

Resource competition and coexistence in heterogeneous metacommunities: Many-species coexistence is unlikely to be facilitated by spatial variation in resources

There is little debate of about the potential of environmental heterogeneity to facilitate species diversity. However, attempts to show the relationship between spatial heterogeneity and diversity empirically have given mixed results. One reason for this may be failure to consider how species respond to the factor in the environment that varies. Most models of the heterogeneity-diversity relationship assume heterogeneity in non-resource environmental factors. These models show the potential for spatial heterogeneity to promote many-species coexistence via mainly the spatial storage effect. Here, I present a model of species competition under spatial heterogeneity a resource factor. This model allows for the stable coexistence of only two species. Partitioning the model to quantify the contributions of variation-dependent coexistence mechanisms shows contributions from only one mechanism, growth-density covariance. More notably, it shows the lack of potential for any contribution from the spatial storage effect, the only mechanism that can facilitate stable many-species coexistence. This happens because the spatial storage effect measures the contribution of different species to specializing on different parts of the gradient of the heterogeneous factor. Under simple models of resource competition, in which all species grow best at high resource levels, such specialization is impossible. This analysis suggests that, in the absence of additional mechanisms, spatial heterogeneity in a single resource is unlikely to facilitate many-species coexistence and, more generally, that when evaluating the relationship between heterogeneity and diversity, a distinction should be made between resource and non-resource factors.

Introduction

The potential of spatial heterogeneity to promote plant species coexistence is well documented theoretically (reviewed in Amarasekare 2003), but empirical support documenting the power and scope of its ability to support diverse natural communities is mixed. For example, Lundholm (2009) reviewed 41 observational studies and 11 experimental studies that quantified the relationship between plant species diversity and spatial environmental heterogeneity and found that, while many studies documented positive relationships between the two, the cross-study effect size was not significantly different from zero.

One potential reason for the uncertainty observed in the relationship between plant species diversity and spatial environmental heterogeneity is that the strength of the effect depends on what aspect of the environment is varying; specifically whether it is resource or non-resource factors that vary over space. In experiments and observational studies where a non-resource environmental factor (e.g. soil type, pH) varies, positive relationships between spatial heterogeneity and species diversity are often observed (Reynolds et al. 1997, and many more, reviewed in Lundholm 2009). However, there is surprisingly little empirical support for strong positive relationships between the degree of spatial heterogeneity in a limiting resource and plant species diversity at the local scale (Stevens and Carson 2002, Bakker et al. 2003, Reynolds et al. 2007, Lundholm 2009). For example, categorizing the factors in the studies reviewed by Lundholm (2009) based upon whether they are resource or non-resources factors, reveals that a significant relationship was found between species diversity and spatial heterogeneity for 71%

37 (49 of 69) of non-resource factors, but only 28.5% (2 of 7) of resource factors¹. These results
38 suggest an important question: should we expect that resource variation should have the same
39 effect on diversity as non-resource variation?

40 To understand why resource heterogeneity may less effectively facilitate species diversity
41 requires insight into how these factors affect variation dependent species coexistence
42 mechanisms (Chesson 2000a). If plant species are competing for a common resource, then in a
43 uniform environment, the species that can maintain a positive growth rate at the lowest resource
44 concentration (lowest R^* Tilman 1982) is expected to drive all others to extinction. If spatial
45 environmental heterogeneity is to facilitate species coexistence, it must cause variation over
46 space in the identity of the species that has lowest R^* (Amarasekare 2003). For the case of non-
47 resource spatial heterogeneity, Chesson (2000a) has identified the three variation dependent
48 coexistence mechanisms that cause variation in competitive ability over space and thus facilitate
49 coexistence: 1) spatial relative non-linearity, which can occur if species have different non-
50 linear responses to a common competitive environment. 2) growth-density covariance, which
51 measures a species ability to concentrate its population in the areas that best promote growth (in
52 the absence of competition), and 3) spatial storage effect, which occurs when different species
53 experience best growth in different areas of the environment. Of these three mechanisms, the
54 storage effect is potentially the most important in that it is evoked by many kinds of trait
55 differences among species (making it potentially common) and has been shown to allow the
56 coexistence of many species (Chesson 1994).

57 While others have shown that spatial variation in resource supply rates can facilitate

¹ Factors related to water (e.g. soil moisture) were left out of these tallies since they can often act as both resource and non-resource factors.

58 coexistence, a similar partitioning of the mechanisms involved has not been reported. One
59 potential reason for the lack of attention to the difference in resource and non-resource spatial
60 variation is that prominent early theoretical papers made assumptions that minimized the
61 differences between them. For example, Tilman and Pacala (1993) and Abrams (1988) published
62 models that assumed the environment consists of discrete patches containing multiple limiting
63 resources, and that there is no, or only limited dispersal between patches, or that dispersal occurs
64 at a time-scale much slower than that of local competitive exclusion. These assumptions
65 approximate a situation where the spatial scale of heterogeneity is much larger than the
66 characteristic dispersal distances of the species in the community (i.e. most dispersal events
67 occur within patches, few between patches). Under these conditions, spatial heterogeneity creates
68 opportunities for species coexistence if each species is the best competitor at some ratio of
69 resource supply rates represented in a subset of patches (i.e., R^* changes over space). This result
70 is similar to the general result obtained from models of non-resource, environmental
71 heterogeneity based coexistence (Chesson 2000a).

72 Recently however, researchers have begun studying models that assume that competitive
73 exclusion and dispersal occur over similar time-scales (Abrams and Wilson 2004, Golubski et al.
74 2008). This assumption approximates the case where the spatial scale of resource heterogeneity
75 is shorter than typical dispersal distances, and is probably more typical of the systems measured
76 in field studies. These models predict that a poor resource competitor may coexist with a better
77 resource competitor, if the better resource competitor experiences more inter-patch dispersal
78 (Abrams and Wilson 2004). Coexistence in this case is possible because dispersal results in a net
79 loss of individuals from the richest patches which in turn reduces the population's ability to
80 depress resource concentrations in those patches as low as it would in the absence of dispersal;

81 allowing persistence of a competitor that experiences less inter-patch dispersal but has a higher
82 R^* (in a uniform environment). However, the identity and relative strength of the coexistence
83 mechanisms involved are yet to be quantified.

84 The assumption that competition and dispersal occur simultaneously increases the
85 complexity of the models, leading most researchers to model systems consisting of only a small
86 number of patches (Abrams and Wilson 2004, Golubski et al. 2008). As a result, these models
87 lack the generality that would allow them to be scaled up to quantify metacommunity-level
88 phenomena such as variation-dependent coexistence mechanisms (i.e. the storage-effect, relative
89 nonlinearity, and growth-density covariance, Chesson 2000a,b). In this article, I derive a simple
90 metacommunity model of plant competition for a single, spatially variable resource. I derive
91 approximate analytical relationships for regional species coexistence from which
92 metacommunity-scale population growth rates may be partitioned into the variation-dependent
93 and variation-independent coexistence mechanisms. These mechanisms are used to argue why
94 spatial variation for resources is less effective than non-resource spatial variation in facilitating
95 coexistence of many species.

96 Model

97 The goal of this model is to answer the questions “how many species can coexist via
98 spatial heterogeneity in resource supply and by what means?” To answer these questions, I
99 define a simple model of plants growing in a spatially heterogeneous environment, and then use
100 the framework developed by Chesson (1994) to partition the regional growth rates implied by the
101 model into contributions from variation-independent and variation-dependent mechanisms.

