Background. Autonomy or choice can lead to improved learning in various educational domains. The purpose of this online study was to examine whether giving participants a choice regarding the frequency of their received feedback (either after each individual trial or after a block of trials) in a computerized alternate task-switching task, will affect their performance. **Methods.** Participants ($N = 148$) were randomly assigned to three groups: choice group ($n = 49$), online feedback group ($n = 51$), and summary feedback group ($n = 48$). From those three groups we created two groups: a choice group and a no-choice group ($n = 49$ in each group). All participants performed eight familiarization trials, a pre-test of 24 trials, five blocks of 24 trials for practice, and a post-test of 24 trials. After completing the task, the participants were asked about their perceived feeling of choice and completed the short form of the International Positive and Negative Affect Schedule. **Results.** Results showed that participants in the choice group had higher perceived choice compared with the participants in the no-choice group (8.41 vs. 5.47 out of 10, respectively). However, this higher perceived choice did not materialize into better performance in practice or in the post-test.

Providing Choice of Feedback Affects Perceived Choice but Does Not Affect Performance

Abstract

20 **Background.** Autonomy or choice can lead to improved learning in various educational
21 domains. The purpose of this online study was to examine whether giving participants a choice
22 regarding the frequency of their received feedback (either after each individual trial or after a
23 block of trials) in a computerized alternate task-switching task, will affect their performance.
24 **Methods.** Participants ($N = 148$) were randomly assigned to three groups: choice group ($n = 49$),
25 online feedback group ($n = 51$), and summary feedback group ($n = 48$). From those three groups
26 we created two groups: a choice group and a no-choice group ($n = 49$ in each group). All
27 participants performed eight familiarization trials, a pre-test of 24 trials, five blocks of 24 trials
28 for practice, and a post-test of 24 trials. After completing the task, the participants were asked
29 about their perceived feeling of choice and completed the short form of the International Positive
30 and Negative Affect Schedule.
31 **Results.** Results showed that participants in the choice group had higher perceived choice
32 compared with the participants in the no-choice group (8.41 vs. 5.47 out of 10, respectively).
33 However, this higher perceived choice did not materialize into better performance in practice or
34 in the post-test.

Introduction

40   **Introduction**

41 Autonomy (or choice) is considered a basic biological (Leotti et al., 2010) and psychological
42 (Deci & Ryan, 2008) need. Providing individuals with choice enhances their intrinsic motivation
43 (Patall et al., 2008) and self-efficacy (Wulf et al., 2014). Self-efficacy, in turn, is a predictor of
44 performance (Feltz et al., 2008). Autonomy support can enhance motor performance and
45 learning (Wulf & Lewthwaite, 2016), enhance learning engagement (Jang et al., 2010), and lead
46 to more adaptive learning behaviors (Schweder & Raufelder, 2021). Autonomy can be offered by
47 allowing participants to choose when to receive feedback (i.e., self-controlled feedback,
48 Chiviacowsky, 2014); by providing choice of training devices, Hartman, 2007; by using
49 autonomy-supportive instructional language, Hooyman et al., 2014; by letting participants
50 choose the amount of practice, Lessa & Chiviacowsky, 2015; or even by providing choices that
51 are irrelevant to the task at hand (e.g., choose the color of a golf ball, Lewthwaite et al., 2015).
52   One instructional method that is often used to improve performance and learning is
53 augmented feedback. Feedback can be given in various forms that are either controlled by the
54 instructor or by the learner. For example, learners can be given choice regarding the type, the
55 timing, and the frequency of the feedback they receive. Feedback, for example, can be given
56 after each trial (immediate or online feedback) or at the end of a series of trial (summary
57 feedback). Guadagnoli and Lee (2004) suggested that whether online feedback or summary
58 feedback yields larger learning effects depends on task difficulty. Specifically, these authors
59 argued that for a difficult task, more frequent feedback might yield larger learning effects
60 compared with summary feedback, while the opposite is true for a simpler task.
61   This moderating effect of task difficulty on the benefits of feedback frequencies has been
62 shown by Guadagnoli et al. (1996; Exp. 2). In this experiment, participants tried to strike a
63 padded force transducer with their right fist to match a predefined force (easy task) and with their
64 right fist and immediately followed by their left fist (complex task). Findings of this study
65 showed that for the simple task, providing summary feedback after 15 trials led to better
66 performance in a retention test compared with feedback after five trials or after each individual
67 trial. This was true for both novice and experienced participants. In contrast, for the complex
68 task, providing novice participants with feedback after each individual trial led to better retention
69 compared with the provision of summary feedback after 15 trials.
70   In light of the abovementioned findings, if feedback frequency has a different impact on
71 performance according to task difficulty, then it could be important to examine whether
72 providing participants with the autonomy to choose their feedback frequency would lead to
73 improved performance, even if, for example, they choose the "*wrong*" feedback (e.g., summary
74 feedback for a difficult task). In the current study we implemented a computerized alternate task-
75 switching task that includes more difficult switch trials compared with less difficult no-switch
76 trials (Monsell, 2003).
77   Therefore, the purpose of the current study was to examine whether providing
78 participants with a choice of receiving feedback after each trial or receiving only summary
79 feedback at the end of a block of trials would lead to improved performance in an alternate task-

