Background. Domestication, including selective breeding, can lead to morphological changes of biomechanical relevance. In birds, limbs proportion and sternum characteristics are of great importance and have been studied in the past for its relation with flight, terrestrial locomotion and animal welfare. In this work we studied the effects of domestication and breed formation in limb proportions in chicken, mallard ducks and Muscovy ducks.

Methods. Here we analysed the scaling of limb proportions. First, we quantified the proportional length of three long bones of forelimb (humerus, radius and carpometacarpus) and hind limb (femur, tibiotarsus and tarsometatarsus) of red jungle fowl and its domestic counterpart, chickens (*Gallus gallus*), and of analogous comparisons for mallard duck (*Anas platyrhynchos*) and Muscovy duck (*Cairina moschata*). We compared sternum characteristics in red jungle fowl and 9 chicken breeds.

Results. We found a lack of significant change in the proportions of long bones of chicken and Muscovy duck due to domestication, but significant differences in the case of mallard ducks. Variation of evolvability, allometric scaling, and heterochrony may serve to describe some of the patterns of change we report. Flight capacity loss in mallard ducks resulting from domestication may have a relation with the difference in proportions. The lack of variation in proportions that could distinguish domestic from wild forms of chicken and Muscovy ducks may reflect less intensive selection for flight capacity. In chicken, some of the differences identified in the traits discussed are breed-dependent. The study of the sternum revealed a higher frequency of notched carina sterni in the red junglefowl compared to domestic chicken. The condition of crooked keel, however, is not unique to chicken. Despite some similar morphological changes identified across species, this study highlights the lack of universal patterns in domestication and breed formation.

20 **Abstract**

21 **Background.** Domestication, including selective breeding, can lead to morphological changes of
22 biomechanical relevance. In birds, limbs proportion and sternum characteristics are of great
23 importance and have been studied in the past for its relation with flight, terrestrial locomotion
24 and animal welfare. In this work we studied the effects of domestication and breed formation in
25 limb proportions in chicken, mallard ducks and Muscovy ducks.

26 **Methods.** Here we analysed the scaling of limb proportions. First, we quantified the proportional
27 length of three long bones of forelimb (humerus, radius and carpometacarpus) and hind limb
28 (femur, tibiotarsus and tarsometatarsus) of red jungle fowl and its domestic counterpart, chickens
29 (*Gallus gallus*), and of analogous comparisons for mallard duck (*Anas platyrhynchos*) and

30 Muscovy duck (*Cairina moschata*). We compared sternum characteristics in red jungle fowl and
31 9 chicken breeds.

32 **Results.** We found a lack of significant change in the proportions of long bones of chicken and
33 Muscovy duck due to domestication, but significant differences in the case of mallard ducks.
34 Variation of evolvability, allometric scaling, and heterochrony may serve to describe some of the
35 patterns of change we report. Flight capacity loss in mallard ducks resulting from domestication
36 may have a relation with the difference in proportions. The lack of variation in proportions that
37 could distinguish domestic from wild forms of chicken and Muscovy ducks may reflect less
38 intensive selection for flight capacity. In chicken, some of the differences identified in the traits
39 discussed are breed-dependent. The study of the sternum revealed a higher frequency of notched
40 carina sterni in the red junglefowl compared to domestic chicken. The condition of crooked keel,
41 however, is not unique to chicken. Despite some similar morphological changes identified across
42 species, this study highlights the lack of universal patterns in domestication and breed formation.

43

44 **Introduction**

45 Through domestication, much morphological diversity has been generated (Darwin, 1868; Herre
46 & Röhrs, 1990). Domesticated animals exhibit phenotypic changes compared to their wild
47 counterparts (Clutton-Brock, 1999). This is the case in domestic birds, as in recent works on the
48 skulls of pigeons and chickens (Young, et al., 2017; Stange, et al., 2018) and the integument in
49 chickens (Núñez-León, et al., 2019). In contrast, postcranial anatomy, including limb bones, has
50 rarely been dealt with analytically and globally in domesticated species (see Wayne 1986 for
51 dogs; van Grouw 2018 for an overview for many species), despite having been widely studied in
52 - - bird evolutionary biology (Middleton & Gatesy, 2000; Dyke & Nudds, 2009; Nudds, et al.,
53 2013). Mentioned in Darwin's 1868 'Variation in Animals and Plants Under Domestication',
54 changes in limb length (or lack thereof) in domestic birds can be observed. Especially notable is
55 the reduction of wing length of the mallard duck after domestication (Darwin, 1868).

56 Limb proportions can be of importance in biomechanical processes such as flight ability.

57 Middleton and Gatesy (2000) highlighted the humerus relative proportion in the forelimb, where
58 flightless birds have relatively longer humeri while flight manoeuvrability is being linked to
59 shorter humeri. The selective pressure for flight is thus expected to influence the relative
60 proportion of the different bones in the forelimb (Mason, 1984). Chickens are considered short-

61 distance non-migrant flyers, however their flight capability is breed-dependent (Schippers, et al.,
62 2013). Although certain breeds are known to have completely lost their flight capacity (e.g.
63 Ukokkei and Polish breeds) this is largely attributed to the unfitnes of their plumage for such
64 task (Ekarius, 2007; Smith, 2018). Other breeds are short-distance flyers, including the wild type
65 red junglefowl (RJF), but differences in flight capacity have been reported depending on the
66 weight of the breed: the heavier, the less prone to sustained flight (Darwin, 1868; Schippers, et
67 al., 2013).

68 It is generally agreed that domestic mallard ducks have lost their flight capacity when compared
69 to their wild counterpart, which in contrast to chickens, are long distance migratory birds
70 (Accordi & Barcellos, 2006). This change has been attributed to a gain in weight and reduction
71 in the proportional wing length (Darwin, 1868; Cnotka, 2006). Because domestic Muscovy
72 ducks can fly (Anon., 2016; Anon., 2017), their feathers are trimmed or clipped to discourage
73 flight in breeding farm (Smith, 2007). Unlike the case of differences in wing length between
74 domestic and wild mallards, finding osteological differences between domestic and wild
75 Muscovy ducks has proven more difficult (Angulo, 1998; Stahl, et al., 2006).

76 Another skeletal element of biomechanical importance in birds is the sternum, the site of
77 attachment of the pectoralis muscle, important for producing mechanical work during
78 downstroke and pronating the wing, and the supracoracoideus muscle, which elevates and
79 supinates the wing during upstroke (Biewener, 2011). This element varies in shape and
80 proportions and is a source of intensive study in poultry research concerned with welfare due to
81 widespread reports of damage ranging between 30 and 100% of commercial hens (Fleming, et
82 al., 2004; Harlander-Matauschek, et al., 2015; Toscano, et al., 2020). Keel damage may include
83 crookedness or bending, as well as fractures (Casey-Trott, et al., 2015). The problem appears
84 somewhat historical as it was referred to by Darwin (1868, p. 282) as ‘generally so much
85 deformed that it is scarcely possible to compare its form strictly in the several breeds’. The
86 crookedness of the keel has been largely studied in the context of its causes, its relation with
87 animal welfare, and its effect on productivity (Blount, 1933; Warren, 1937; Waters, 1949;
88 Fleming, et al., 2004) and the market value of the domestic chicken (Hyre, 1995). Keel
89 crookedness has been reported to have environmental and genetic origins, appearing mostly
90 when chickens are given the opportunity to perch (Blount, 1933; Warren, 1937; Waters, 1949).
91 However, whether crookedness of the keel is associated with domestication in its initial, less

92 intense phase (Vigne, 2011), or if it appeared only with breed formation and improvement has
93 not been determined. Deformations of the keel can be divided into two types: fractures, defined
94 as sharp bends, fragmented sections or shearing of the keel; and deviations, defined as
95 abnormally shaped bone containing section(s) that vary from an ideally perfect two-dimensional
96 straight plane that has not resulted from fracture (Casey-Trott, et al., 2015). Here we use the term
97 ‘crookedness’ to denote exclusively the deviations, not fractures, of the keel, as defined in
98 Casey-Trott et al. (2015).