102 Finally, I use a sequential invasion approach with the mutual invasion criterion to determine how
 103 many species each mechanism allows to coexist at equilibrium.

104 In a set of discrete patches, $x=\{1,2,3,\dots,N\}$, let $n_{jx}(t)$ be the density of species j in patch x
 105 at time t , and let $R_x(t)$ be the resource concentration in patch x . n_{jx} decreases over time at the per
 106 capita mortality rate m_j , and increases by reproduction in the current patch, which occurs at the
 107 resource-dependent per-capita growth rate $b_j R_x$, plus the contributions of dispersal into patch x
 108 from other patches. Let p_j be the proportion of seeds produced by adults of species j in any patch
 109 that remain in that patch and assume that the $1 - p_j$ seeds that leave natal patches are evenly
 110 redistributed among all patches (including the natal patch). Resources are increased in patches at
 111 a constant rate S_x and are reduced through the establishment of plants. The resource model is
 112 kept intentionally simple to allow analytical treatment. The inclusion of additional loss terms for
 113 resources, for example to adult plant maintenance or leaching do not affect the conclusions
 114 (Supplemental Appendix S2). The dynamics of this coupled system are described by,

$$\begin{aligned}
 \frac{dn_{jx}}{dt} &= -m_j n_{jx} + b_j R_x \left(p_j n_{jx} + (1 - p_j) \langle n_j \rangle_x \right) \\
 \frac{dR_x}{dt} &= S_x - \sum_j Q_j b_j R_x \left(p_j n_{jx} + (1 - p_j) \langle n_j \rangle_x \right)
 \end{aligned}
 \tag{1a-b}$$

116 In eqn 1, Q_j is the amount of resource required for establishment; S_x is the patch-specific
 117 resource supply rate and $\langle \cdot \rangle_x$ indicates a mean taken over patches. For a single species, this
 118 system has one stable equilibrium point per patch at,

$$n_{jx}^* = \frac{S_x}{Q_j m_j}, \quad R_{jx}^{*m} = \frac{m_j S_x}{b_j \left(p_j S_x + (1 - p_j) \langle S \rangle_x \right)},
 \tag{2a-b}$$

120 where the m in R_{jx}^{*m} is used to differentiate this equilibrium concentration of resource from the
121 traditional R^* , that occurs in an uncoupled or homogenous system and is independent of
122 resource supply rate.

123 Eqn.2 shows that, in this model, dispersal has no effect on equilibrium density, n_{jx}^* .
124 However, the equilibrium resource concentration, R_{jx}^{*m} does depend on the amount of dispersal
125 between patches and the resource supply rate in patch x relative to the mean supply rate in the
126 metacommunity. Specifically, if dispersal between patches is high, species j leaves a higher
127 concentration of resources behind in patches with above average supply rates and a lower
128 concentration in patches with below average supply rates than it would in a homogenous
129 environment. This occurs because patches with high supply rates are net exporters of recruits and
130 patches with low supply rates are net importers of potential recruits. The increased concentration
131 of available resources in high supply rate patches allows the invasion and possible coexistence of
132 a species that has a higher R^* , but experiences less inter-patch dispersal (Abrams and Wilson
133 2004)(Fig. 1).

134 *Derivation of variation dependent mechanisms.*

135 One way to measure potential for coexistence is with the mutual invasion criterion. This
136 criterion states that a set of species can coexist with one another if each can invade the
137 equilibrium assemblage of the other species in the set. In practice, one calculates growth rate of
138 a species with inter-specific competition set at the value determined by the competitors at
139 equilibrium and intra-specific competition set to zero. This is called the low-density growth rate
140 of the species. In a spatial context, we are interested in coexistence at the larger scale of the set

141 of all patches, so we calculate what is called the low-density metacommunity scale (or regional)
 142 growth rate.

143 Chesson (2000a) has shown how a low density metacommunity-scale growth rate can be
 144 calculated and written in terms of variation dependent coexistence mechanisms. First, the local
 145 growth rate is decomposed into terms quantifying the direct effects of environmental variation
 146 (E), variation in competition (C) and their interaction

$$147 \quad r_{jx} = \mathcal{E}_x - \mathcal{C}_{jx} + \gamma_j \mathcal{E}_x \mathcal{C}_{jx}, \quad (3)$$

$$148 \quad \text{where } \mathcal{E}_x = G_j(E_x, C_j^*), \mathcal{C}_{jx} = -G(E^*, C), \gamma_j = \frac{\partial G_j}{\partial \mathcal{E} \partial \mathcal{C}_j}.$$

149 The quantities E and C are the population parameters affected by environmental variation and the
 150 effect of competition (which is also affected by environmental variation) respectively, G is the
 151 growth rate of species j as a function of E and C and the (*) indicates the equilibrium level of the
 152 value.

153 The metacommunity-scale growth rate of species j , \tilde{r}_j , in a spatially heterogeneous environment

$$154 \quad \text{is found by taking the mean of } r_{jx} \text{ over all individuals in the metapopulation, } \tilde{r}_j = \frac{1}{\sum_x n_{jx}} \sum_x r_{jx} n_{jx}.$$

$$155 \quad \text{It can be written in terms of a spatial mean by defining relative local density as } \nu_{jx} = \frac{n_{jx}}{\langle n_j \rangle_x}.$$

$$156 \quad \text{Substituting } \nu_{jx} \text{ into } \tilde{r}_j \text{ gives } \tilde{r}_j = \langle r_j \nu_j \rangle_x, \text{ which can be rewritten as } \tilde{r}_j = \langle r_j \rangle_x + \text{cov}(r_j, \nu_j)_x,$$

157 where $\text{cov}(\cdot)_x$ indicates a spatial covariance (Chesson 2000a). Plugging eqn 3 into this result

158 gives,

159
$$\tilde{r}_j = \langle \mathcal{E} \rangle_x - \langle \mathcal{C}_j \rangle_x + \gamma_j \langle \mathcal{E} \mathcal{C}_j \rangle_x + \text{cov}(r_j, v_j)_x. \quad (4)$$

160 To argue that any of the terms in eqn 4 contribute to coexistence, the difference between
 161 invader's and residents' values must be positive. Because, by definition the metacommunity
 162 growth rate of the resident is zero, it can be subtracted from the right side of eqn 4 without
 163 changing the left side. Thus, the metacommunity growth rate of the invader, denoted by subscript
 164 i , can be rewritten in terms of contributions from multiple coexistence mechanisms by
 165 subtracting the metacommunity growth rate of the residents, denoted by subscript r . Subtracting
 166 the metacommunity growth rate of the residents gives,

167
$$\tilde{r}_i = \Delta E - \Delta C + \Delta I + \Delta \kappa \quad (5)$$

168 where

169
$$\begin{aligned} \Delta E &= \langle \mathcal{E}_i \rangle_x - q_{ir} \langle \mathcal{E}_r \rangle_x \\ \Delta C &= \langle \mathcal{C}_i \rangle_x - q_{ir} \langle \mathcal{C}_r \rangle_x \\ \Delta I &= \gamma_i \langle \mathcal{E}_r \mathcal{C}_i \rangle_x - q_{ir} \gamma_r \langle \mathcal{E}_r \mathcal{C}_r \rangle_x \\ \Delta \kappa &= \text{cov}(r_i, v_i)_x - q_{ir} \text{cov}(r_r, v_r)_x \end{aligned} \quad (6)$$

170 and the scaling factor is $q_{ir} = \frac{\partial \mathcal{E}_i}{\partial \mathcal{E}_r}$ is chosen to make the resulting expression more biologically
 171 interpretable. For example, in this case, it allows ΔC to be expressed as a difference in the R^*
 172 values of the species.