80 switching task. We hypothesized that: (a) participants in the choice group would outperform
81 participants in the no-choice group during practice and would show greater improvement from
82 pre- to post-test, (b) participants in the choice group would experience greater positive affect (as
83 observed in previous studies, e.g., Joussemet et al., 2004; Lemos et al., 2017) compared with
84 participants in the no-choice group, (c) participants in the online feedback group would perform
85 better than participants in the summary feedback group (because such knowledge of results can
86 serve as guidance during practice and lead to improved performance; Salmoni et al., 1984), and
87 (d) if one type of feedback would be better than another, we would observe preference-
88 performance dissociation among some participants (e.g., participants will choose a type of
89 feedback that will be detrimental to their performance. Indeed, this dissociation has been
90 reported previously in a number of tasks: (a) a flying task in novices (Wright & O'Hare, 2015),
91 (b) choice-RT tasks (Ziv & Lidor, 2021), and (c) a golf-putting task (Ziv et al., 2020). In
92 addition, a manipulation check will show that participants in the choice group will perceive
93 greater choice than participants who received no choice.
94

Materials & Methods

95
96 *Experimental Approach*
97   The study was designed and conducted on a cloud-based experimental software
98 (www.gorilla.sc; Anwyl-Irvine et al., 2020). We aimed at examining whether allowing
99 participants to choose the feedback frequency they receive – feedback after each trial or
100 summary feedback after a block of 24 trials, would lead to improved performance [i.e., faster
101 reaction time (RT) and higher accuracy] in an alternate task-switching task compared with
102 participants who received feedback without the ability to choose. To answer this question in a
103 laboratory-based experiment, we would have to allocate the participants to two groups: a choice
104 group and a no-choice group. For every participant who chooses the type of feedback in the
105 choice group, the same feedback is given without choice to one of the participants in the no-
106 choice group. However, in an online study this is not always possible.
107   Therefore, participants were first allocated automatically into three experimental groups:
108 (a) a summary feedback group – feedback after each block of trials, (b) an online feedback group
109 – feedback after each trial (thumbs up or down), and (c) a choice group – a choice of either
110 summary or online feedback. These three groups allowed us to create the two required groups:
111 (a) a choice group (which was the original group) and a no-choice group (equal in numbers to the
112 choice group and based on participants from the original online feedback and summary feedback
113 groups).
114 *Pre-Registration and Raw Data Repository*
115 The study was pre-registered on aspredicted.org (https://aspredicted.org/d4gv3.pdf). Analyses
116 that were not pre-registered are reported in the "exploratory analysis" section. The raw dataset is
117 available on OSF (https://osf.io/p5wgx/?view_only=0ca32fa378874982b6ca28df88604413).
118 *Participants*