99 In this study, we analysed the limb proportions of three domestic species: chicken (*Gallus*
100 *gallus*), mallard duck (*Anas platyrhynchos*) and Muscovy duck (*Cairina moschata*) in order to
101 determine whether there has been changes due to domestication and breed formation. We
102 examined this matter in the context of evolvability, allometry, heterochrony, and selective
103 pressures (artificial selection) that affect flight capacity. In the case of chickens, we examined
104 these changes also among a diversity of breeds. Further, we investigated variation in the sternum
105 by coding discrete features that characterize its variation between fowl and chicken in order to
106 study differences among breeds. Specifically, we examined the crookedness of the keel,
107 extensively studied in the past but never comparing breeds (Blount, 1933; Warren, 1937; Waters,
108 1949; Hyre, 1995; Fleming, et al., 2004; Kittelsen, et al., 2020), plus three other features:
109 presence of a notch on the ventral margin of the carina sterni, sponginess or smoothness of the
110 foramen pneumaticum and pars cardiaca and shape of the caudal end of the trabecula mediana.

111

112 **Materials & Methods**

113 **Measurements.** We took measurements of the length of the humerus, radius and
114 carpometacarpus of the forelimb and length of the femur, tibiotarsus and tarsometatarsus and of
115 the hind limb. For each bone, we measured the length as the maximum length of the bone
116 parallel to the measuring device (using digital calipers to the nearest tenth of a mm), coinciding
117 with the anatomical structures shown in *Fig. 1*.

118 We considered the proportion of a bone to be the proportion of that bone with respect to the total
119 length of the limb. The total length of the forelimb was taken as the sum of the lengths of the
120 carpometacarpus, radius and humerus, while the total length of the hind limb was taken as the
121 sum of the lengths of the tarsometatarsus, tibiotarsus and femur (*Fig. 2*).

122 **Specimens.** We compared proportions between the wild and domestic forms of different bird
123 species: *Gallus gallus*, *Anas platyrhynchos* and *Cairina moschata* (*Table 1*). We chose these
124 three species for their historical importance in bird domestication and wide availability in
125 osteological collections where the labelling as wild and domestic forms is reliable. We only
126 considered adult skeletally mature specimens for this work, with individuals considered adults
127 when the epiphyses of all long bones were externally completely fused to the diaphyses.
128 As the wild forebearer of the chicken we used the RJF (Al-Nasser, et al., 2007; Lawal, et al.,
129 2020) although there has been introgression of grey junglefowl. (Eriksson, et al., 2008; Lawal, et
130 al., 2020). For the mallard duck and the Muscovy duck, we have used their wild counterparts
131 available in the visited museum osteological collections.

132 In *Gallus gallus*, we measured 29 RJFs and 103 domestic chickens for the forelimb and 28 RJFs
133 and 99 chickens for the hind limb (*Table 2*). We excluded the modern meat lines (broilers) due to
134 their short life span, resulting in an insufficient osteological maturation to be considered valid as
135 adult specimens with the criterion used in this work, since the epiphyses of their long bones are
136 not completely fused to the diaphyses (Zuidhof, et al., 2014; Bennett, et al., 2018). In *Anas*
137 *platyrhynchos*, 56 wild and 32 domestic specimens were measured. Of the 32 domestic mallards,
138 seven were from known breeds (four Aylesbury, two Black Labrador or Buenos Aires Drake and
139 one Khaki Campbell). Given the low number of labelled breeds, we only made the distinction
140 between wild and domestic mallards. In *Cairina moschata*, 39 wild and 17 domestic specimens
141 were measured.

142 The specimens used for this study are housed in the Paläontologisches Institut und Museum,
143 Universität Zürich (Switzerland), Naturmuseum Senckenberg (Germany), Staatssammlung für
144 Anthropologie und Paläoanatomie München (Germany), Zoologisches
145 Institut/Populationsgenetik (former Institut für Haustierkunde), Christian-Albrechts-Universität
146 zu Kiel (Germany), Natural History Museum at Tring, Bird Collection, General and Darwin
147 collection (United Kingdom).

148 **Analyses.** We performed independent two-tailed student's t-tests to check for differences in the
149 limb bones proportions in their respective limb between wild and domestic forms for all species.
150 Further, we performed independent two-tailed student's t-tests to check for differences in limb
151 length, as a proxy for body size, between domestic and wild forms of the three species in this
152 study (*Fig.3*). In the case of *Gallus gallus*, we also tested if there are significant differences in

153 the proportions among breeds (*Table 3*). For this, we used only domestic breeds with sample size
154 greater than four, namely Araucana, bantam, Chabo, cochin, Ukokkei, ‘Italiener’, Kömpfer,
155 Shamo and Polish as well as the RJF. Due to violation of assumptions of normality and
156 homoscedasticity (*Table S1* and *Table S2* in supplementary materials), we performed non-
157 parametric Kruskal-Wallis tests.

158 In order to determine the explanatory power of body size on long bone proportions in *Gallus*
159 *gallus*, *Anas platyrhynchos*, and *Cairina moschata*, we performed linear regressions using hind
160 limb and forelimb total length as a proxy of body size, respectively. We contrasted the log-
161 transformed values of each bone with the log-transformed values of the total length of the
162 correspondent limb. Total limb length is the best approximation available, since the age of the
163 used specimen might be variable, even though all were skeletally mature, and using the mean
164 breed weight or size could be more problematic. To determine if the regression slopes were equal
165 to 1 (null hypothesis of isometry), we determined if the 95% confidence intervals of the slopes
166 included 1.0. We assumed positive or negative allometry to best explain a given scaling
167 relationship if the confidence interval of the regression did not include 1, with a slope of > 1.0 or
168 < 1.0 , respectively. Similar as for the adult sample described here, we extracted data about limb
169 bone dimensions of chicken embryos and juveniles from the literature and determined allometric
170 growth patterns as described for the adult sample. In order to illustrate the distribution of
171 proportions of the hind limb bones in the morphospace of *Gallus gallus* during pre-hatching
172 development, data were taken from Thomas, (2014) and Faux and Field (2017) and we
173 performed the same analyses as for the regression slopes of the three species previously
174 mentioned. The results are displayed in *Fig. 4* and *Table 4*.

175 In the following summary of feature variations, we account for five characters of the sternum of
176 *Gallus gallus* across nine different domestic breeds and the RJF as their wild counterpart.
177 Sternum characters were coded in 63 *Gallus gallus* specimens from which 12 were RJF and the
178 rest belonged to domestic breeds.

179 **Description of character states.**

180 • Carina sterni is defined as ‘straight’ when the direction of growth is maintained in a
181 straight line, as opposed to ‘crooked’, in which the growth is tortuous with one or multiple
182 pronounced torsions (*Fig. 5a*).

- 183 • Carina sterni is defined as ‘notched’ when the direction of the lower margin of the carina
184 in lateral view changes direction, creating a notch. It is defined as ‘non notched’ if this does not
185 happen (*Fig.5b*).
- 186 • Pars cardiaca (PC) and Foramen pneumaticum (FP) are described as ‘spongy’ or
187 ‘smooth’ depending on the type of external appearance, either porous or flat respectively
188 (*Fig.5c*).
- 189 • The caudal end of the trabecula mediana of the sternum is differentiated between
190 ‘fanned’ (end wider than the rest of the trabecula in dorsal view) and ‘straight’ (end as wide as
191 the rest of the trabecula in dorsal view; *Fig.5d*).

192

193 **Results**

194 The two-tailed, independent t-test for the proportion of long bones of the forelimbs and hind
195 limbs performed comparing wild versus domestic in three species: *Gallus gallus*, *Anas*
196 *platyrhynchos* and *Cairina moschata* show that significant differences in limb proportions only
197 occur in *Anas platyrhynchos* (*Table 2*). Domestic mallard ducks, compared to their wild
198 counterpart, have proportionally longer humeri and shorter radii and carpometacarpi in the case
199 of the wing, and proportionally longer tarsometatarsi and shorter femurs in the case of the hind
200 limb (*Fig. 6*).

201 The Kruskal-Wallis test comparing limb proportions among chicken breeds revealed significant
202 differences in the selected breeds (*Table 3*). The detailed pairwise comparison is shown in *Fig. 7*
203 and the supplementary materials for breeds with sample size equal or greater than five (*Table*
204 *S3*).

205 A brief comparison of the total forelimb length, showing the substantial size variation, in
206 different breeds of *Gallus gallus* is provided in *Table 5*. The lengths of the long bones are
207 strongly and significantly correlated with the total size of the corresponding limb as a proxy for
208 body size in chicken, mallard ducks, and Muscovy ducks (*Fig. 8, Table 6*). Pairwise comparisons
209 of total limb length between wild and domestic forms in each species, as a proxy for body size,
210 show that the domestic varieties are larger than the wild ones in *Gallus gallus* and *Anas*
211 *platyrhynchos* but no significant differences were observed in *Cairina moschata* (*Fig. 3*). Our
212 observations on the characters of the sternum are summed up in *Table 7*.