173 The quantity ΔE measures differences in the average environment experienced by the
 174 invader and resident. The quantity ΔC can contain both the fluctuation independent difference of
 175 the average competition experienced by residents and invaders and a measure of the effect of
 176 variation in competition. The combination $\Delta E - \Delta C$ is often rewritten to separate it into variation

177 dependent ΔN and variation independent \tilde{r}_i' parts, where $\tilde{r}_i' = \Delta E - \zeta_i^*$ and $\Delta N = \Delta C - \zeta_i^*$. The
178 quantity ζ_i^* is the value of competition the invader experiences as a consequence of the resource
179 equilibrium the residents create (Chesson 2000a). The quantity \tilde{r}_i' the growth rate the invader
180 would experience in the absence of variation. The quantity ΔN has been called relative-
181 nonlinearity and can facilitate coexistence if species exhibit different non-linear responses in
182 growth rate to variations in competition, specifically if the species with the larger non-linearity in
183 response experiences lower variance in competition. For most models that would describe the
184 growth of plants, this mechanism can only facilitate coexistence of two species (Chesson 1994).

185 The quantity ΔI is the storage effect (Chesson 1994) it measures the covariance between
186 the direct effect of environmental variation and the effect of competition on the growth rate of
187 the invader. This mechanism is potentially very powerful and can facilitate coexistence on many
188 species. An example of many species coexistence via spatial storage effect would where there
189 are many patches and each species is the best competitor in at least one patch (Sears and Chesson
190 2007).

191 The final mechanism, $\Delta \kappa$, is growth-density covariance. It measures the ability of the
192 invader to concentrate its population into patches that are best at supporting growth. The species
193 that is better able to do this will experience an overall boost to metacommunity scale growth rate.
194 This mechanism is most directly related to dispersal.

195 *Derivation of variation dependent mechanisms for spatial resource heterogeneity*

196 Following Chesson (2000), the model (eqns. 1) can be written in terms of variation in
197 environment, E_x (the life history character that varies in space) and competition, C_x . In the case

198 of the present model, where only the supply rate of resources varies over space, environmental
 199 variation does not directly affect individuals, it only affects competition; thus $E_x = 0$ and
 200 $C_x = -R_x$. Making these substitutions, the model in eqns. 1 can be rewritten as,

$$\begin{aligned} \frac{dn_{jx}}{dt} &= -m_j n_{jx} - b_j C_x \left(p_j n_{jx} + (1-p_j) \langle n_j \rangle_x \right) \\ \frac{dC_x}{dt} &= -S_x + \sum_j Q_j b_j C_x \left(p_j n_{jx} + (1-p_j) \langle n_j \rangle_x \right) \end{aligned} \quad (7)$$

203 The local growth rate is then, $r_{jx} = -m_j - b_j p_j C_x - (1-p_j) b_j \langle C \rangle_x$. Notice that in this case, due to
 204 dispersal between patches $r_{jx} \neq \frac{1}{n_{jx}} \frac{dn_{jx}}{dt}$. Instead, r_{jx} is derived by considering the fitness of an
 205 individual in patch x (Miller and Chesson 2009). Taking the mean over space, as described in the
 206 previous section gives the metacommunity-scale growth rate, $\tilde{r}_i = -\langle \zeta_i \rangle_x + \text{cov}(r_i, v_i)_x$, where
 207 $\langle \zeta_i \rangle_x = m_i + b_i \langle C \rangle_x$. Assuming a single resident, denoted by subscript r , allows calculation of the
 208 various coexistence mechanisms for the case of two species. This is helpful to determining the
 209 presence or absence of the various mechanisms implied by this model. Plugging into eqn 6 and
 210 scaling by b_i to put the results in the natural time scale of generations instead of an absolute time
 211 scale (e.g. months or years) (Chesson 2008) gives (for details see Supplemental Appendix S1),

$$\begin{aligned}
\frac{\Delta E}{b_i} &= 0 \\
\frac{\Delta C}{b_i} &= -\frac{m_i}{b_i} + \frac{m_r}{b_r} \\
\frac{\Delta I}{b_i} &= 0 \\
\frac{\Delta \kappa}{b_i} &\approx \frac{m_r}{b_r} (1-p_r)^2 \langle s^2 \rangle_x \left(\frac{p_i}{1-p_i} - \frac{p_r}{1-p_r} \right).
\end{aligned}
\tag{7}$$

213 Rewriting $\Delta E - \Delta C$ terms of \tilde{r}_i' and ΔN gives,

$$\begin{aligned}
\frac{\tilde{r}_i'}{b_i} &= -R_i^* + R_r^*, \\
\frac{\Delta \kappa}{b_i} &\approx \text{var}(s)_x (1-p_r)^2 R_r^* \left(\frac{p_i}{1-p_i} - \frac{p_r}{1-p_r} \right).
\end{aligned}
\tag{8}$$

215 where $\frac{m_j}{b_j} = R_j^*$. Notice in this case $\Delta N = 0$ since ΔC contains no variation dependent terms.

216 Biologically, \tilde{r}_i'/b_i is a comparison of abilities to reduce resources in a homogenous
217 environment. Specifically, eqn 9 states that invaders are benefited by the ability to reduce
218 resources to a lower level than the resident in a homogenous environment (Tilman 1982). It also
219 suggests that in the absence of spatial heterogeneity ($\text{var}(s)_x = 0$) coexistence is impossible
220 because only the species with the lowest R^* would have a positive growth rate as an invader.

221 In addition, eqn. 9 shows that only differences in dispersal can allow coexistence in this
222 model. The storage effect (ΔI) and relative nonlinearity (ΔN) have no effect on invader's
223 metacommunity-scale growth rate and thus do not contribute to coexistence. The effect of
224 growth-density covariance ($\Delta \kappa$) on the growth rate of the invader depends upon R_r^* times the
225 odds of seeds staying in natal patches relative to the resident's. Invaders whose seeds are less

226 widely dispersed than those of the resident species are benefited by growth-density covariance.
227 Thus, this model allows coexistence of species if there is a tradeoff competitive ability (R^*) and
228 dispersal fraction (p). In addition, coexistence is facilitated by only one variation-dependent
229 mechanism, grow-density covariance.

230 *How many species does growth-density covariance support?*

231 I used a sequential invasion approach based on adaptive dynamics (Geritz et al. 1998) to
232 determine how many species can coexist based on this model. This approach attempts to find the
233 trait values for invaders that allow invasion in a given context. In this case, at each step, I find
234 the values for the trait p_i that allows an invader to have a positive meta-community growth rate
235 (often written as $S(p_i)$ in the adaptive dynamics literature) in an assemblage of n resident species,
236 i.e., $S_{\{p_m\}}(p_i) > 0$. If this species can 1) coexist with the current resident strategies and resist
237 exclusion by similar strategies (i.e. similar values p), then it is added the list of residents. Species
238 are added one at a time until there is no value of p_i that leads to positive metacommunity-scale
239 growth rate. Because the approximated expression for growth-density covariance from eqn. 9
240 assumes small variation in supply rate and has singularities at $p_i=1$ and $p_r=1$, I use simulation of
241 eqn 1 to calculate invasion growth rate. Numerical simulations of the residents were run until
242 they reached a steady state. The resulting value of resource concentration was plugged into the
243 matrix that described each patches' contribution to an invader's low-density growth-rate in patch
244 x . The dominant eigenvalue of this matrix is an estimate of the meta-community scale low-
245 density growth rate of the invader. For the simulations, I assumed Log-normal distributed supply
246 rates and trade-offs between R_j^* and p_j of the form $R_j^* - p_j^\tau = Z$ where Z is an arbitrary constant

247 and τ affects the shape of the trade-off. The following example considers a linear tradeoff,
248 between competitive ability and dispersal i.e., $\tau = 1$.