119   We recruited participants on Prolific (www.prolific.co) – an online platform that allows
120   individuals with access to the Internet to participate in online studies. The participants were paid
121   2.5 British Pounds for their participation. The participants were between the ages of 18-35, were
122   fluent in English, and reported no chronic illnesses.
123   We used G*Power (Faul et al., 2007) to perform *a priori* power analysis for a two-way
124   analysis of variance [ANOVA; group (choice/no-choice) X Test (pre/post)] comparing RTs. The
125   effect size for this analysis was based on a recent study that examined the provision of choice in
126   similar online tasks (Ziv & Lidor, 2021). This estimation showed an expected effect size of $\eta^2_p =$
127   .13 corresponding to Cohen's f = 0.38 suggesting that participants in the choice group will show
128   faster RTs compared to the participants in the no-choice group. Because small studies tend to
129   have larger effect sizes (the Winner's Curse; Button et al., 2013), we decided to reduce the effect
130   size by 20% and used Cohen's f = 0.30. We entered this effect size into the power analysis with
131   the following parameters: alpha (two-sided) = .05, power = .90, and correlation among repeated
132   measures = .5. The power analysis suggested that 90 participants (45 for the choice group and 45
133   for the no-choice group) were required to detect differences between groups with 85% power.
134   To account for possible dropouts, we started with a total of 151 volunteers who
135   completed the experiment. Based on our pre-registration exclusion criteria for participation, three
136   participants were removed from the study. This left us with 148 participants who were randomly
137   assigned by the software to three groups: (a) choice group (*n* = 49, 36 females, mean age = 25.4
138   ± 4.4 years); (b) online feedback group (*n* = 51, 34 females, mean age = 27.2 ± 4.7 years); and
139   (c) summary feedback group (*n* = 48, 29 females, mean age = 26.8 ± 4.8 years). From those three
140   groups, we then created two groups: choice group (*n* = 49, 24 chose to receive summary
141   feedback and 25 chose to receive online feedback), and no-choice group (*n* = 49, the first 24
142   participants from the summary feedback group and the first 25 participants from the online
143   feedback group).
144   All participants completed an electronic informed consent form on the study's website
145   prior to participation. If participants chose not to participate, the software forwarded them to a
146   thank you screen, and they were excused from the study. The study was approved by the Ethics
147   Committee of the Academic College at Wingate (approval # 308).
148   ***Task***
149   In this task, a blue or green rectangle or square were shown at the upper part or the lower part of
150   the computer screen. When the shape was located at the upper part of the screen, the participant
151   was required to press "f" if the shape was blue and to press "j" if the shape was green. However,
152   when the shape was located at the bottom part of the screen, the participant was required to press
153   "f" if the shape was square, and "j" if it was rectangle. The stimuli were presented with no time
154   limit until the participants pressed a key. The presentation of the shapes at the upper or lower
155   parts of the screen alternated every two shapes.
156   ***Procedure***
157   Data collection was done remotely as each participant participated on their own computer. After
158   reading the informed consent form and agreeing to participate in the study, all participants

