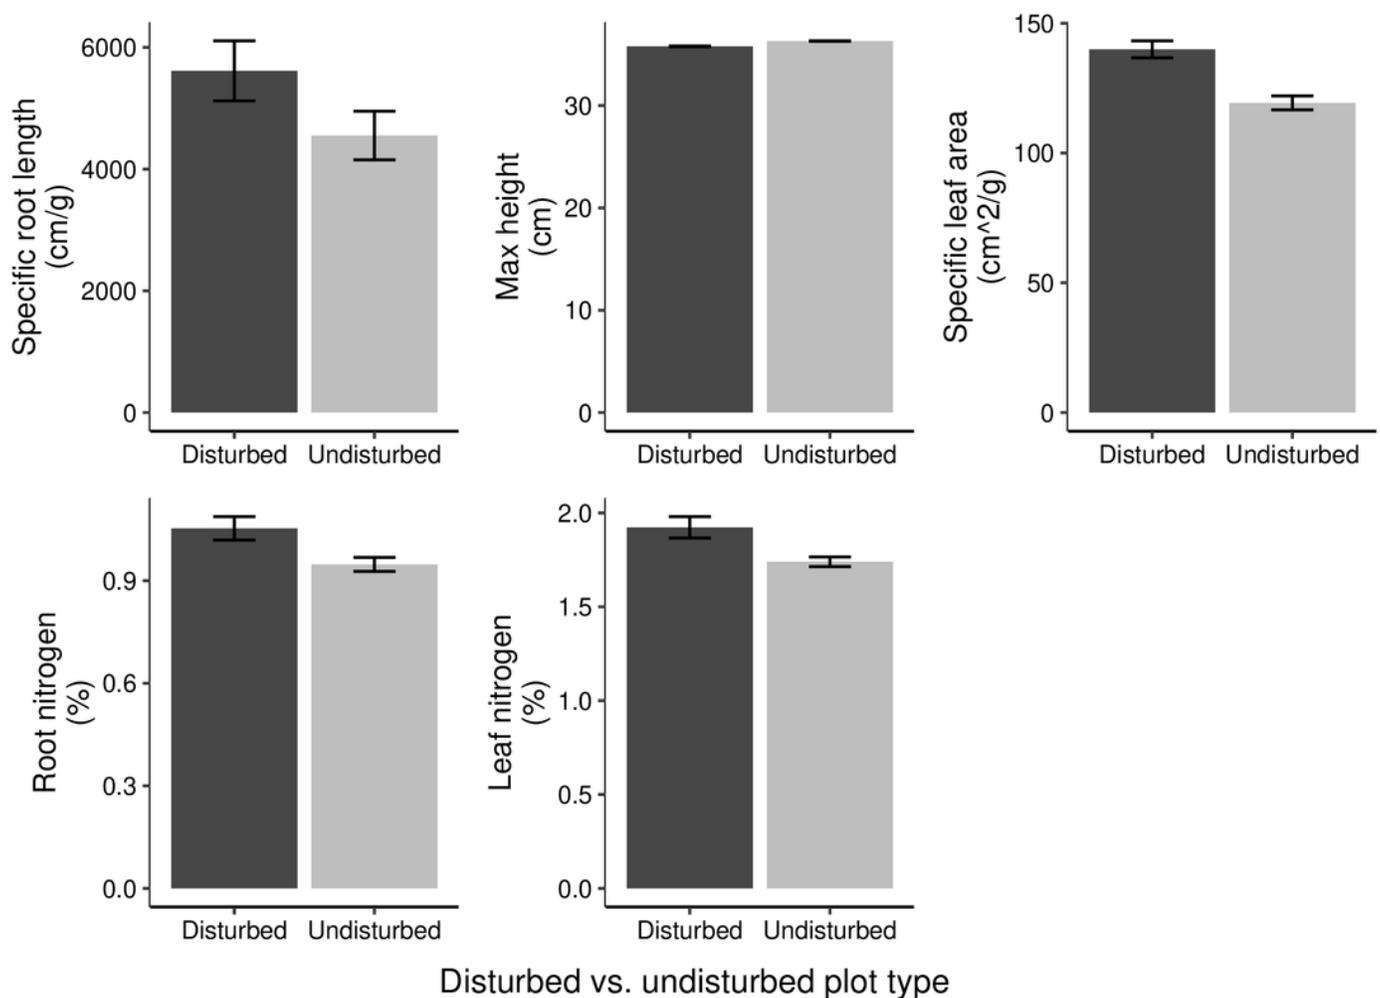

Figure 4

Estimates of functional diversity values in 2020 disturbed and undisturbed communities.

Comparisons of functional richness, functional evenness, functional divergence, and Rao's quadratic entropy between disturbed and undisturbed communities. Functional richness was log-transformed to meet the assumption of normality and was multiplied by negative one. Error bars represent standard error. Associated statistics are found in Table 3.