249 Figure 2 shows a contour plot for the invasibility of strategy p_i in the presence of resident p_r . The
250 black region of Figure 2 represent negative invader growth rates (i.e. the invasion is
251 unsuccessful), the white regions shows areas of positive growth rates. It shows that any resident
252 strategy $p_r < 1$ can be invaded by $p_i = 1$. However, the strategy $p_r = 1$ is also able to be invaded
253 by any $p_i < 1$. Thus, I set $p_{r1}=1$ and looked for values of p_{r2} that could coexist with p_{r1} and were
254 not excluded by other similar strategies. Figure 3 shows that given $p_{r1}=1$, any resident strategy
255 $p_{r2}>0$ can be invaded by $p_i < p_{r2}$. Thus, since $p_{r2}=0$ can also coexist with $p_{r1}=1$, it was added to the
256 resident list. Figure 3 also suggests that there is no third strategy p_i that can coexist with $p_{r1}=1$
257 and $p_{r2}=0$, since $S_{\{p_{r1}=1, p_{r2}=0\}}(p_i) < 0$ for all possible values of p_i (i.e. a vertical line drawn from
258 $p_{r2}=0$ passes only through the black region of the graph). This suggests that in this model, a
259 tradeoff between competitive ability R_j^* and dispersal p_j , allows coexistence of only two species.
260 To assure these results were robust, I simulated systems of simultaneous competition among
261 many species from along the trade-off manifold (Supplemental Appendix S2). Those
262 simulations also show an observed maximum of two coexisting species for nonlinear tradeoffs
263 with $\tau < 1$; additional loss terms in the resource equation, and saturating growth responses. For
264 non-linear tradeoffs with $\tau > 1$ no coexistence was possible.

265 Discussion

266 This analysis shows that spatial variation in resources allows for fewer coexistence
267 mechanisms and lower potential species diversity compared to spatial variation in non-resource
268 factors. Although spatial resource variation promotes coexistence if there is a tradeoff between

269 competitive ability and the ability to retain offspring in good patches, this tradeoff allows the
270 coexistence of only a 2 species.

271 Coexistence under spatial resource variation lacks contributions from the spatial storage
272 effect, a powerful mechanism that allows the coexistence of many species. The storage effect is
273 absent because all species grow best in the same patches (high resource patches). As a result,
274 environmental responses and competition are perfectly and equally correlated for all species,
275 allowing no advantages in good patches when a species is rare. In other words, the feedback that
276 organisms have on the resource, make it impossible for any to specialize on a particular supply
277 rate along a gradient.

278 Although the mechanism of resource competition analyzed in this model is simplified,
279 the qualitative results are quite general. For example, the relationship of R^* to the
280 metacommunity-scale coexistence mechanisms described by scale transition theory does not
281 depend on the simplified model of local resource competition presented in eqns 1. If the
282 establishment rate of seeds is a saturating function (e.g. Monod functions with equal half
283 saturation constants) of the amount of resources present, then \tilde{r} ' is still a comparison of the
284 (more complicated) R^* s of the invader and resident, and the relative importance of the variation
285 dependent mechanism is the same. The situation is more complex if species growth rates are
286 different non-linear functions of resource concentration, but, even in this case, spatial variation in
287 one only facilitate 2 species coexistence (Supplemental Appendix S2).

288 In this model, competition was for a single resource. Increasing the number of limiting
289 resources can increase the number of species that can coexist at equilibrium. Golubski et al.
290 (2008) found that a maximum of four species could coexist in a system with two resources,

Figure 1

R^* as a function of dispersal

Concentration of resources left behind at equilibrium (R^*_{jx}) along a spatial gradient of resource supply rates. The R^*_{jx} of a species depends on the supply rate of the patch and the amount of interpatch dispersal (Black lines: $R^* = 0.4$, $p = 1$, solid; $p = 0.66$, dashed; $p = 0.33$, dash-dot; $p = 0$, dotted). As a result, a species with a higher R^* may invade the metacommunity if it experiences less interpatch dispersal (Grey line: $R^* = 0.5$; $p = 0.9$) because it can have a R^*_{jx} lower [i] in patches with the highest supply rates.

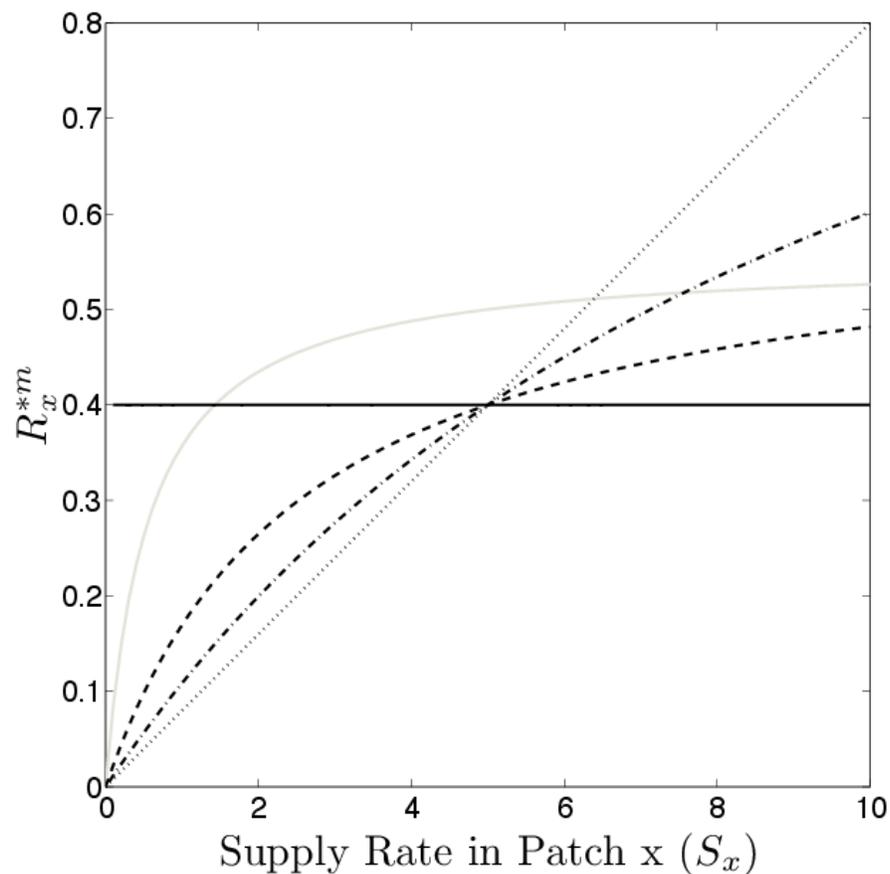

Figure 2

Invasion analysis

Contour plot of the growth rate of an invader with dispersal p_i as a function of resident dispersal p_r , assuming a tradeoff between competitive ability (R^*) and dispersal (p). Black regions show areas of negative invader growth rate; white regions, positive. The graph shows that $p_i=1$ can invade a meta-community with a resident with $p_r < 1$. It also shows that $p_r=1$ can be invaded by any $p_i < 1$, suggesting coexistence with this strategy is possible. Parameter values for this graph are $R_j^* = 1 - p_j$ in a system of 20 patches and $S_x \sim \text{LogNormal}(1, 1.5)$.