159   performed eight familiarization trials of the task. In these trials, both online feedback (a thumbs-
160   up or thumbs-down image appeared after each trial) and summary feedback (number and
161   percentage of correct trials) were provided. Then, the participants performed a pre-test of 24
162   trials with no feedback. This was followed by a practice session that included five blocks of 24
163   trials, where feedback was provided based on group affiliation. The participants in the online
164   feedback group saw a thumbs-up symbol or a thumbs-down symbol for a correct or an incorrect
165   key press, respectively, after each trial but did not receive summary feedback. The participants in
166   the summary feedback group, on the other hand, only received information about the number of
167   correct responses and percentage of correct responses after each of the five blocks of 24 trials
168   (e.g., *"You scored 21 out of 24. That's 88% correct"*) but did not receive online feedback. The
169   participants in the choice group were asked whether they wanted to receive online or summary
170   feedback and received the appropriate type of feedback based on their choice. After the five
171   practice blocks were completed, the participants performed a post-test of 24 trials with no
172   feedback. Finally, participants were asked to rate whether they believed that they had a choice
173   over the type of feedback they received on a scale of 1 (not at all) to 10 (very much), and were
174   then asked to complete the short form of the International Positive and Negative Affect Schedule
175   (PANAS). This questionnaire was selected because it was developed in order to provide valid
176   assessment of affect cross-culturally, and therefore is suitable for an online study where
177   participants are from different countries and/or cultures (Thompson, 2007). The questionnaire is
178   composed of 10 items that are rated on a scale of 1 (not at all) to 5 (very much): Determined,
179   attentive, alert, inspired, active, afraid, nervous, upset, ashamed, and hostile. The questionnaire
180   enables After completing this questionnaire, the participants were thanked for their participation
181   and the study ended.
182   ***Data Analyses***
183   In our pre-registration, we decided to exclude mean RTs of under 300 msec or over 2,500 msec.
184   This happened five times in the pre-test and seven times during practice. We also decided to
185   exclude blocks with 13 or less correct responses out of 24. This occurred nine times in the pre-
186   test, three times during the practice stage, and once in the post-test. Finally, we excluded
187   participants who had at least two blocks during practice with 13 or less correct responses. This
188   led to the exclusion of three participants from the study.
189   Normality was assessed using Kurtosis and Skewness values (values <2 were considered
190   acceptable). For RT, this was mostly the case (except for Kurtosis values of 4.06, 3.73, and 3.24
191   for Blocks 3, 4, and 5, respectively, during practice), and therefore we used parametric statistics
192   to analyze these data. For the number of correct responses, this was not the case (except for the
193   pre-test) and therefore non-parametric statistics were used. We conducted a two-way ANOVA
194   [Group (choice/no-choice) X Test (pre/post)] to assess differences in RTs. In addition, we
195   conducted a two-way ANOVA [Group (choice/no-choice) X Block (1-5)] to assess performance
196   during practice, and a three-way ANOVA [Group (online feedback/summary feedback) X
197   Switch (yes/no) X Test (pre/post)] to assess differences in the switch or the no-switch trials only.
198   Bonferroni post-hoc analyses and 95% confidence intervals were used for post-hoc testing. For

199 analyzing the correct responses we used the Mann-Whitney test. Analyses were conducted using
200 SPSS (version 25, IBM, United States) and the significance level was set at alpha = .05.
201
Results
203 There were no gender differences in any of the dependent variables.
204 ***Manipulation Check - Perception of Choice***
205 The participants in the choice group rated their perception of choice on a scale of 1 to 10 higher
206 (8.41 ± 2.42) than the participants in the no-choice group (5.47 ± 3.37) during the experiment,
207 $t(96)$ = 4.96, p <.001, Cohen's d = 1.00.
208 ***Differences between Pre- to Post-Test***
209 ***RT.*** RTs for the pre-test and the post-test for both choice and no-choice groups are presented in
210 Figure 1. A two-way ANOVA [Group (choice/no-choice) X Test (pre/post)] with repeated
211 measures on the Test factor revealed a Test effect, $F(1, 90)$ = 32.45, $p < .001$, η^2_p = .27. The RT
212 in the pre-test (1,265.54 ± 395.00 msec) was longer than the RT in the post-test (1,047.42 ±
213 259.22 msec). There was no Group effect, $F(1, 90)$ = 0.06, p = .81, η^2_p = .00, and no interaction,
214 $F(1, 90)$ = 0.06, p = .81, η^2_p = .00.
215 **Insert Figure 1 about here**
216 ***Correct responses.*** A Mann-Whitney test revealed no differences between the choice group and
217 the no-choice group in the pre-test (U = 1,157.00, p = .53; 10.88 ± 1.50 versus 10.93 ± 1.52,
218 respectively) or in the post-test (U = 1,198.00, p = .86; 11.64 ± 0.64 versus 11.65 ± 0.63,
219 respectively).
220 ***Differences between Practice Blocks***
221 ***RT.*** A two-way ANOVA [Group (choice/no-choice) X Test (pre/post)] with repeated measures
222 on the Block factor revealed no Group effect, $F(1, 93)$ = 0.44, p = .51, η^2_p = .01, no Block effect,
223 $F(3.05, 284.01)$ = 2.01, p = .11, η^2_p = .02, and no interaction, $F(4, 372)$ = 0.30, p = .88, η^2_p = .00.
224 ***Correct responses.*** A Mann-Whitney test revealed no differences between the choice group and
225 the no-choice group in any of the practice blocks (p values > .26 for Blocks 1-4, p = .045 for
226 Block 5 – not significant after using the false discovery rate method to account for multiple
227 comparisons, Benjamini & Hochberg, 1995). The mean number of correct responses ranged
228 between 22.31 and 23.04 out of 24 in all five blocks.
229 ***Differences between Types of Feedback***
230 ***RT.*** A three-way ANOVA [Group (online feedback/summary feedback) X Switch (yes/no) X
231 Test (pre/post)] revealed a Switch effect, $F(1, 89)$ = 171.14, $p < .001$, η^2_p = .66. The RTs for
232 switch trials (1,356.95 ± 341.18 msec) were longer than the RTs for no-switch trials (1,031.76 ±
233 254.51 msec). There was also a Test effect, $F(1, 89)$ = 59.97, $p < .001$, η^2_p = .40. RTs in the pre-
234 test (1,327.30 ± 364.30 msec) were longer than the RTs in the post-test (1,104.61 ± 314.12
235 msec). There was no Group effect, $F(1, 89)$ = 0.08, p =.78, η^2_p = .00, no Group X Test
236 interaction, $F(1, 89)$ = 2.52, p = .12, η^2_p = .03, no Group X Switch interaction, $F(1, 89)$ = 0.15, p
237 =.70, η^2_p = .00, no Switch X Test interaction, $F(1, 89)$ = 1.47, p =.23, η^2_p = .02, and no Group X
238 Switch X Test interaction, $F(1, 89)$ = 0.05, p = .82, η^2_p = .00.