213

214 Discussion

215 Given the previous studies on differences between wild and domestic animals and the
216 importance in locomotion of forelimb and hind limb proportions and sternum characteristics, we
217 aimed to determine whether differences exist between wild and domestic forms of three bird
218 species and to shed light on the possible underlying mechanisms.

219 We observed no evidence of significant differences between wild and domestic forms of *Gallus*
220 *gallus* in the proportional length of the long bones of the forelimbs (humerus, radius and
221 carpometacarpus) and hind limbs (femur, tibiotarsus and tarsometatarsus; *Table 1*). However,
222 when the RJF and breeds of domestic chicken were analysed as individual groups, significant
223 differences were detected (*Fig.7, Table S3*). One possible interpretation is for diversification to
224 have taken multiple directions in the case of the limb proportions in domestic birds, but selection
225 has not provoked a unique directionality, maintaining the same mean proportions between
226 domestic and wild forms in all bones. The most notable case of breed-specific specialisation is
227 the Chabo, also known as Japanese bantam. Chabo is a true bantam breed (i.e. it does not present
228 a large variant) with characteristically short legs (Roberts, 2008). The short leg trait is associated
229 with a dominant allele of gene *Cp*, which is lethal in homozygosis (Shibuya, et al., 1972;
230 Shibuya & Kuroda, 1973) and is selected as a distinct characteristic of the breed (Van Grouw,
231 2018). The *Cp* gene accelerates differentiation of chondrocytes accompanied by suppression of
232 their proliferation, leading to stunted limb long bone growth (Shibuya, et al., 1972). Similar
233 phenotypes are also known in domestic dogs (e.g. Dachshund, Corgi) and cats, and represent
234 cases of specialisation in breed formation (Rimbault & Ostrander, 2012).

235 Our results further show that proportions of the bones in *Anas platyrhynchos* vary significantly
236 when comparing wild and domestic forms (*Table 1; Fig.6*). Unlike wild and domestic *Gallus*
237 *gallus*, domestic forms of the mallard duck thus show a set of proportions in the long bones that
238 is significantly different from the wild form. Since body size differences were marked between
239 the wild and domestic forms of the three investigated species, with the domestic forms being on
240 average larger than their wild relatives in *Gallus gallus* and *Anas platyrhynchos* (*Fig.3*), we
241 compared the log-transformed length of the long bones with the log-transformed total length of
242 the limb as a proxy for body size to investigate the influence of allometric scaling on limb size
243 proportions (*Fig.8, Table 6*). Limb proportions were found to scale with size in an inconsistent
244 way in the different species (*Table 6*). The observed difference of limb proportions in wild and

245 domestic mallards (*Table 1; Fig. 6*) could thus be interpreted as the result of allometric scaling
246 due to particularly pronounced size differences in the wild vs. the domestic sample (*Fig. 3*).
247 Specifically, in the case of the mallard's forelimb, the humerus scales positively allometrically,
248 the radius isometrically, and the carpometacarpus negatively allometrically, leading to
249 proportionally longer humeri and shorter radii in larger specimens (*Fig. 2, Fig. 8, Table 6*).
250 Although no ontogenetic study is available for mallard ducks so far as a comparison, this same
251 tendency for allometric scaling of the limb bones can be extracted from the data available in the
252 literature regarding embryological growth of *Gallus gallus* (Faux & Field, 2017) and ontogenetic
253 development after hatching (Thomas, et al., 2016; Jackson & Diamond, 1996) (*Fig. 4A* and
254 *Fig. 4B*). As the body size of the embryo and hatched birds increases, their limb proportions
255 change in a similar tendency (except tibiotarsus and tarsometatarsus in post-hatching growth,
256 *Fig. 4, Table 4*) as we observe in differently sized adult chickens (*Fig. 8a,b, Table 6*). This can
257 also be observed for wing growth in *Larus californicus*, which shows a progressive decrease in
258 the humerus length relative to the radius and carpometacarpus (Middleton & Gatesy, 2000). This
259 suggests that the differences in proportions of the limbs among adult chickens might be at least
260 partially related to allometric scaling during development and growth. Differences in limb
261 proportions among breeds could thus be related to different sizes of breeds.
262 As differences in limb proportions between the wild and the domestic groups are not apparent in
263 chicken and Muscovy ducks (*Fig. 6, Table 1*), although allometric scaling of limb bones was
264 observed (*Fig. 8, Table 6*), a lack of pronounced size differences (*Fig. 3*) between wild and
265 domestic could explain the lack of proportional differences.
266 The literature shows implications of different allometries in limbs. An apparent inverse
267 correlation of the proportion of the humerus in the wing with aerial maneuverability in birds has
268 been proposed in the past (Middleton & Gatesy, 2000). Moreover, flightlessness is reportedly
269 linked to a proportionally long humerus compared to the rest of the long bones of the wing in
270 theropods (Middleton & Gatesy, 2000) and steamer ducks (Tachyeres) (Livezey & Humphrey,
271 1986).
272 Experiments on the domestication of the wild mallard resulted in bigger body sizes and rapid
273 loss (after three generations) of the ability to fly (Darwin, 1868). Mason (1984) proposed that
274 this loss of flight capacity might be due to the loss of positive selection for flying ability: under
275 the care of humans, mallards are usually granted access to a reliable source of food at a specific

276 location, thus flight becomes less essential for survival. An alternative explanation could be that
277 the selection of the species for specific traits could have pleiotropic effects that lead to a
278 reduction of flight capacity. These hypotheses remain to be tested in future work. The loss of the
279 capacity to fly may be related to the proportion of the limbs, which upon less selection due to
280 lack of necessity to fly may have become significantly different from their wild counterpart
281 (*Table S2*). Other skeletal, muscular and perhaps neurological changes may also be related to the
282 loss of flight capacity. In the case of the hind limb, we observed in domestic forms of the mallard
283 duck a relative shortening of the femur and elongation of the tarsometatarsus. Gatesy and
284 Middleton (1997) reported an apparent gradient of cursoriality increasing with tarsometatarsal
285 proportion among theropod species with similar Tibiotarsus/Femur ratios. The pattern we
286 observe in the domestic mallard duck, together with a decrease in flight adaptations (above), is
287 consistent with a more terrestrial, although not necessarily highly cursorial, lifestyle of the
288 domesticated vs. the wild form.

289 Changes in limb proportions are not observed in *Cairina moschata*. Its proportions remain
290 indistinguishable from the wild form, as opposed to *Anas platyrhynchos* (*Table 1*). Changes in
291 flight habits might not have been similar between the wild and domestic forms of mallard ducks
292 and Muscovy ducks. While some populations of wild mallard ducks are migratory (Bellerose &
293 Crompton, 1970), domestic mallards rarely fly as much and many breeds lack flight capacity
294 entirely (Smith, et al., 1989). Muscovy ducks, on the other hand, although non-migratory birds
295 (Accordi & Barcellos, 2006), have been reported to fly frequently (Anon., 2016; Anon., 2017).
296 This suggesting that their flight habits might not have changed so markedly as to produce a
297 different morphology. Alternatively, and related to the allometric scaling relationships
298 considered above, it is noteworthy that in contrast to the other two species, limb bones of the
299 forelimb were found to consistently scale isometrically in the Muscovy duck, suggesting
300 restricted evolvability concerning forelimb proportions in this species. An analogous conclusion
301 was reached when postulating lower evolvability in cats versus dogs when reporting largely
302 isometric versus allometric in the skulls, respectively (Sánchez-Villagra, et al., 2017).
303 The variations on the sternum of *Gallus gallus* (*Table 7*) show that the RJF generally possesses a
304 notched carina sterni, a smooth surface of the pars cardiaca and foramen pneumaticum and a
305 fanned caudal end of the trabecula mediana. The RJF develops a crooked keel in half of our
306 observed specimens (*Table 7*). The crookedness of the keel has been shown to be hereditary and

307 influenced by early roosting conditions (Blount, 1933; Warren, 1937; Waters, 1949). Our
308 observations reveal that this is not a feature unique to domestic varieties, as has been previously
309 reported (Kittelsen, et al., 2020).