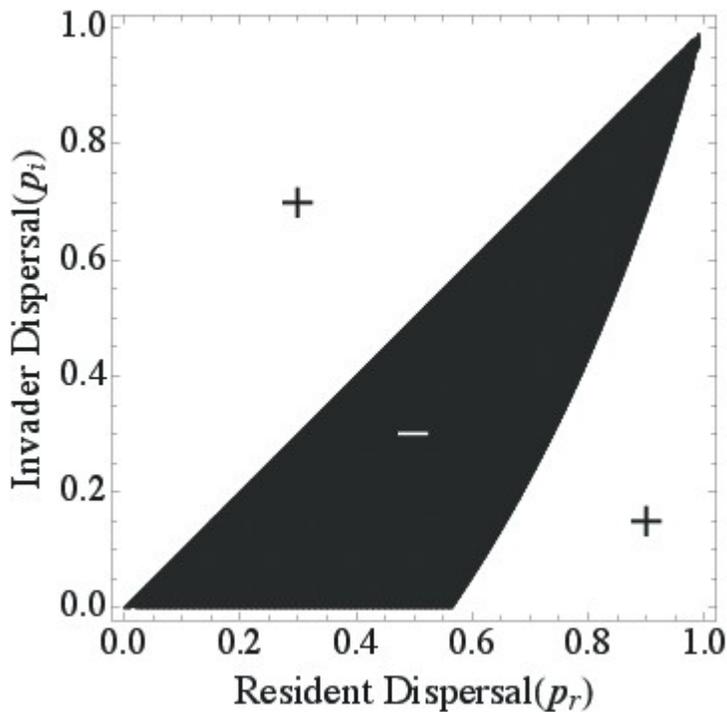

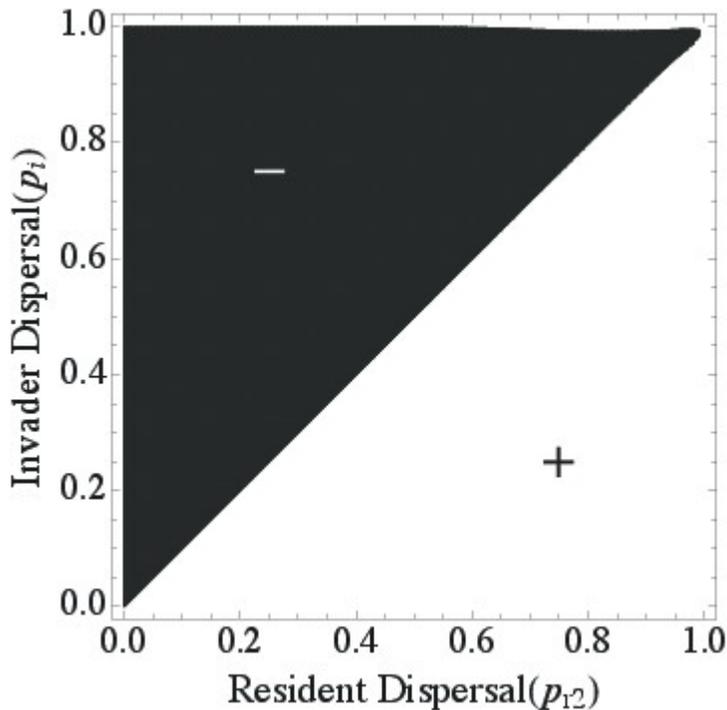

Figure 3

2 Species Invasion Analysis

Contour plot of the growth rate of an invader with dispersal p_i as a function of resident dispersal $p_{r1}=1, p_{r2}$, assuming a tradeoff between competitive ability (R^*) and dispersal (p). Black regions show areas of negative invader growth rate; white regions, positive. The graph shows that given $p_{r1}=1$, $p_{r2}>0$ can be invaded by and excluded by p_i . Thus, it shows that given $p_{r1}=1$ and $p_{r2}=0$, no third strategy p_i has a positive growth rate; confirming that stable coexistence of only two species is possible. Parameter values for this graph are $R_j^*=1-p_j$ in a system of 20 patches and $S_x \sim \text{LogNormal}(1,1.5)$.

16 Equation Chapter 1 Section 1

17 Introduction

18 The potential of spatial heterogeneity to promote plant species coexistence is well
19 documented theoretically (reviewed in Amarasekare 2003), but empirical support documenting
20 the power and scope of its ability to support diverse natural communities is mixed. For example,
21 Lundholm (2009) reviewed 41 observational studies and 11 experimental studies that quantified
22 the relationship between plant species diversity and spatial environmental heterogeneity and
23 found that, while many studies documented positive relationships between the two, the
24 cross-study effect size was not significantly different from zero.

25 One potential reason for the uncertainty observed in the relationship between plant
26 species diversity and spatial environmental heterogeneity is that the strength of the effect
27 depends on what aspect of the environment is varying; specifically whether it is resource or
28 non-resource factors that vary over space. In experiments and observational studies where a
29 non-resource environmental factor (e.g. soil type, pH) varies, positive relationships between
30 spatial heterogeneity and species diversity are often observed (Reynolds et al. 1997, and many
31 more, reviewed in Lundholm 2009). However, there is surprisingly little empirical support for
32 strong positive relationships between the degree of spatial heterogeneity in a limiting resource
33 and plant species diversity at the local scale (Stevens and Carson 2002, Bakker et al. 2003,
34 Reynolds et al. 2007, Lundholm 2009). For example, categorizing the factors in the studies
35 reviewed by Lundholm (2009) based upon whether they are resource or non-resources factors,
36 reveals that a significant relationship was found between species diversity and spatial
37 heterogeneity for 71% (49 of 69) of non-resource factors, but only 28.5% (2 of 7) of resource

38 factors¹. These results suggest an important question: should we expect that resource variation
39 should have the same effect on diversity as non-resource variation?

40 To understand why resource heterogeneity may less effectively facilitate species diversity
41 requires insight into how these factors affect variation dependent species coexistence
42 mechanisms (Chesson 2000a). If plant species are competing for a common resource, then in a
43 uniform environment, the species that can maintain a positive growth rate at the lowest resource
44 concentration (lowest R^* Tilman 1982) is expected to drive all others to extinction. If spatial
45 environmental heterogeneity is to facilitate species coexistence, it must cause variation over
46 space in the identity of the species that has lowest R^* (Amarasekare 2003). For the case of
47 non-resource spatial heterogeneity, Chesson (2000a) has identified the three variation dependent
48 coexistence mechanisms that cause variation in competitive ability over space and thus facilitate
49 coexistence: 1) spatial relative non-linearity, which can occur if species have different non-linear
50 responses to a common competitive environment. 2) growth-density covariance, which measures
51 a species ability to concentrate its population in the areas that best promote growth (in the
52 absence of competition), and 3) spatial storage effect, which occurs when different species
53 experience best growth in different areas of the environment. Of these three mechanisms, the
54 storage effect is potentially the most important in that it is evoked by many kinds of trait
55 differences among species (making it potentially common) and has been shown to allow the
56 coexistence of many species (Chesson 1994).