239   *Correct responses.* There were no differences in correct responses between the participants in the
240   online feedback group and the participants in the summary feedback group in the pre-test or the
241   post-test (all *p* values > .13).
242   *PANAS Scores*
243   There were no differences between the choice group and the no-choice group in any of the 10
244   attributes in the PANAS questionnaire (all *p* values > .09). There were also no differences
245   between these attributes when examining all three original groups (i.e., choice, online feedback,
246   and summary feedback; all *p* values > .4).
247   **Exploratory Analysis**
248   *Variability of RT*
249   As seen in Figure 1, the variability in the RTs of the choice group in the post-test appear to be
250   smaller than the variability in all other conditions. Indeed, the standard deviation of the choice
251   group, which was 399.05 msec in the pre-test, dropped to 207.39 msec in the post-test. In the no-
252   choice group, the standard deviation, which was 395.53 msec in the pre-test, dropped to 299.15
253   msec in the post-test.
254   *Post-test analysis with the pre-test as a covariate*
255   It has been previously suggested that a one-way ANCOVA on a post-test with a pre-test as a
256   covariate provides more statistical power and statistical precision compared with a two-way
257   ANOVA (Group X Test) with repeated measures on the Test factor (see Rausch et al., 2003;
258   Senn, 2006). However, similar to our main analyses, this ANCOVA did not reveal any
259   significant differences between the choice group and the no-choice group, $F(1, 89) = 0.206$, $p =$
260   .65, $\eta^2_p = .00$. In addition, no significant differences were found when examining the original
261   three groups, $F(2, 130) = 0.85$, $p = .43$, $\eta^2_p = .13$.
262   **Discussion**
263   The purpose of the current study was to examine whether providing participants with a choice
264   over feedback delivery would lead to improved performance in an alternate task-switching task.
265   We hypothesized that choice would lead to improved performance, affect, and perceived choice.
266   In addition, we hypothesized that online feedback would lead to better performance compared
267   with summary feedback. The only hypothesis that was supported by the data of the current study
268   was that providing participants with a choice leads to higher perceived choice. There were no
269   other differences in performance or in positive affect between groups.
270   Our findings do not support previous findings regarding autonomy support (e.g.,
271   Chiviacowsky, 2014; Iwatsuki et al., 2017; Iwatsuki & Otten, 2020; Lewthwaite et al., 2015).
272   For example, one previous study provided choice regarding the order of performance of two
273   computerized RT-based tasks (a choice-RT task and a Simon task) (Ziv & Lidor, 2021).
274   Participants who were given a choice had faster RTs compared with participants who were not
275   given a choice.
276   While it is not directly apparent why providing choice of feedback did not lead to
277   improved performance in the current study, a number of explanations can be discussed. First, it is
278   possible that the task was too easy to reveal any differences. However, we do not think this is the