310 Most domestic variants exhibit straight carina sterni, with the notable exception of the Chabo and
311 Ukokkei breeds. One possible explanation might be that the shortness of the legs in the Chabo
312 and the inability to fly of the Ukokkei are responsible for a more direct contact with higher
313 pressure on the keel with the perching structure of their environments, as it has been shown to be
314 a determinant factor for its appearance (Blount, 1933; Warren, 1937; Waters, 1949; Pickel, et al.,
315 2011; Casey-Trott, et al., 2015). Behaviour, especially flying and perching, could be an
316 important factor distinguishing breeds but could not be assessed in this study.

317 The notch in the carina sterni seems to be a rare condition in domestic breeds, while it is the most
318 common condition in the wild form, contrary to the other features observed with a more general
319 distribution. The sponginess of the pars cardiaca and foramen pneumaticum is a rare condition in
320 most breeds except for the case of the Araucana breed. Most breeds show a fanned end of the
321 sternum as is the case of the wild form. In summary, these results reveal that the crookedness of
322 the keel is not unique to domestic forms and, while the prevalence of the notch in the carina
323 sterni can be distinguishing between the wild and domestic forms, the variation of the different
324 characters are not segregated among the breeds.

325

326 **Conclusions**

327 This study shows how the allometric growth of *Gallus gallus* can help us understand the
328 variation in limb proportions of differently sized breeds. Furthermore, we show that significant
329 differences in the proportions of limb bones of wild and domestic *Anas platyrhynchos* exist,
330 whereas no significant differences between wild and domestic forms of *Gallus gallus* and
331 *Cairina moschata* were found. We offer possible explanations for these differences such as an
332 extension of the allometric growth of domestic Mallard ducks, loss of positive selection for
333 flying ability, and/or pleiotropic effects or evolvability constraints, which could inspire future
334 research. Furthermore, we observed that the condition of crooked keel is not unique to domestic
335 forms of *Gallus gallus* and a higher number of cases of notched carina sterni can be found in
336 RJF. These findings add new observations to the study of keel characteristics that can be added
337 to the body of knowledge of domestication and poultry welfare.

338

339 Acknowledgements

340 We thank Jorge Carrillo-Briceño, Gabriel Aguirre-Fernández, and Evelyn Hüppi who helped in
341 the preparation of the UZH materials, curators in Tring Mark Adams, Joanne Cooper and Hein
342 van Grouw (Natural History Museum, Bird Collection, Tring, General and Darwin collection),
343 curator in Staatssammlung für Anthropologie und Paläoanatomie München Henriette Obermaier,
344 curator in Naturmuseum Senckenberg Gerald Mayr, and curator in Zoologisches
345 Institut/Populationsgenetik Christian-Albrechts-Universität zu Kiel Renate Lücht for allowing
346 access to the skeletal materials, curator in National BioResouce Project (Nagoya University,
347 Japan) for materials of Chabo and Polish strains. We thank Judith Recht for editorial help and
348 Erin Maxwell (Stuttgart) for constructive criticisms that led us to reanalysis of some of the data.
349 We thank both Stiftung für wissenschaftliche Forschung an der Universität Zürich (STWF-18-
350 025), and the Swiss National Science Foundation SNF grant (31003A-169395) to M.R.S.-V.) for
351 support.

	Carpometacarpus	0.956 (0.926, 0.986)	Negative allometry	0.9791	9.903*10 ³ (1, 86)	<2.2*10 ⁻¹⁶
	Femur	0.977 (0.941, 0.996)	Negative allometry	0.9844	5.423*10 ³ (1, 86)	<2.2*10 ⁻¹⁶
	Tibiotarsus	0.99 (0.973, 1.008)	Isometry	0.9933	1.268*10 ⁴ (1, 86)	<2.2*10 ⁻¹⁶
	Tarsometatarsus	1.054 (1.023, 1.085)	Positive allometry	0.9819	4.677*10 ³ (1, 86)	<2.2*10 ⁻¹⁶
<i>Cairina moschata</i>	Humerus	0.992 (0.971, 1.013)	Isometry	0.9941	9.336*10 ³ (1, 54)	<2.2*10 ⁻¹⁶
	Radius	0.987 (0.954, 1.021)	Isometry	0.9849	3.513*10 ³ (1, 54)	<2.2*10 ⁻¹⁶
	Carpometacarpus	1.026 (0.968, 1.083)	Isometry	0.9595	1.28*10 ³ (1, 54)	<2.2*10 ⁻¹⁶
	Femur	0.988 (0.954, 1.022)	Isometry	0.9846	3.455*10 ³ (1, 54)	<2.2*10 ⁻¹⁶
	Tibiotarsus	0.97 (0.95, 0.99)	Negative allometry	0.9944	9.641*10 ³ (1, 54)	<2.2*10 ⁻¹⁶
	Tarsometatarsus	1.068 (1.029, 1.108)	Positive allometry	0.9819	2.933*10 ³ (1, 54)	<2.2*10 ⁻¹⁶

Table 7 (on next page)

Table of characters and character states by breed.

Characters and character states: carina sterni (straight or crooked), carina sterni (notched or non-notched), pars cardiaca (PC) and foramen pneumaticum (FP) (spongy or smooth), trabecula mediana: (fanned or straight). Numbers in the table indicate the number of specimens per character state.

1

<u>Breed</u>	<u>Carina sterni</u>		<u>Carina sterni</u>		<u>PC and FP</u>		<u>Trabecula mediana</u>	
	<u>Crooked</u>	<u>Straight</u>	<u>Notched</u>	<u>Non-notched</u>	<u>Spongy</u>	<u>Smooth</u>	<u>Fanned</u>	<u>Straight</u>
<u>Araucana</u>	<u>1</u>	<u>6</u>	<u>1</u>	<u>6</u>	<u>4</u>	<u>3</u>	<u>3</u>	<u>2</u>
<u>Bantam</u>	<u>0</u>	<u>7</u>	<u>2</u>	<u>5</u>	<u>2</u>	<u>5</u>	<u>7</u>	<u>0</u>

<u>TOTAL</u>	<u>26</u>	<u>37</u>	<u>19</u>	<u>44</u>	<u>20</u>	<u>43</u>	<u>40</u>	<u>20</u>

Figure 1

Anatomical structures used to define measurements parallel to the longitudinal axis of the limb bones (indicated with red dots).

Humerus (A): caput humeri (B) and cotylus ventralis (C); Radius (D): cotyla humeralis (E) and facies articularis radiocarpalis (F); Carpometacarpus (G): trochlea carpalis (H) and facies articularis digitalis minor (I); Femur (J): trochanter femoris (K) and condylus lateralis (L); Tibiotarsus (M): crista cnemialis cranialis (N) and epicondylus lateralis (O); Tarsometatarsus (P): crista medialis hypotarsi (Q) and trochlea metatarsi III (R) Shown bones belonging to domestic chicken (*Gallus gallus*, Araucana)