57 While others have shown that spatial variation in resource supply rates can facilitate
58 coexistence, a similar partitioning of the mechanisms involved has not been reported. One

1 1 Factors related to water (e.g. soil moisture) were left out of these tallies since they can often act
2 as both resource and non-resource factors.

59 potential reason for the lack of attention to the difference in resource and non-resource spatial
60 variation is that prominent early theoretical papers made assumptions that minimized the
61 differences between them. For example, Tilman and Pacala (1993) and Abrams (1988) published
62 models that assumed the environment consists of discrete patches containing multiple limiting
63 resources, and that there is no, or only limited dispersal between patches, or that dispersal occurs
64 at a time-scale much slower than that of local competitive exclusion. These assumptions
65 approximate a situation where the spatial scale of heterogeneity is much larger than the
66 characteristic dispersal distances of the species in the community (i.e. most dispersal events
67 occur within patches, few between patches). Under these conditions, spatial heterogeneity creates
68 opportunities for species coexistence if each species is the best competitor at some ratio of
69 resource supply rates represented in a subset of patches (i.e., R^* changes over space). This result
70 is similar to the general result obtained from models of non-resource, environmental
71 heterogeneity based coexistence (Chesson 2000a).

72 Recently however, researchers have begun studying models that assume that competitive
73 exclusion and dispersal occur over similar time-scales (Abrams and Wilson 2004, Golubski et al.
74 2008). This assumption approximates the case where the spatial scale of resource heterogeneity
75 is shorter than typical dispersal distances, and is probably more typical of the systems measured
76 in field studies. These models predict that a poor resource competitor may coexist with a better
77 resource competitor, if the better resource competitor experiences more inter-patch dispersal
78 (Abrams and Wilson 2004). Coexistence in this case is possible because dispersal results in a net
79 loss of individuals from the richest patches which in turn reduces the population's ability to
80 depress resource concentrations in those patches as low as it would in the absence of dispersal;
81 allowing persistence of a competitor that experiences less inter-patch dispersal but has a higher

104 In a set of discrete patches, $x=\{1,2,3,\dots,N\}$, let $n_{jx}(t)$ be the density of species j in patch x at
 105 time t , and let $R_x(t)$ be the resource concentration in patch x . n_{jx} decreases over time at the per
 106 capita mortality rate m_j , and increases by reproduction in the current patch, which occurs at the
 107 resource-dependent per-capita growth rate $b_j R_x$, plus the contributions of dispersal into patch x
 108 from other patches. Let p_j be the proportion of seeds produced by adults of species j in any patch

109 that remain in that patch and assume that the $1 - p_j$ seeds that leave natal patches are evenly
 110 redistributed among all patches (including the natal patch). Resources are increased in patches at
 111 a constant rate S_x and are reduced through the establishment of plants. The resource model is kept
 112 intentionally simple to allow analytical treatment. The inclusion of additional loss terms for
 113 resources, for example to adult plant maintenance or leaching do not affect the conclusions
 114 (Supplemental Appendix S2). The dynamics of this coupled system are described by,

$$\frac{dn_{jx}}{dt} = -m_j n_{jx} + b_j R_x \left(p_j n_{jx} + (1 - p_j) \langle n_j \rangle_x \right)$$

$$\frac{dR_x}{dt} = S_x - \sum_j Q_j b_j R_x \left(p_j n_{jx} + (1 - p_j) \langle n_j \rangle_x \right)$$

115 .* MERGEFORMAT (a-b)

116 In eqn 1, Q_j is the amount of resource required for establishment; S_x is the patch-specific

117 resource supply rate and $\langle \cdot \rangle_x$ indicates a mean taken over patches. For a single species, this
 118 system has one stable equilibrium point per patch at,

$$n_{jx}^* = \frac{S_x}{Q_j m_j}, \quad R_{jx}^{*m} = \frac{m_j S_x}{b_j \left(p_j S_x + (1 - p_j) \langle S \rangle_x \right)}$$

119 .* MERGEFORMAT (a-b)

120 where the R_{jx}^{*m} is used to differentiate this equilibrium concentration of resource from the
121 traditional R^* , that occurs in an uncoupled or homogenous system and is independent of
122 resource supply rate.

123 Eqn.2 shows that, in this model, dispersal has no effect on equilibrium density, n_{jx}^* .

124 However, the equilibrium resource concentration, R_{jx}^{*m} does depend on the amount of dispersal
125 between patches and the resource supply rate in patch x relative to the mean supply rate in the
126 metacommunity. Specifically, if dispersal between patches is high, species j leaves a higher
127 concentration of resources behind in patches with above average supply rates and a lower
128 concentration in patches with below average supply rates than it would in a homogenous
129 environment. This occurs because patches with high supply rates are net exporters of recruits and
130 patches with low supply rates are net importers of potential recruits. The increased concentration
131 of available resources in high supply rate patches allows the invasion and possible coexistence of
132 a species that has a higher R^* , but experiences less inter-patch dispersal (Abrams and Wilson
133 2004)(Fig. 1).

134 *Derivation of variation dependent mechanisms.*

135 One way to measure potential for coexistence is with the mutual invasion criterion. This
136 criterion states that a set of species can coexist with one another if each can invade the
137 equilibrium assemblage of the other species in the set. In practice, one calculates growth rate of
138 a species with inter-specific competition set at the value determined by the competitors at
139 equilibrium and intra-specific competition set to zero. This is called the low-density growth rate

140 of the species. In a spatial context, we are interested in coexistence at the larger scale of the set
 141 of all patches, so we calculate what is called the low-density metacommunity scale (or regional)
 142 growth rate.

143 Chesson (2000a) has shown how a low density metacommunity-scale growth rate can be
 144 calculated and written in terms of variation dependent coexistence mechanisms. First, the local
 145 growth rate is decomposed into terms quantifying the direct effects of environmental variation
 146 (E), variation in competition (C) and their interaction

$$147 \quad r_{jx} = \mathcal{E}_x - C_{jx} + \gamma_j \mathcal{E}_x C_{jx}, \quad \backslash * \text{MERGEFORMAT } ()$$

$$148 \quad \text{where } \mathcal{E}_x = G_j(E_x, C_j^*), \quad C_{jx} = -G(E^*, C), \quad \gamma_j = \frac{\partial G_j}{\partial E \partial C_j}.$$

149 The quantities E and C are the population parameters affected by environmental variation and the
 150 effect of competition (which is also affected by environmental variation) respectively, G is the
 151 growth rate of species j as a function of E and C and the (*) indicates the equilibrium level of the
 152 value.