279 case because similar and even easier computerized tasks (e.g., a Simon task) have been used in
280 previous studies and were sensitive enough to show differences in performance between a choice
281 group and a no-choice group (e.g., Ziv & Lidor, 2021). It is also possible that the task may have
282 been too difficult, thereby leading to relatively mild improvements. In such a case, a lengthier
283 intervention that includes a larger number of practice blocks, as well as a retention test that takes
284 place 24-48 hours after the practice session could expose the benefits of an autonomy support
285 intervention. In short interventions, the effect of autonomy support may simply not be robust
286 enough. Indeed, differences in retention or transfer tests, but not during practice are frequently
287 found in studies on various motor learning interventions (e.g., Ávila et al., 2021; Chiviacowsky
288 & Lessa, 2017; Ziv et al., 2019).
289   Another possible explanation for the null findings in the current study is that our post-test
290 took place immediately after practice (i.e., immediate retention) and not, for example, after a
291 longer period (e.g., 24-48 hours; delayed retention). Indeed, the effects of practice are often not
292 observed in an immediate-retention test, however may materialize in a delayed-retention test.
293 Kantak and Winstein (2012), in their review, showed that in 26 out of 41 studies (63%), the
294 effects of practice on performance in an immediate-retention test and a delayed-retention test
295 differed. Out of these 26 studies, in 19 studies (73%) significant effects of practice on
296 performance were found in the delayed-retention test but not in the immediate-retention test, and
297 only in three studies the effects were seen in the immediate-retention test but not in the delayed-
298 retention test.
299   A possible explanation for the lack of effect in an immediate-retention test is that the
300 memory consolidation process takes place in the hours after learning and during sleep, and
301 therefore it has no time to materialize in an immediate-retention test (Kantak & Winstein, 2012).
302 In a more recent meta-analysis (McKay et al., 2022), reduced feedback frequency did not lead to
303 any changes in either immediate- or delayed-retention tests. The lack of differences in
304 performance between the summary feedback group and the online feedback group supports the
305 findings of McKay et al.'s meta-analysis.
306   While most published studies on autonomy support found it to be beneficial for motor
307 performance and learning, some studies did not find this effect (e.g., McKay & Ste-Marie,
308 2020a; McKay & Ste-Marie, 2020b; Yantha et al., 2021). McKay and Ste-Marie (2020a), for
309 example, found trivial and statistically insignificant differences between participants who were
310 given a choice over the color of a golf ball that they used compared to no-choice participants
311 who were not given this choice. Mckay and Ste-Marie (2020b), revealed no differences in dart-
312 throwing performances between participants who were given a choice of dart color compared
313 with participants who were not given this choice. Similar to the results of the current study, this
314 lack of difference in performance was accompanied by significantly greater perceived choice in
315 the choice group. Yantha et al. (2021) showed that self-controlled feedback schedules are not
316 better than no-choice or predetermined feedback schedules when learning a golf-putting task.
317 Finally, a recent meta-analysis on the effects on self-controlled learning (McKay et al., 2021)
318 suggests that when considering both published and unpublished literature, the benefits of self-