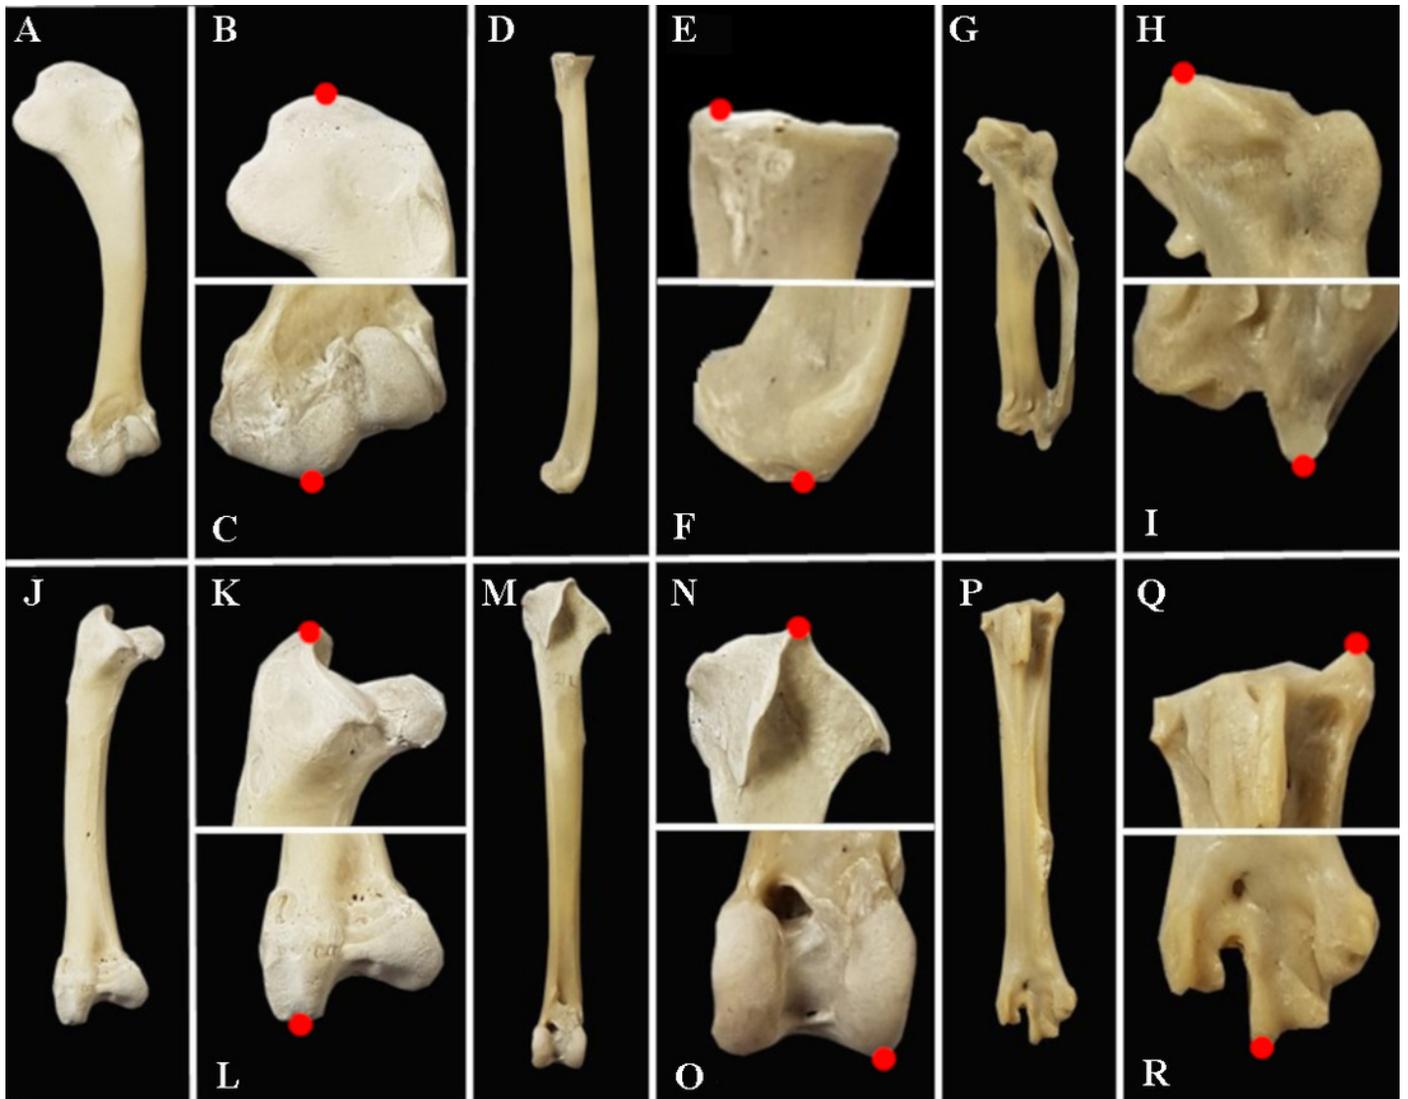

Figure 2

Forelimb and hind limb proportions of the three bones in each limb represented graphically in a ternary plot.

For the hind limb (A), the considered bones are femur (black), tibiotarsus (red) and tarsometatarsus (blue); for the forelimb (B), the considered bones are humerus (black), radius (red) and carpometacarpus (blue); a ternary plot is used to show the proportions for each limb (C).

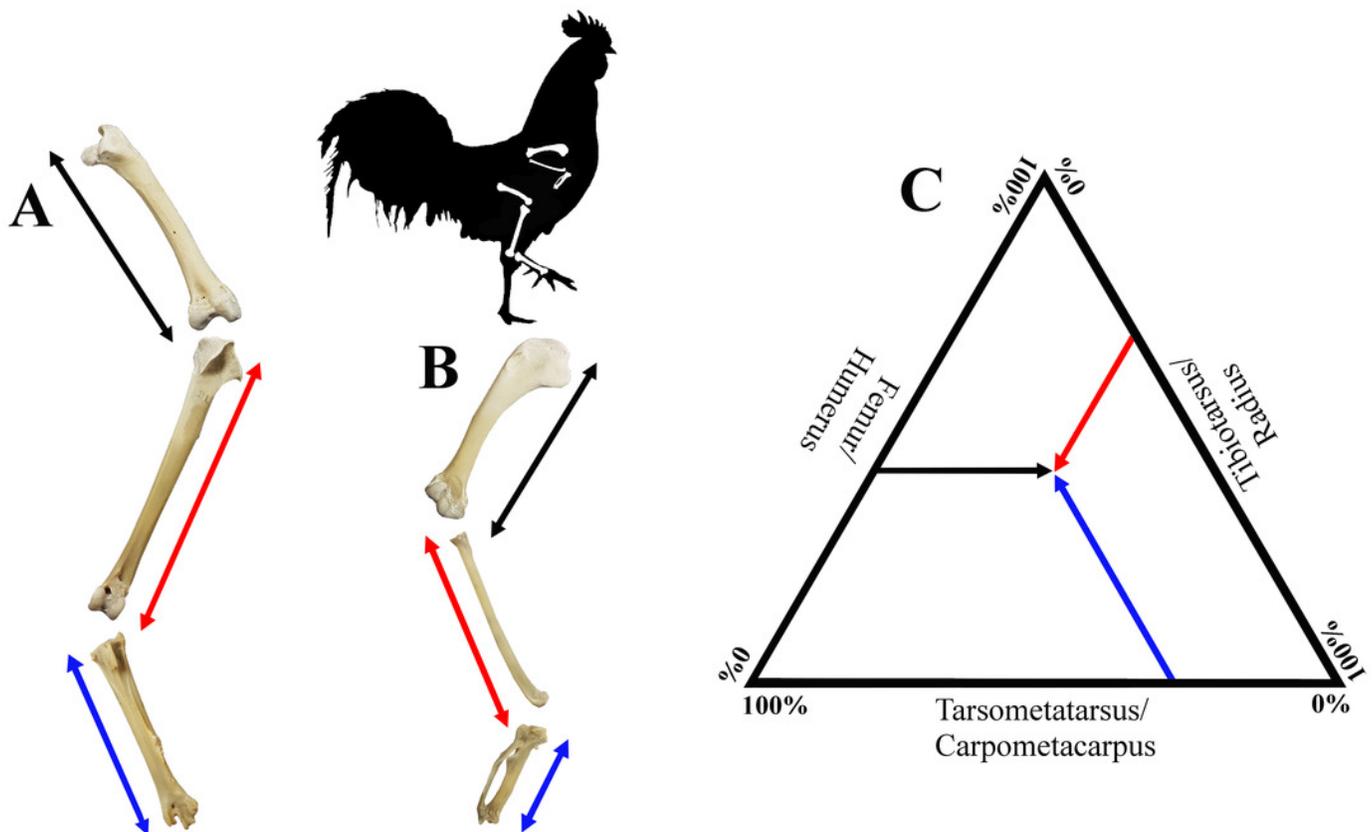

Figure 3

Boxplots comparing limb length between wild and domestic forms.

(A and B) For chicken; (C and D) for Mallard ducks and (E and F) for Muscovy ducks. T test results are included and show t statistic (t) with associated degrees of freedom (df); p = p-value.