153 The metacommunity-scale growth rate of species j , \hat{r}_j , in a spatially heterogeneous environment

$$154 \quad \text{is found by taking the mean of } r_{jx} \text{ over all individuals in the metapopulation, } \hat{r}_j = \frac{1}{\sum_x n_{jx}} \sum_x r_{jx} n_{jx}.$$

$$v_{jx} = \frac{n_{jx}}{\langle n_j \rangle_x}$$

155 It can be written in terms of a spatial mean by defining relative local density as

156 Substituting v_{jx} into \hat{r}_j gives $\hat{r}_j = \langle r_j v_j \rangle_x$, which can be rewritten as $\hat{r}_j = \langle r_j \rangle_x + \text{cov}(r_j, v_j)_x$,

157 where $\text{cov}(\cdot)_x$ indicates a spatial covariance (Chesson 2000a). Plugging eqn 3 into this result
158 gives,

$$\hat{r}_j = \langle \mathcal{E} \rangle_x - \langle C_j \rangle_x + \gamma_j \langle \mathcal{E} C_j \rangle_x + \text{cov}(r_j, v_j)_x$$

159 .* MERGEFORMAT ()

160 To argue that any of the terms in eqn 4 contribute to coexistence, the difference between
161 invader's and residents' values must be positive. Because, by definition the metacommunity
162 growth rate of the resident is zero, it can be subtracted from the right side of eqn 4 without
163 changing the left side. Thus, the metacommunity growth rate of the invader, denoted by subscript
164 i , can be rewritten in terms of contributions from multiple coexistence mechanisms by
165 subtracting the metacommunity growth rate of the residents, denoted by subscript r . Subtracting
166 the metacommunity growth rate of the residents gives,

$$\tilde{r}_i = \Delta E - \Delta C + \Delta I + \Delta \kappa$$

167 .* MERGEFORMAT ()

168 where

$$\begin{aligned} \Delta E &= \langle \mathcal{E} \rangle_x - q_{ir} \langle \mathcal{E} \rangle_x \\ \Delta C &= \langle C_i \rangle_x - q_{ir} \langle C_r \rangle_x \\ \Delta I &= \gamma_i \langle \mathcal{E} C_i \rangle_x - q_{ir} \gamma_r \langle \mathcal{E} C_r \rangle_x \\ \Delta \kappa &= \text{cov}(r_i, v_i)_x - q_{ir} \text{cov}(r_r, v_r)_x \end{aligned}$$

169 .* MERGEFORMAT ()

$$q_{ir} = \frac{\partial C_i}{\partial C_r}$$

170 and the scaling factor is q_{ir} is chosen to make the resulting expression more biologically

171 interpretable. For example, in this case, it allows ΔC to be expressed as a difference in the R^*
 172 values of the species.

173 The quantity ΔE measures differences in the average environment experienced by the

174 invader and resident. The quantity ΔC can contain both the fluctuation independent difference of
 175 the average competition experienced by residents and invaders and a measure of the effect of

176 variation in competition. The combination $\Delta E - \Delta C$ is often rewritten to separate it into variation

177 dependent ΔN and variation independent \tilde{r}_i' parts, where $\tilde{r}_i' = \Delta E - C_i^*$ and $\Delta N = \Delta C - C_i^*$. The

178 quantity C_i^* is the value of competition the invader experiences as a consequence of the resource

179 equilibrium the residents create (Chesson 2000a). The quantity \tilde{r}_i' the growth rate the invader

180 would experience in the absence of variation. The quantity ΔN has been called

181 relative-nonlinearity and can facilitate coexistence if species exhibit different non-linear

182 responses in growth rate to variations in competition, specifically if the species with the larger

183 non-linearity in response experiences lower variance in competition. For most models that

184 would describe the growth of plants, this mechanism can only facilitate coexistence of two
 185 species (Chesson 1994).

186 The quantity ΔI is the storage effect (Chesson 1994) it measures the covariance between
 187 the direct effect of environmental variation and the effect of competition on the growth rate of
 188 the invader. This mechanism is potentially very powerful and can facilitate coexistence on many
 189 species. An example of many species coexistence via spatial storage effect would where there
 190 are many patches and each species is the best competitor in at least one patch (Sears and Chesson
 191 2007).

192 The final mechanism, $\Delta \kappa$, is growth-density covariance. It measures the ability of the
 193 invader to concentrate its population into patches that are best at supporting growth. The species
 194 that is better able to do this will experience an overall boost to metacommunity scale growth rate.
 195 This mechanism is most directly related to dispersal.

196 *Derivation of variation dependent mechanisms for spatial resource heterogeneity*

197 Following Chesson (2000), the model (eqns. 1) can be written in terms of variation in

198 environment, E_x (the life history character that varies in space) and competition, C_x . In the case
 199 of the present model, where only the supply rate of resources varies over space, environmental

200 variation does not directly affect individuals, it only affects competition; thus $E_x = 0$ and

201 $C_x = -R_x$. Making these substitutions, the model in eqns. 1 can be rewritten as,

$$\begin{aligned}\frac{dn_{jx}}{dt} &= -m_j n_{jx} - b_j C_x \left(p_j n_{jx} + (1-p_j) \langle n_j \rangle_x \right) \\ \frac{dC_x}{dt} &= -S_x + \sum_j Q_j b_j C_x \left(p_j n_{jx} + (1-p_j) \langle n_j \rangle_x \right)\end{aligned}\tag{7}$$

202

203

204

$$r_{jx} = -m_j - b_j p_j C_x - (1-p_j) b_j \langle C \rangle_x$$

The local growth rate is then, . Notice that in this case, due to

205

$$r_{jx} \neq \frac{1}{n_{jx}} \frac{dn_{jx}}{dt}$$

dispersal between patches . Instead, r_{jx} is derived by considering the fitness of an

206

individual in patch x (Miller and Chesson 2009). Taking the mean over space, as described in the

207

$$\tilde{r}_i = -\langle C_i \rangle_x + \text{cov}(r_i, v_i)_x$$

previous section gives the metacommunity-scale growth rate, , where

208

$$\langle C_i \rangle_x = m_i + b_i \langle C \rangle_x$$

. Assuming a single resident, denoted by subscript r , allows calculation of the

209

various coexistence mechanisms for the case of two species. This is helpful to determining the

210

presence or absence of the various mechanisms implied by this model. Plugging into eqn 6 and

211

scaling by b_i to put the results in the natural time scale of generations instead of an absolute time

212

scale (e.g. months or years) (Chesson 2008) gives (for details see Supplemental Appendix S1),

$$\frac{\Delta E}{b_i} = 0$$

$$\frac{\Delta C}{b_i} = -\frac{m_i}{b_i} + \frac{m_r}{b_r}$$

$$\frac{\Delta I}{b_i} = 0$$

$$\frac{\Delta \kappa}{b_i} \approx \frac{m_r}{b_r} (1-p_r)^2 \langle s^2 \rangle_x \left(\frac{p_i}{1-p_i} - \frac{p_r}{1-p_r} \right)$$

213 * MERGEFORMAT ()

214 Rewriting $\frac{\Delta E - \Delta C}{b_i}$ terms of \tilde{r}_i' and $\frac{\Delta N}{b_i}$ gives,

$$\frac{\tilde{r}_i'}{b_i} = -R_i^* + R_r^*,$$

$$\frac{\Delta \kappa}{b_i} \approx \text{var}(s)_x (1-p_r)^2 R_r^* \left(\frac{p_i}{1-p_i} - \frac{p_r}{1-p_r} \right)$$

215 * MERGEFORMAT ()

216 where $\frac{m_j}{b_j} = R_j^*$. Notice in this case $\frac{\Delta N}{b_i} = 0$ since $\frac{\Delta C}{b_i}$ contains no variation dependent terms.

217 Biologically, \tilde{r}_i'/b_i is a comparison of abilities to reduce resources in a homogenous
 218 environment. Specifically, eqn 9 states that invaders are benefited by the ability to reduce
 219 resources to a lower level than the resident in a homogenous environment (Tilman 1982). It also
 220 suggests that in the absence of spatial heterogeneity ($\text{var}(s)_x = 0$) coexistence is impossible
 221 because only the species with the lowest R^* would have a positive growth rate as an invader.