319 controlled practice on learning are very small (Hedge's g = 0.11; compared to 0.44 for published
320 studies only). This meta-analysis suggests that bias inflates the effect size of autonomy
321 interventions. The results of the current study support the findings of this meta-analysis and the
322 abovementioned three studies. However, we found smaller variance in the RTs during the post-
323 test in the choice group, compared with the no-choice group. While this finding is only
324 descriptive, it may suggest that the autonomy intervention provided some benefit at least for
325 some participants in the choice group. It is possible, for example, that providing choice of
326 feedback lead to more attentiveness towards the received feedback, which in turn leads to more
327 attention to the task, thus leading to more consistency in performance. This differences in
328 variance can be further examined in additional studies.
329
330   Regardless of choice, based on Guadagnoli and Lee's challenge point framework (2004),
331 we hypothesized that the task performed in our study would be difficult for inexperienced
332 participants, and thus online feedback would lead to better performance compared with summary
333 feedback. This hypothesis was not supported by the data. Therefore, it is possible that this task
334 was not difficult enough and that with a more complex, perhaps real-world task (e.g., a serve in
335 tennis, a golf-putting task), differences between feedback frequencies will materialize. However,
336 as McKay et al., (2020a) showed, different feedback schedules even in a golf-putting task may
337 only lead to trivial and statistically insignificant differences in performance. Finally, the findings
338 of Guadagnoli et al.'s (1996) indicate that differences in performance following different
339 feedback frequency schedules were only seen in a retention test. In the current study, such a test
340 was not included as we only measured performance.
341 **Study Limitations**
342   This study has a number of limitations. First, we calculated our sample size based on a
343 previous study that used the same tasks (e.g., Ziv & Lidor, 2021), and to be cautious reduced the
344 effect size by 20%. This led us to a Cohen's d of 0.6. However, a recent meta-analysis on
345 autonomy support found Hedge's g of 0.54 for the published literature on self-controlled learning
346 (see McKay et al., 2021). It is then possible that our sample size was not large enough to detect
347 this smaller effect size.
348   Second, in such an online study, it is possible that at least some of the participants did not
349 pay attention to the task. However, the mean RTs in the current study (approximately between
350 1,000 to 1,400 msec) are similar to mean RTs reported in similar tasks performed under
351 laboratory conditions. Salthouse et al. (2000), for example, reported values of over 1,000 msec in
352 a switch trail making test. Minear and Shah (2008) reported RTs for three types of switching
353 tasks. For one task, in the first block of practice, RTs were 889 and 1,027 msec for the no-switch
354 and switch trials, respectively, and for the last block of practice these values were 697 and 763
355 msec. For a second task, in the first block of practice, RTs were 926 and 1,333 msec for the no-
356 switch and switch trials, respectively, and for the last block of practice these values were 714 and
357 973 msec. For a third task, in the first block of practice, RTs were 1,020 and 1,395 msec for the

358 no-switch and switch trials, respectively, and for the last block of practice these values were 740
359 and 1,011 msec.
360   In addition, as pre-registered, we removed from the study the RTs of participants who
361 had less than 13 correct responses in a block of 24 trials because such results suggest that the
362 participant was not attentive to the task. In future studies, researchers can use manipulation
363 checks (see, for example, Oppenheimer et al., 2009). Another possible solution for participants'
364 attentiveness to the task in online studies is using a within-group design. Such a design can shed
365 more light on each individual participant's change in performance, and therefore allow more
366 control over varying motivation and attentiveness between participants. It should be noted
367 though that studies that compare performance in computerized tasks between laboratory and
368 remote participation can be useful. A few studies have reported such comparisons for various
369 aspects of online studies and their results mostly suggest that online studies can provide reliable
370 data (e.g., Dandurand et al., 2008; Gould et al., 2015). More specifically, Crump et al. (2013)
371 showed similar results of tasks such as Stroop, task-switching costs, the Flanker test, and the
372 Simon test when performed in the laboratory or online.
373   One final limitation is missing a control condition of a simpler RT task that requires the
374 use of the same two keyboard keys (e.g., a choice-RT task). The differences between the RTs of
375 such a control task and our main switching task could have shed more light on the difficulty and
376 the level of attention required for this task. However, one previous online study required
377 participants to perform a choice-RT task and a Simon task (a choice-RT task that requires
378 inhibition, and therefore is more difficult to perform) with the same two keyboard keys used in
379 the current study and showed the expected differences in RTs in both tasks (choice RT < Simon
380 RT) (Ziv & Lidor, 2021). In addition, Crump et al.'s (2013) study showed that task-switching
381 costs could be found in online studies, similarly to laboratory-based studies. Therefore, we
382 believe that the observations in the current online study represent an accurate assessment of
383 participants' performance.

Conclusions

385 In summary, the results of the current study suggest that providing participants with a choice of
386 feedback increase perceived choice, but it does not affect performance when completing a
387 computerized alternate task-switching task. We suggest that the effects of autonomy support on
388 performance and learning are not straightforward and may be moderated by various variables or
389 conditions.