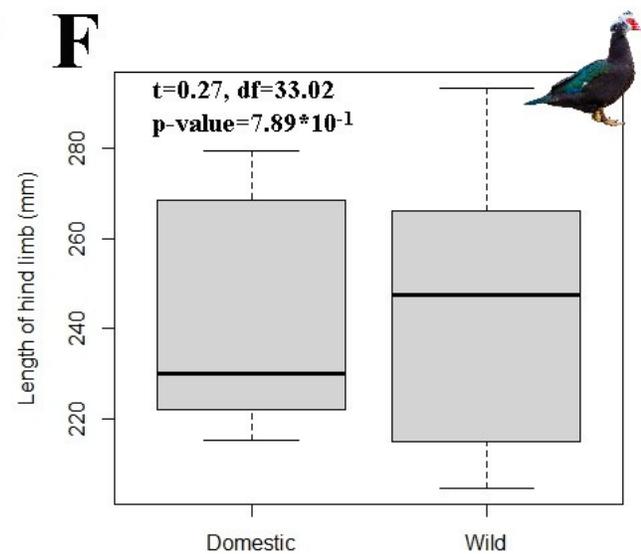

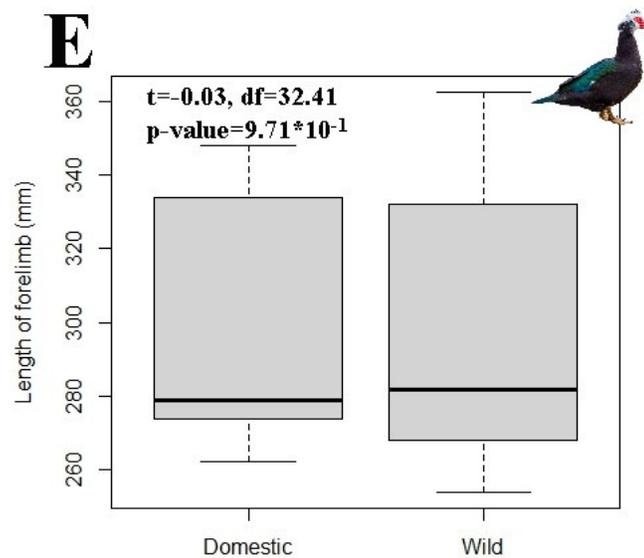

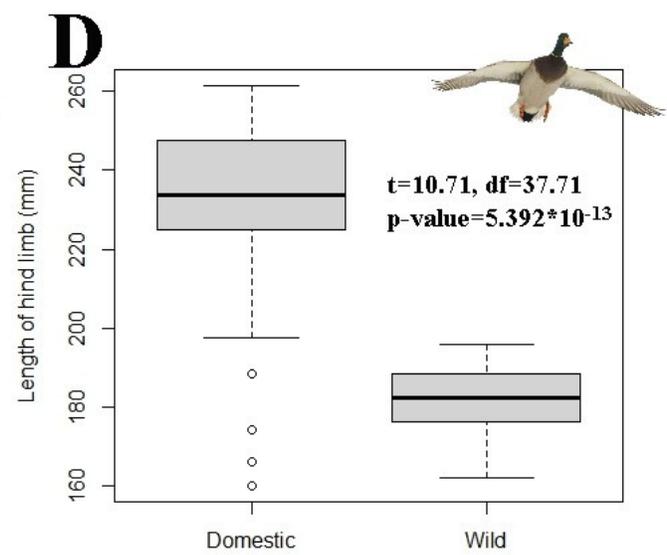

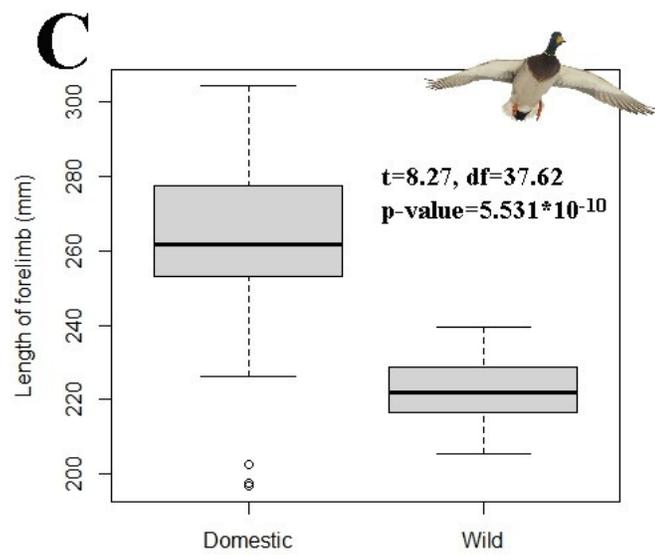

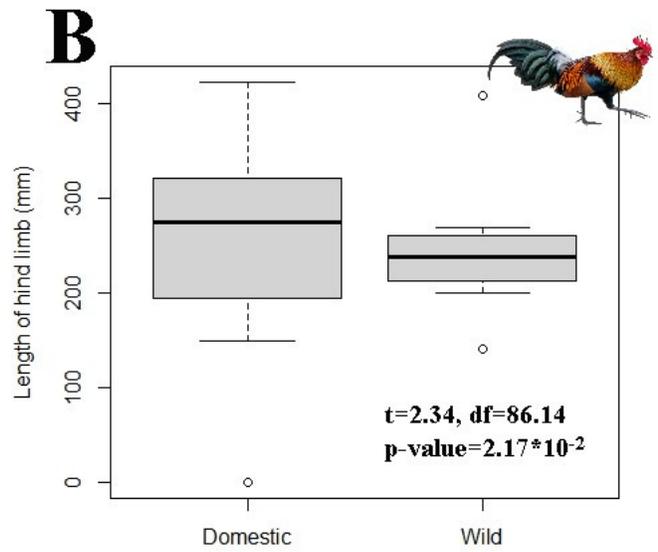

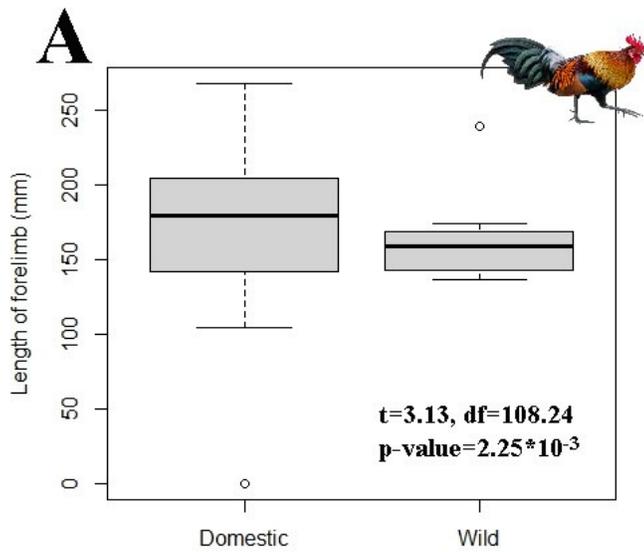

Figure 4

Bivariate plots reflecting the allometric scaling in hind limb of embryological and adult *Gallus gallus*.

(A) Measurements taken from embryos at day 7 of incubation to day 17 (data taken from Faux and Field, 2017). (B) Measurements taken from juveniles from 1 week after hatching to week 36 (data taken from Thomas, 2014). (C) Variation of proportions of adults of chicken breeds and RJF sampled in this study.

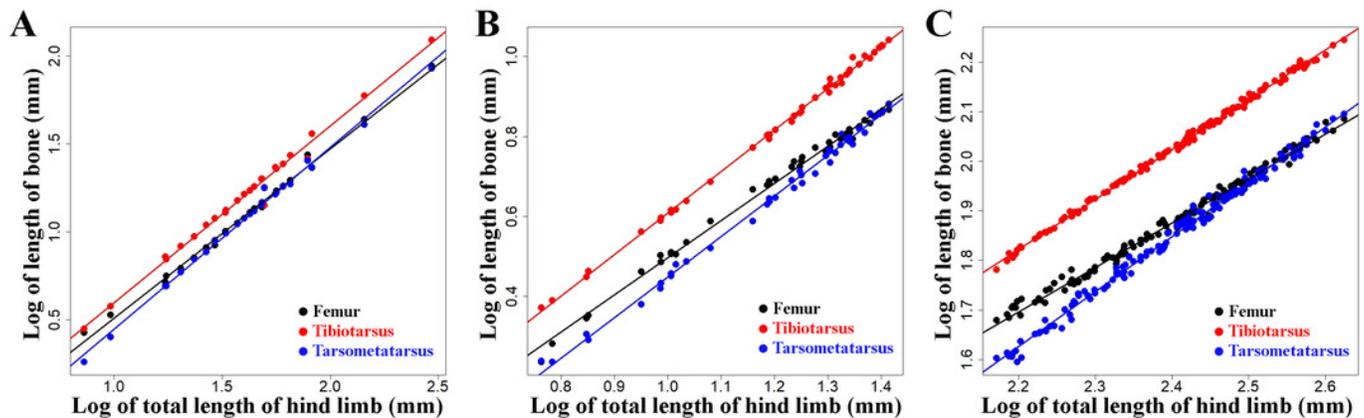

Figure 5

Characters and character states of the sternum in *Gallus gallus*.