222 In addition, eqn. 9 shows that only differences in dispersal can allow coexistence in this

223 model. The storage effect ($\frac{\Delta I}{b_i}$) and relative nonlinearity ($\frac{\Delta N}{b_i}$) have no effect on invader's

224 metacommunity-scale growth rate and thus do not contribute to coexistence. The effect of
 225 growth-density covariance ($\Delta\kappa$) on the growth rate of the invader depends upon R_r^* times the
 226 odds of seeds staying in natal patches relative to the resident's. Invaders whose seeds are less
 227 widely dispersed than those of the resident species are benefited by growth-density covariance.
 228 Thus, this model allows coexistence of species if there is a tradeoff competitive ability (R^*) and
 229 dispersal fraction (p). In addition, coexistence is facilitated by only one variation-dependent
 230 mechanism, grow-density covariance.

231 *How many species does growth-density covariance support?*

232 I used a sequential invasion approach based on adaptive dynamics (Geritz et al. 1998) to
 233 determine how many species can coexist based on this model. This approach attempts to find the
 234 trait values for invaders that allow invasion in a given context. In this case, at each step, I find
 235 the values for the trait p_i that allows an invader to have a positive meta-community growth rate
 236 (often written as $S(p_i)$ in the adaptive dynamics literature) in an assemblage of n resident species,

237 i.e., $S_{\{p_m\}}(p_i) > 0$. If this species can 1) coexist with the current resident strategies and resist
 238 exclusion by similar strategies (i.e. similar values p), then it is added the list of residents. Species
 239 are added one at a time until there is no value of p_i that leads to positive metacommunity-scale
 240 growth rate. Because the approximated expression for growth-density covariance from eqn. 9
 241 assumes small variation in supply rate and has singularities at $p_i=1$ and $p_r=1$, I use simulation of
 242 eqn 1 to calculate invasion growth rate. Numerical simulations of the residents were run until
 243 they reached a steady state. The resulting value of resource concentration was plugged into the

244 matrix that described each patches' contribution to an invader's low-density growth-rate in patch
 245 x . The dominant eigenvalue of this matrix is an estimate of the meta-community scale
 246 low-density growth rate of the invader. For the simulations, I assumed Log-normal distributed

247 supply rates and trade-offs between R_j^* and p_j of the form $R_j^* - p_j^\tau = Z$ where Z is an arbitrary

248 constant and τ affects the shape of the trade-off. The following example considers a linear

249 tradeoff, between competitive ability and dispersal i.e., $\tau = 1$.

250 Figure 2 shows a contour plot for the invasibility of strategy p_i in the presence of resident p_r . The
 251 black region of Figure 2 represent negative invader growth rates (i.e. the invasion is
 252 unsuccessful), the white regions shows areas of positive growth rates. It shows that any resident

253 strategy $p_r < 1$ can be invaded by $p_i = 1$. However, the strategy $p_r = 1$ is also able to be invaded

254 by any $p_i < 1$. Thus, I set $p_{r1}=1$ and looked for values of p_{r2} that could coexist with p_{r1} and were
 255 not excluded by other similar strategies. Figure 3 shows that given $p_{r1}=1$, any resident strategy
 256 $p_{r2}>0$ can be invaded by $p_i < p_{r2}$. Thus, since $p_{r2}=0$ can also coexist with $p_{r1}=1$, it was added to the
 257 resident list. Figure 3 also suggests that there is no third strategy p_i that can coexist with $p_{r1}=1$

258 and $p_{r2}=0$, since $S_{\{p_{r1}=1, p_{r2}=0\}}(p_i) < 0$ for all possible values of p_i (i.e. a vertical line drawn from
 259 $p_{r2}=0$ passes only through the black region of the graph). This suggests that in this model, a

260 tradeoff between competitive ability R_j^* and dispersal p_j , allows coexistence of only two species.
261 To assure these results were robust, I simulated systems of simultaneous competition among
262 many species from along the trade-off manifold (Supplemental Appendix S2). Those
263 simulations also show an observed maximum of two coexisting species for nonlinear tradeoffs
264 with $\tau < 1$; additional loss terms in the resource equation, and saturating growth responses. For
265 non-linear tradeoffs with $\tau > 1$ no coexistence was possible.

266 Discussion

267 This analysis shows that spatial variation in resources allows for fewer coexistence
268 mechanisms and lower potential species diversity compared to spatial variation in non-resource
269 factors. Although spatial resource variation promotes coexistence if there is a tradeoff between
270 competitive ability and the ability to retain offspring in good patches, this tradeoff allows the
271 coexistence of only a 2 species.

272 Coexistence under spatial resource variation lacks contributions from the spatial storage
273 effect, a powerful mechanism that allows the coexistence of many species. The storage effect is
274 absent because all species grow best in the same patches (high resource patches). As a result,
275 environmental responses and competition are perfectly and equally correlated for all species,
276 allowing no advantages in good patches when a species is rare. In other words, the feedback that
277 organisms have on the resource, make it impossible for any to specialize on a particular supply
278 rate along a gradient.

279 Although the mechanism of resource competition analyzed in this model is simplified,
280 the qualitative results are quite general. For example, the relationship of R^* to the
281 metacommunity-scale coexistence mechanisms described by scale transition theory does not
282 depend on the simplified model of local resource competition presented in eqns 1. If the
283 establishment rate of seeds is a saturating function (e.g. Monod functions with equal half
284 saturation constants) of the amount of resources present, then \hat{r}' is still a comparison of the (more
285 complicated) R^* s of the invader and resident, and the relative importance of the variation
286 dependent mechanism is the same. The situation is more complex if species growth rates are
287 different non-linear functions of resource concentration, but, even in this case, spatial variation in
288 one only facilitate 2 species coexistence (Supplemental Appendix S2).

289 In this model, competition was for a single resource. Increasing the number of limiting
290 resources can increase the number of species that can coexist at equilibrium. Golubski et al.
291 (2008) found that a maximum of four species could coexist in a system with two resources,
292 heterogeneous supply rates and species that were capable of integrating growth across patches.
293 However, this was only possible with precise arrangement of species trait parameters, and if
294 resource supply rates of the resources were strongly negatively correlated across patches. I
295 presume that, in this case, adding resource factors does not increase the number of mechanisms;
296 the existing mechanism, growth-density covariance, simple works independently for each
297 resource; although this claim should be explored with further analysis.

298 This analysis suggests that spatial resource heterogeneity is not capable of supporting the
299 robust stable coexistence of many plants species that is observed in many natural systems. The
300 reason for this is that the feedback species have on resources concentrations prevents

301 specialization of different species at different supply rates. It is this kind of specialization of
302 different species along different points of a “niche” axis, which is measured by the spatial
303 storage effect, that allows the robust coexistence of many species. The results of this analysis are
304 consistent with the patterns found in the empirical literature, which finds much more support for
305 the relationship between species diversity and nonresource spatial heterogeneity than resource
306 heterogeneity. Taken together, this work suggests that the consideration whether a factor is a
307 resource or not is crucial for those attempting to understand real patterns in species diversity or
308 those interested in managing a habitat for increased species diversity.

309 Acknowledgements

310 I would like to thank Peter Chesson, Kay Gross, and Gary Mittelbach for helping improve this
311 manuscript. This is contribution No. TBD from the W.K. Kellogg Biological Station, Michigan
312 State University.