(A) Straight carina sterni (CS) (Araucana SAPM-AV-05259), (B) crooked carina sterni (RJF SAPM-AV-05218), (C) non-notched carina sterni (Araucana SAPM-AV-05274), (D) notched carina sterni (RJF SAPM-AV-05218) where notch is indicated by the red arrow, (E) smooth surface and poorly defined concavities of PC and FP (RJF SAPM-AV-05234), (F) spongy well-defined concavities of PC and FP (Araucana SAPM-AV-05259)), (G) Straight end of the trabecula mediana (TM) in dorsal view (Araucana SAPM-AV-05264), (H) fanned end of the trabecula mediana (TM) in dorsal view (RJF SAPM-AV-05266). Specimens are from the Staatssammlung für Anthropologie und Paläoanatomie München. Scale = 1cm.

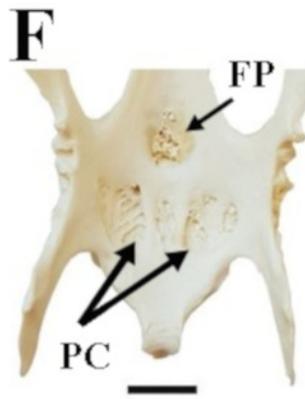

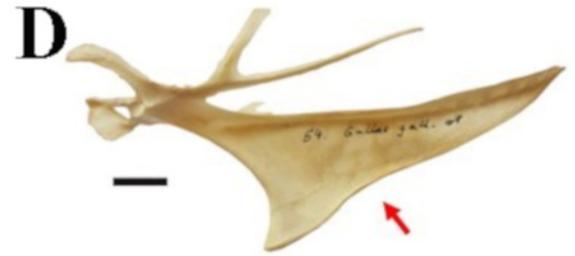

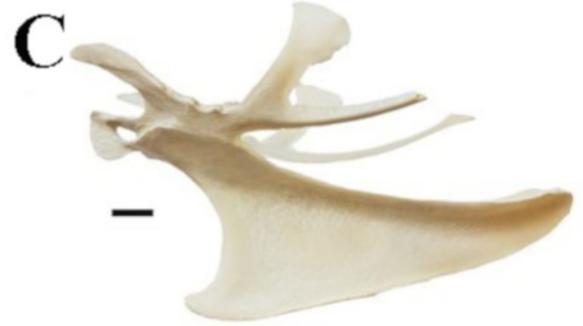

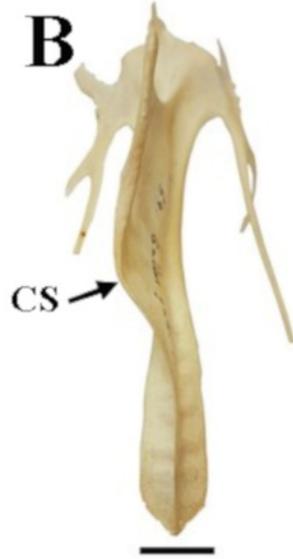

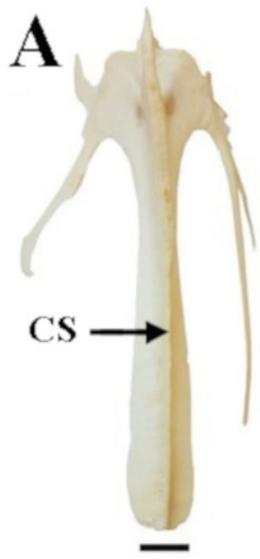

Figure 6

Ternary plots illustrating the proportions in *Gallus gallus* (red), *Anas platyrhynchos* (blue) and *Cairina moschata* (green)

Axes representing the proportions of each bone in the limb as a percentage. (A) for forelimb, (B) for hind limb. Each plot is accompanied with zoomed in areas correspondent to each species differentiating wild forms (red dots) and domesticated forms (black dots). Circles in zoomed areas capture where most points for wild or domestic forms fall. (For statistical comparison of proportions see *Table 1*).

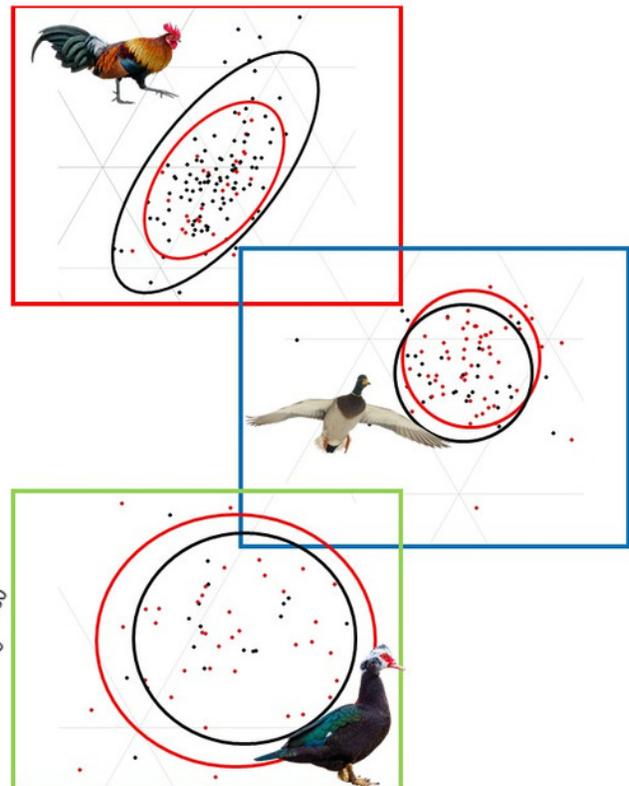

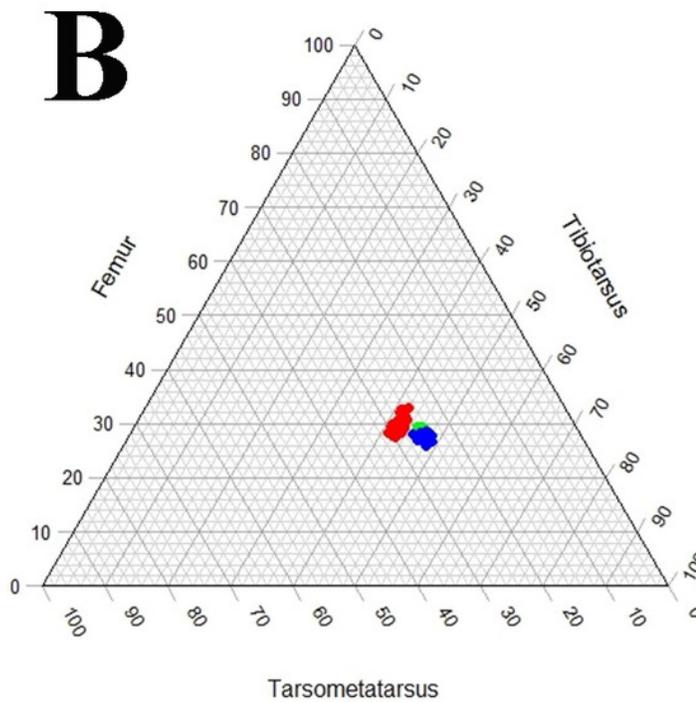

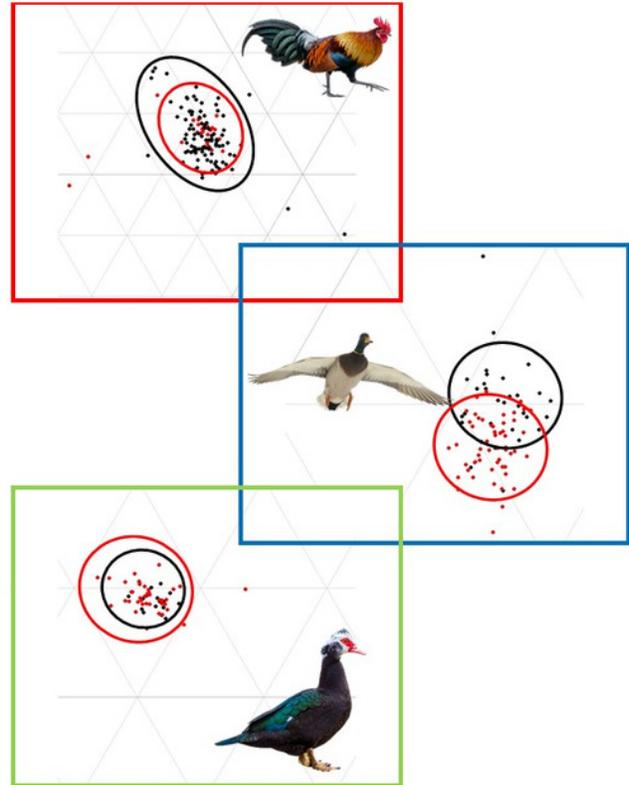

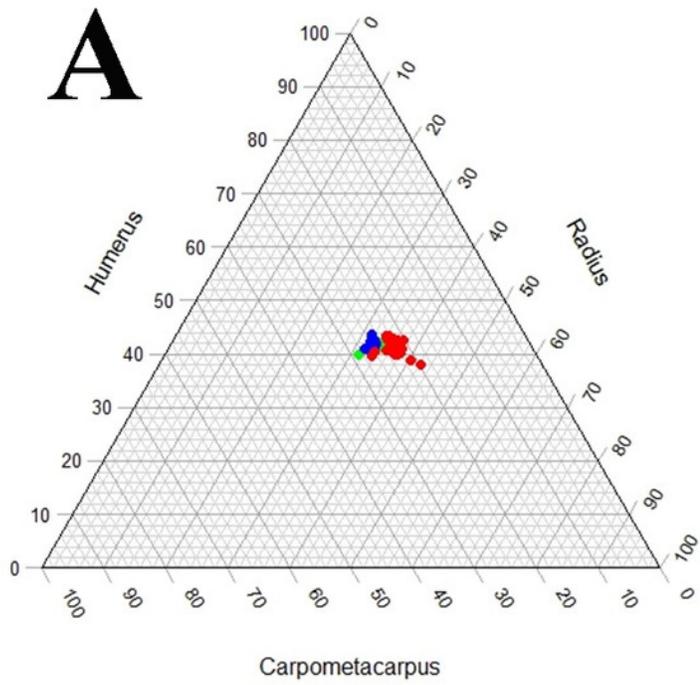

Figure 7

Comparison of limb bones proportions among breeds of chicken.

Each figure depicts the proportion of one bone in its limb (forelimb bones shown on the left panels, hind limb bones on the right panels). On the vertical axis, the proportion of the bone in the limb. On the horizontal axis, the name of the breed to which the above distribution belongs. RJF is highlighted in red.

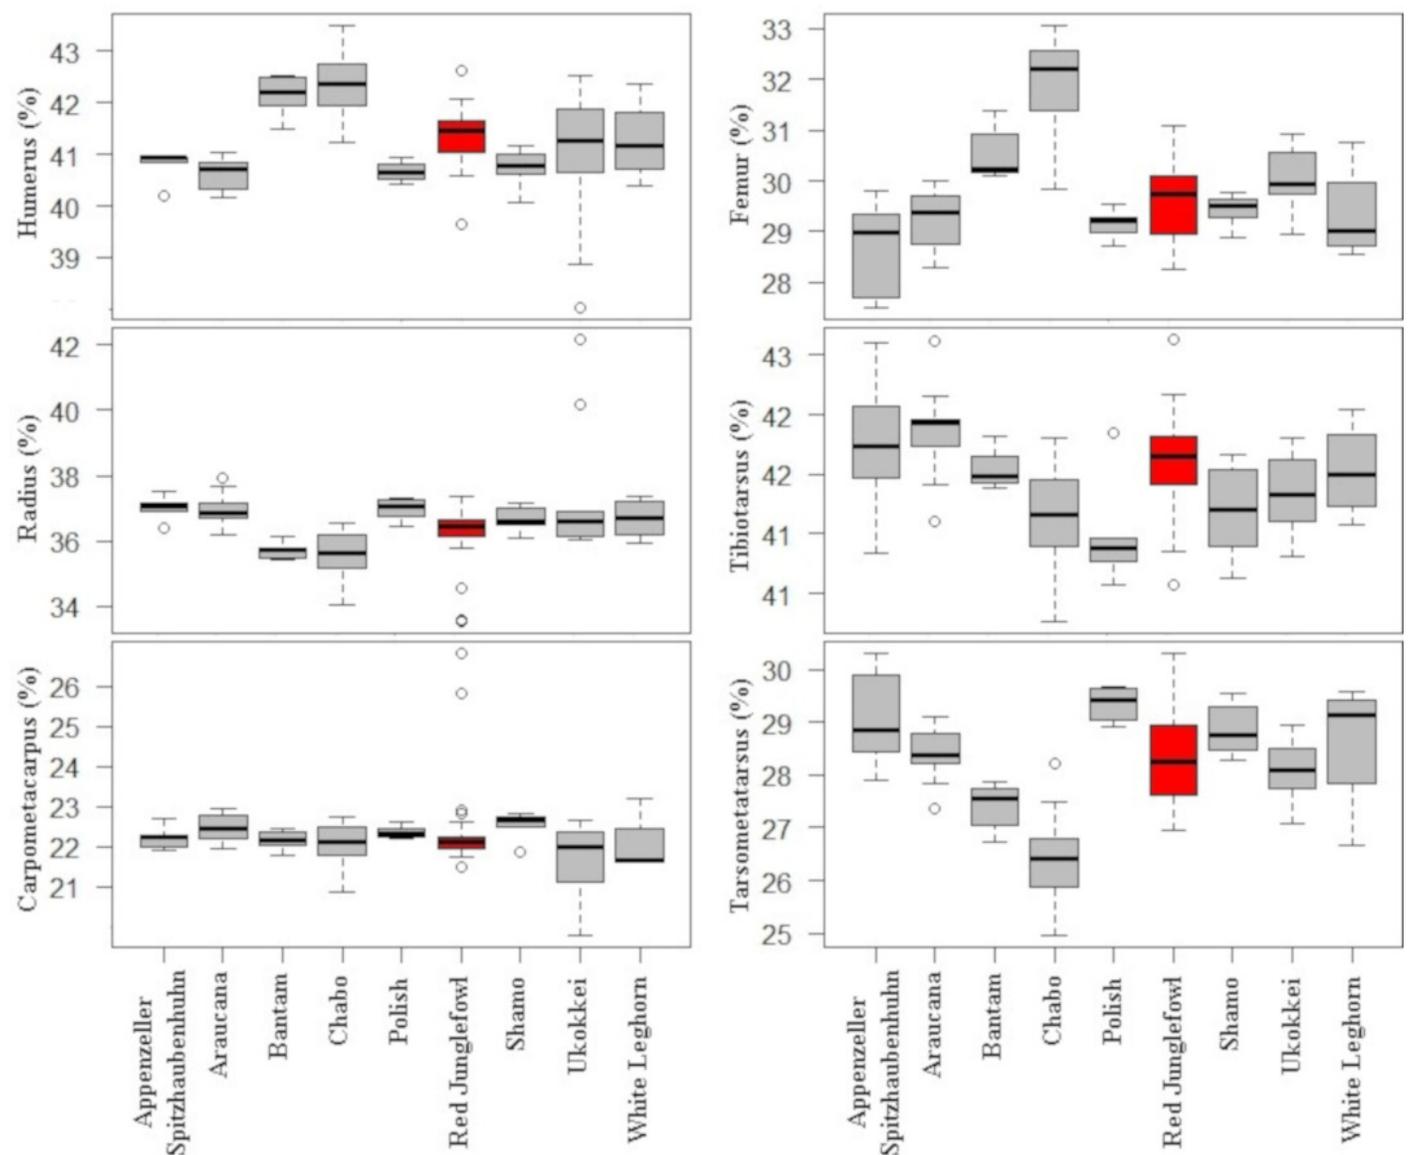

Figure 8

Log-transformed length of individual bone of the forelimb and hind limb vs. log-transformed length of the respective limb as a proxy for body size.

(A and B) for *Gallus gallus*, (C and D) for *Anas platyrhynchos*, (E and F) for *Cairina moschata*.

Domestic breeds are represented with a hollow circle and wild forms are represented with a filled dot. Included are regression equations, regression lines, R squared values, F statistics including degrees of freedom in brackets, and the p-values. Measurements in centimetres.
